2. As hydro-meteorological data derived from an interpolation of measures associated to the Norwegian rain gauge network, a lack of information due to the low density of the network can alter the reliability of empirical and/or physically based models, especially for landslides induced by short term precipitation. Thus, the coupling with other data sources, like radar, constitutes an important topic aimed to improving the forecasting and the performance of models for landslide triggering.

The successive activities will consist in the development of modules concerning runoff generation and slope stability for the DEM-based model, as well as the rainfall nowcasting by using information from several data sources.

Evaluation of the rainfall threshold for shallow and middle-deep landslide triggering: the case of middle-Aniene basin

G. FUBELLI (*), M. TONONI (**) & F. VALERI (°)

Key words: *archive investigation, landslides, rainfall threshold.*

The triggering factor for different types of gravitational phenomena is rainfall. Then, the evaluation of rainfall thresholds for landslide triggering is a useful technique for forecasting such phenomena and can therefore be useful to the public authorities and local population by providing the critical rainfall values beyond which it is appropriate to consider a state of alert. The following work has been done basing on the previous study of DAHAL & HASEGAWA (2008), GUZZETTI *et al.* (2004), PARONUZZI & GNECH (2007), representative rainfall thresholds for landslides in Nepal Hymalaya and in agreement with Province of Rome. The study area is located in the middle Aniene River basin, about 50 km E of Rome, and has an extension of approximately 100 km^2.

The study area is characterized by a Tortonian in age sequence made of calcarenite, marl and turbidite deposits. Our investigation has been focused on the sylico-clastic deposits of the Formazione di Frosinone (upper Tortonian in age) and the cover material over them.

In order to establish a relationship between landslide occurrence and the amount of rainfall, an inventory of all the landslides occurred in the area in the past 30 years has been carried out by field survey and archive investigation. They were later recovered from the website *idrografico.roma.it* data 2003 to 2011 rainfall of the rain gauges of Arsoli, Licenza, Palestrina, Subiaco, Tivoli and Trevi. The rainfall data prior to 2003 from the same stations, except for that from the Palestrina station, were instead obtained from the Province of Rome archive. The data relating to the Tivoli rainfall station during 1980-2000 were available only for the years 2000, 1999, 1996, 1994, 1992, 1991, 1985, 1983 and 1980. Only for the event on March 17, 2011 were taken into account also the rainfall data from the S. Vito Romano station. All data has been then digitized with Microsoft Excel 2010.

At this point we calculated the cumulative rainfall in 3 days, 10 days, 1 month and 3 months for each of the 41 dates when one or more events occurred and 164 histograms like those in Fig. 1 have been constructed.

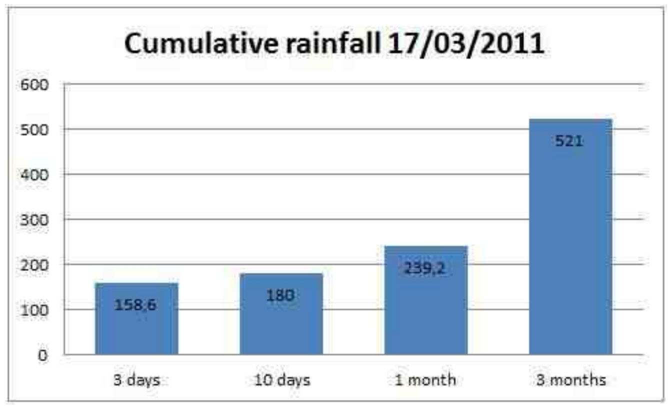

Fig. 1 – Cumulative rainfall of the 2011, march, 17.

The following step has been to recover from the relevant municipalities and the Province of Rome practices relating the interventions done on landslide affected roads in order to trace the onset dates of these phenomena.

Subsequently, with the program ArcGis 9.3, 41 shape files of punctual type have been created, one for each event date. The positions of the precipitation stations have been identified on the topographic map and marked with a point, for each of the 41 shape files. Then an attributes table was created where cumulative rainfall values for each station to 3 days, 10 days , 1 month and 3 months previously calculated have been reported.

To switch between punctual and discrete data to areal and continuous data, the Spatial Analyst Interpolate to Raster, Spline command has been used. The method of Spline, in fact, is an interpolation method that estimates the values using a mathematical function by obtain a surface that passes exactly through the input points.

There are two methods of Spline: Regularized and Tension. The method we chose was Tension method in which, unlike the Regularized method, builds the surface interpolating with a range of values longer constrained to our input data. For the additional parameters. Weight and Number of points, the default values of 0.1 and 12 have been left. This method was used for all the 41 dates, thus obtaining 164 rainfall maps in total (Fig. 2).

Comparing the geographical positions of landslides with the rainfall maps, the thresholds trigger for each event have been

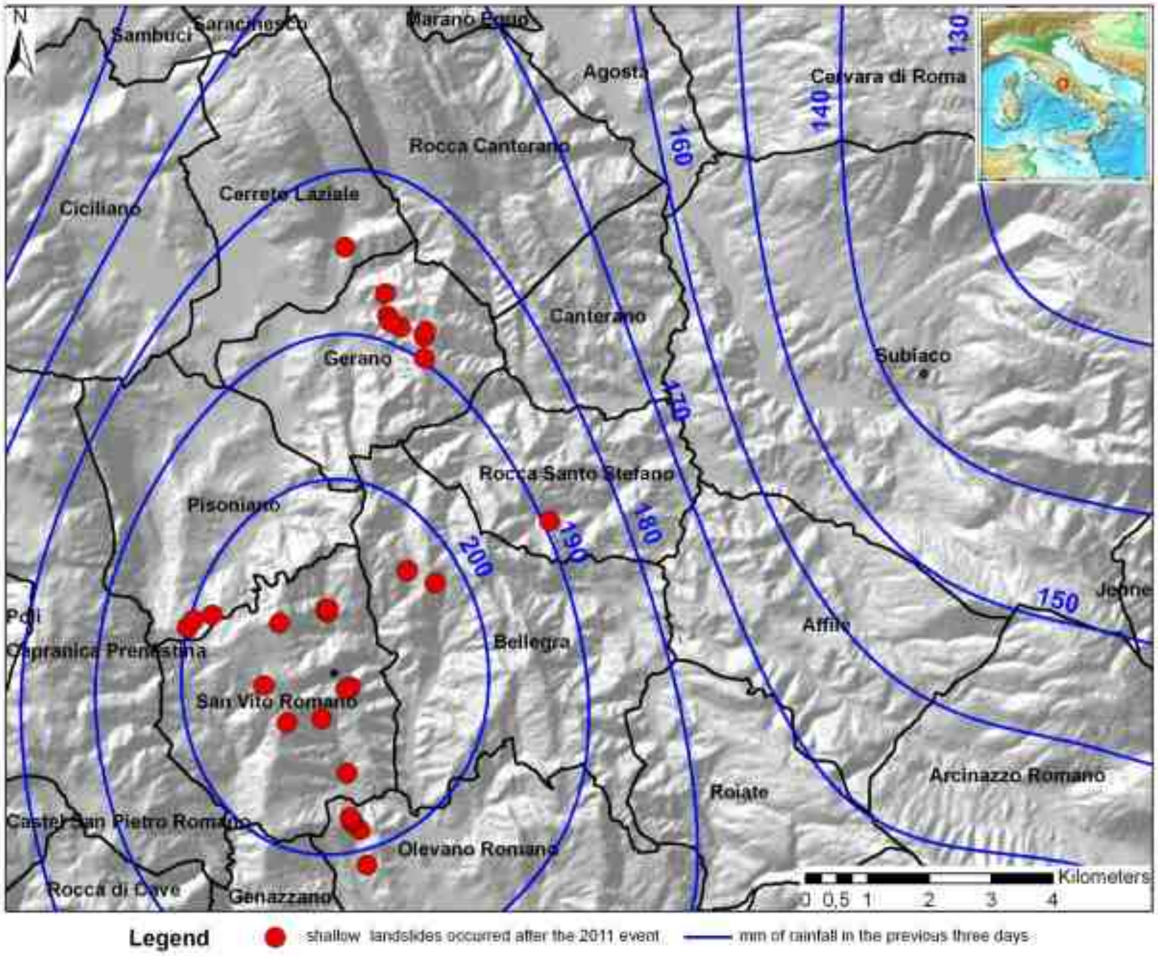

Fig. 2 –Amount of rainfall during the previous three days of 2011, march, 17 event, obtained by SPLINE method. The shallow landslides occurred over a threshold of 180 mm of rain.

calculated. We observe that the influence of 3 days precipitation influence mostly the shallow landslides, but only if in the last month there was almost 170 mm of rainfall. Another important consideration is that the middle-deep landslides are strongly influenced by the geometry of the surface of rupture, the stratigraphy of the body, and if or not are present more than one surface of rupture. While is possible to estimate a mean threshold of 150 mm of rainfall in the three days before the event if the rainfall of the previous month was 170 mm, for the middle-deep landslides is more difficult to estimate a reasonable threshold.

Landslide hazard connected to deep seated gravitational slope deformations and prolonged rainfall: Maierato landslide case history

GUERRICCHIO A. (*), DOGLIONI A. (**), FORTUNATO G. (*), GALEANDRO A. (**), GUGLIELMO E. (*), VERSACE P. (*) & SIMEONE V. (**)

Key words: *Calabria region; DSGSD; large landslide, landslide predisposing and triggering factors; Maierato landslide.*

INTRODUCTION

Large deep-seated landslides and gravitational slope deformations (DSGSD) can severely affect the morphology of large part of the territory conditioning both the stream network patterns, as well as landslide and flood hazard (GUERRICCHIO *et alii*, 2010b). Deformations induced by these large gravitational phenomena contribute to disarticulate slope masses affecting also both rainfall/runoff ratio and the surficial morphology and the shear strength of the involved masses. The fractures and the irregular surface shape, due to the DSGSD favour rainfall infiltration and may represent important predisposing factors of landslides.

The work focuses on the impact of the jointed effect of deep-seated gravitational slope deformations (DSGSD) and antecedent rainfalls respectively as predisposing and triggering factors of the large landslide occurred in the town of Maierato (VV) South Italy on the 15th of February 2010.

GEOLOGICAL CHARACTERS

Maierato is on the East side slope of an asymmetric horst due to the tectonic uplift separating Maierato area from Tyrrhenian sea (GUERRICCHIO *et alii*, 2010a), almost at the NE beginning of the long Mesima graben. The relative basement is made by metamorphic Paleozoic rocks outcropping at the tophill of the horst. Along the slope there is a wedge of sedimentary deposits with increasing thickness toward the lower part of the slope. According to Cassa per il Mezzogiorno (1971) and to boreholes survey campaign developed by University of Calabria Engineering Faculty in the lower part of Maierato slope the sequence of sedimentary deposits is about 70-80 m thick. Generally, it starts with a level of Miocene transgressive sands and coarse sands about 20 m thick, passing to a level of consistent clay and silty-clays (Miocene) of few meters and then by yellowish-white evaporitic limestone and calcareous sandstones up to 25 m thick, with thin layers of silts and silty clays. The sequence is closed by silty-clays and silts layers (lower-middle Pliocene) and Pleistocene continental deposits. Anyway the stratigraphic sequence along the slope is quite irregular because it is severely disturbed by a huge ancient DSGSD, (Fig. 1), and old landslides induced by the morphological disturbances and by the severe seismic history of this area (GUERRICCHIO *et alii*, 2010a), that have deeply disturbed and partly disarticulated the deposits overlying the metamorphic relative basement. Then, there are many morphological steps and bulges affecting the slope, due to secondary scarps and toes.

The main scarp of the DSGSD creates in the upper part of the slope a large trench along the NE-SW direction, which is drained towards NE by the upper part of Ceramida ditch and

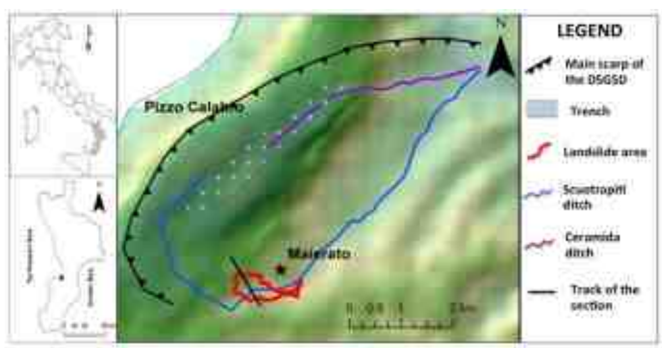

Fig. 1 - Main features of Maierato landslide area.

towards SW by Scuotrapiti ditch (Fig. 1). Scuotrapiti has a strange bow-shaped pattern driven by the bound of the large DSGSD and finally flows at the toe of Maierato slope toward north.

Rainfalls, infiltrating in the trench, supply aquifers hosted in the permeable layers lying over the metamorphic basement, creating a multilayer flow system. Groundwater flows quite irregularly due to the severe permeability variation both vertically and horizontally and to the presence of clayey layer interbedded in more permeable strata. In fact, piezometric measurements developed during the Calabria University survey

(*) Calabria University – Department of Soil Defense – Cosenza – Italy.

(**) Technical University of Bari – Department of Civil Engineering and Architecture – Bari – Italy.

campaign showed, in the same borehole, different groundwater levels at different depths. This confirms a multiple level groundwater circulation. In the deep more permeable layers groundwater may flows under pressure due to the confinement of the marly-clay levels. There groundwater pressure can be really high (GATTINONI *et alii*, 2011), in particular during severe rainfall periods. It is because groundwater supplying these levels infiltrates mainly in the upslope trench and flows with a short path in quite permeable layers. Thus, pressure head losses can be quite small.

These groundwater levels were partly drained by several springs, located in the quite flat area called "Giardino" on the SW side of Maierato, at the base of the slope before the large landslide. It is close the SW boundary toes of the DSGSD, close to Scuotrapiti ditch. There, groundwater can more easily be drained because of the deformation due to the DSGSD and to the secondary scarps affecting the whole slope. Therefore, it was easier for the upward flow of the deep groundwater to reach the surface.

MAIERATO LANDSLIDE

On February 15th 2010, a large landslide occurred in the SW neighbourhood of Maierato town after a period of prolonged, not severe, rainfalls. In Fig. 2 is reported a geological cross section of the landslide. Its activation was preceded by a phase of several days during which severe deformations were measured in "Giardino" area. The landslide activation occurred in a sudden way and the landslide behaved like a plastic-fluid volume. The area was already cleared and under monitoring due to the observed deformations. Therefore, no fatalities occurred and it was possible to film the activation phase. TV images were so impressive that the landslide became quite famous, attracting the interest of several researchers (GUERRICCHIO *et alii*, 2010a; GATTINONI *et alii*, 2011; COMERCI & DI MANNA, 2010; ANTRONICO *et alii*., 2010; GUERRICCHIO *et alii*, 2011).

Looking at TV images, it appears that the landslide movement propagated upslope, causing a series of breaks and detachments as a sort of multiple rotational slide driven by a plastic-fluid substratum, generating a complete "disarticulation" of the landslide body. During the movement this one was disaggregated into blocks, mainly of few cubic meters. This originated a large flow of blocks of Miocene evaporitic limestones and sandstones and Pliocene sandstones and sands. They create a disjointed mass of muddy fluid calcareous-clays and mud material. To explain this behaviour it was necessary to have a severe loss of strength in deep levels. It may be due to the relevant increase of deep pore water pressure.

During the prolonged rainfalls period preceding the landslide, deep groundwater levels were copiously and continuously supplied. Springs were not able to drain enough groundwater, thus pore pressure increased slowly, but continuously. Therefore, in that area at the toe of the slope, there was a continuous decrease of effective stresses and then of the strength. The movements were registered at the base of the slope in "Giardino" area, possibly related to deep pore water pressure increase. The supply of further rainfalls made it possible to have a quick pore pressure increase until an almost complete loss of effective stresses, that may explain why the landslide activated like a movement of masses overlying a plastic-fluid substratum.

The landslide was so severe that completely destroyed the original geological structure of the area and groundwater flow system. Therefore, groundwater levels measured today, even if are necessary survey elements, cannot be considered as reliable values to analyse what occurred on the 15th February.

THE RAINFALL PRECEDING THE EVENT

On the base of the proposed mechanism it is relevant a detailed analysis of the amount and distribution of rainfall preceding the event. The latest two winters before the landslide, and specially the 2009-2010 winter, were very rainy with regular and well-distributed rainfalls (GUERRICCHIO *et alii*, 2010a; GUERRICCHIO *et alii*, 2011). These kinds of rainfalls likely favoured the infiltration instead of runoff and then groundwater supply.

The twenty days before the landslide were characterized by continuous rain every day. The total amount of rainfall during these twenty days was more than 250 mm of rainfall with a rainfall peak of 35 mm, exactly the day before the landslide (Fig. 3). These cannot be considered as relevant events in terms of rainfall intensity. Anyway the sequence of rainy days, even if not hydrologically exceptional, was quite "singular". Then, rainfall sequence could be considered quite exceptional in terms of infiltration processes and therefore crucial for the activation of the large landslide of Maierato.

On this base a special procedure for rainfall analysis was attempted to give evidence of the exceptionality of prolonged continuous rainfall instead of the total rainfall amount (GUERRICCHIO *et alii*, 2011). The time series of rainfall data was filtered, assuming to cut daily precipitation heights at 25 mm. The assumption is that it is quite difficult to have an infiltration amount higher than 25 mm/d in the soils outcropping in that area. On this premise, the rainfall events preceding the landslide have a return period of about 100 years, and then they can be considered exceptional.

CONCLUSION

The DSGSD involving the slope of Maierato created a predisposing factor for infiltration and for a quite irregular groundwater circulation, locally under pressure, that can be considered as a predisposing scenario for the activation of the large Maierato landslide. The landslide was triggered by the particular long rainfall periods, preceding the landslide. These rainfalls were not exceptional from the hydrological point of view, but singular in terms of rainfall distribution. This likely produced severe infiltration, feeding deep groundwater levels. Due to the particular stratigraphic sequence, infiltrated water could create locally high groundwater pressure head, up to a severe decrease of effective stresses at the toe of the slope, thus favouring the collapse.

Maierato landslide confirms how in the alert systems for landslide activation triggered by rainfalls, it must be considered not only the total rainfall amount, but also its time distribution and geomorphic scenario. Both this elements can condition landslide activation and has to be considered in landslide alert approaches.

A complete model for landslides prediction. Validation for the analysis of infiltration processes in pyroclastic soils

LUCIO OLIVARES (*), EMILIA DAMIANO (*) & GIOVANNA CAPPARELLI (**)

Key words: *Infiltration tests, Landslides, Numerical analysis, Pyroclastic soils.*

INTRODUCTION

The complexity of the infiltration process in slopes covered by partially saturated soils requires the use of a numerical model to foresee the slope's response to rainfall.

The scientific literature in this field proposes a large number of mathematical models which differ each other for the purpose of the applications, the investigated area, for the base equations and the resolution techniques that they adopt (SIMPSON e CLEMENT, 2003). The main aim of these models is to reproduce the subsoil water circulations in space and time, bearing in mind the effects produced by other basic hydrological phenomena such as meteorological factors, surface flows and evapotranspiration.

However, the model's reliability has to be verified and can be improved through careful a validation test of the model itself. The validation test of the numerical model is not easy to achieve. Especially if the intended use of these models is the prediction of the triggering conditions.

The work presents the validation test of SUSHI model (Saturated Unsaturated Simulation for Hillslope Instability) (CAPPARELLI & VERSACE, 2011), by using the results of infiltration tests in homogenous and stratified slope models that were carried out employing the physical model realized by the Second University of Naples (DAMIANO & OLIVARES,2010).

The SUSHI model describes hydraulic phenomena on slope scale, with special interest given to rainfall infiltration phenomena and spatial-temporal changes in pore pressure in the subsoil. In particular, by solving the Richards' equation, it analyses the water circulation in saturated and non-saturated layers, in non-stationary conditions.

It's aimed, prevalently, at analysis of the stability of steep slopes with a covering of granular material whose stability is guaranteed by suction induced cohesion.

The model, therefore, might be the appropriate hydrologic-hydrological module to be used with a geotechnical module in order to form a more complete, comprehensive and articulated slope model (CASCINI & VERSACE, 1986).

The results obtained from the laboratory trial, discussed in following, contributed both to the improving of the model's analytical procedures and to the better understanding of certain water circulation mechanisms in non-saturated strata.

After a brief description of the model, the laboratory trials, the elaborations carried out and the test results are illustrated in the following paragraphs

SUSHI MODEL

The model analyses water circulation in the subsoil and simulates the phenomena which occur, in transitory conditions, either in non-saturated or in saturated zones, in a domain which is spatially bidimensional. It is based on the Richards equation (1931), expressed as a function of suction ψ, given the need to analyse stratified soils with saturated and non-saturated strata.

By adopting a Cartesian orthogonal reference system *Oxz*, with axis *z* inclined downwards, following an approach adopted by Paniconi et al., (1991), the equation used is the following:

$$\frac{\partial}{\partial x}\left[K(\psi)\frac{\partial \psi}{\partial x}\right]+\frac{\partial}{\partial z}\left[K(\psi)\left(\frac{\partial \psi}{\partial z}-1\right)\right]=C_{SU}(\psi)\frac{\partial \psi}{\partial t} \qquad (1)$$

where $K(\psi)$ is the hydraulic conductivity which is a function of suction ψ for non-saturated soils.

The Richards equation does not accept analytical solutions, with the exception of the cases in which simplifying hypotheses and/or boundary conditions are introduced (*Iverson*, 2000; *Chen et al.*, 2003).

Among different numerical type solutions proposed by technical literature (WEEKS *et alii*, 2004; MENZIANI *et alii*, 2007), in SUSHI model spatial-temporal discretization is carried out following the method's procedures to finite differences, while numerical resolution is obtained using the iterative techniques of the S.O.R. method (WANG & ANDERSON, 1995).

INSTRUMENTED FLUME TO ANALYSE THE INFILTRATION PROCESS

In order to investigate the complex hydrologic slope response in a controlled environment and under simple stratigraphic and boundary conditions, two types of infiltration tests were performed on a small scale slope on pyroclastic soils taken from the Cervinara site. Artificial rainfall was applied by spray nozzles installed above the lateral sides of a flume which produced nebulized water.

The tests were performed on homogeneous slopes: the infiltration process in a deposit with a slope of 40° lying on an impervious base is presented.

In all tests, to simulate a hydraulic boundary condition of free flow at the toe of the slope a geotextile drain was positioned. Dimensions of small-scale slopes are selected as regards the thickness/length ratio to consider the assumption of an infinite slope valid: in particular, homogeneous slopes were reconstituted with a thickness of 10 mm and a length higher than 110 cm, while the layered slope has a thickness of 20 mm and a length of 170 cm. During the infiltration (constant rainfall) and evaporation stages, the artificial slope was instrumented in order to monitor water content (by the TDR technique), displacements (by laser transducers and the PIV technique), suction (by mini-tensiometers) and positive pore pressures (by miniaturized pore pressure transducers). More details about test results, the characteristics of the apparatus and the monitoring system are reported in Olivares and Damiano (2007) and Olivares et al. (2009).

In figure 1 the results of two tests are summarised which show, for states of stresses corresponding to 10 cm of thickness, the typical response of a loose and dense soil, respectively. In both the tests during infiltration a marked suction decrease occurred starting from the ground surface towards the base of the model as confirmed by the delay (about 6-8 minutes) of the deep tensiometers installed at the bottom of the model slope. As revealed by settlement measurements recorded by laser sensors, the volumetric collapse is significant in the case of loose soil and negligible in the case of dense soil. In both cases, about 10 minutes before instability, the superficial tensiometers reached constant suction values (about 2-3 kPa) while the deepest devices recorded a practically nil value of suction and the pore pressure transducers started to record a positive value at the base of the slope, highlighting the development of water ponding.

Calibration of the numerical model was carried out on the basis of results of infiltration tests. A 2D analysis was performed, schematizing the slope model assuming for the initial conditions a constant value of suction equal to the mean value recorded at the beginning of the tests.

The experimental data of dense soil test in terms of suction against time at two different depths are compared with the results of two numerical simulations (Figure 2).

The measured and simulated values are in good agreement and demonstrate the validity of the model that seems to be able to correctly simulate the infiltration processes.

The results show the importance of model parameter calibration based on flume infiltration test results, since infiltration rates and boundary conditions applied to the model slope resemble real slope conditions.

Development of rainfall thresholds for landslide early warning in Sicily: a method based on the use of rainfall annual maxima series

DAVID J. PERES (*) & ANTONINO CANCELLIERE (*)

Key words: *Debris flow, Landslide triggering, Peloritani Mountains, Erei Mountains.*

INTRODUCTION

It is widely recognized that landslide risk can be reduced by implementing structural measures as well as non structural measures, such as early warning (KEEFER *et alii*, 1987; DE VITA & REICHENBACH 1998; VERSACE, 2010; CAPPARELLI & VERSACE, 2011).

In this work a methodology for determining empirical rainfall thresholds for landslide early warning, based on the use of the annual maxima of rainfall for sub-daily durations is proposed. The main advantage of using such data is that they are available from the Hydrological Annals of the former Italian Hydrological Service, for a long past period (in many cases of about 70 years). Thresholds are derived combining the rainfall data with the landslide information of the AVI (Aree Vulnerate Italiane) inventory, compiled by the National Council of Research - Research Institute for Hydro-geological Protection (Istituto di Ricerca per la Protezione Idrogeologica), CNR-IRPI (GUZZETTI *et alii*, 1994; GUZZETTI & TONELLI, 2004), with reference to the past century.

The proposed approach is based on the landslide-triggering rainfall events as well as the non triggering ones, in order to maximize a benefit function that measures the performance of an hypothetical early warning system based on the thresholds. The benefit function may allow to take into account the influence of the fact that minor impacts may generally be assumed for a false alarm rather than for a missed alarm.

The methodology is applied at the Peloritani Mountains and the Erei Mountains, the most landslide-prone areas of Sicily.

METHODOLOGY

The use of rainfall annual maxima of given durations T_i, enables to formulate thresholds in terms of precipitation cumulated on a duration of T_i hours. More precisely, the proposed method consists of the following steps:

- Identification of the rain gauges available in the investigated area and collection of the annual maxima of precipitation of the various durations (rainfall value and date of occurrence);
- Collection of the landslide events occurred in the area (date of occurrence and any other relevant information);
- Classification of the precipitation events between the ones that have the same date of occurrence of a landslide (raw set of Positives, P^*), and the ones that were observed when no landslide occurred (raw set of Negatives, N^*). For both of the raw sets, P^* and N^*, the highest magnitude rainfall events are excerpted, obtaining the set of Positives P and the set of Negatives N.
- Determination of the thresholds of cumulative rainfall of given duration, via the maximization of an objective function B that measures the performances of an hypothetical early warning system based on the tentative threshold value x relative to the duration T_i, given by:

$$B(x(T_i);\, w) = (N_{TP} - N_{FN}) + w\,(N_{TN} - N_{FP}) \quad \text{with } w \leq 1$$

where N_{TP} is the number of positives with rainfall values greater than $x(T_i)$ (True Positives); N_{FN} is number of positives below the threshold (False Negatives); N_{TN} the number of negatives below the threshold (True Negatives); N_{FP} the number of negatives above the threshold (False Positives) and w a parameter that represents the ratio of the weight of a *FP* relative to a *FN*, that is not greater than one, because the consequences of a *FN* are generally worse than the ones of a *FP*.

DATA

Hilly and mountainous areas of Sicily are often hit by landslides when intense rainfall events occur. The most landslide-prone areas of the island are the Peloritani Mountains (Messina territory, N-E Sicily) (FOTI *et alii*, 2012) and the Erei Mountains (Enna territory, Central Sicily). The application of the illustrated methodology has been carried out with reference to these two areas (separately), using the rainfall annual maxima series of duration 1, 3, 6, 12 and 24 hours of the rain gauges available in the areas (12 for the Peloritani and 8 for the Erei Mountains area), Fig. 1.

(*) Dipartimento di Ingegneria Civile e Ambientale, Università degli Studi di Catania, V.le A. Doria, 6. 95125 – Catania. e-mail: djperes@dica.unict.it

Fig. 1 – Investigated areas and relative rain gauges considered in the analysis.

A selection of the information on landslide events of the AVI inventory retrieved from the website http://sici.irpi.cnr.it/ (Informative System on Hydrogeological Distasters, Sistema Informativo delle Catastrofi Idrogeologiche) has been made relatively to the two areas. Being the time coverage of these data limited to 2001, an update to 2006 has been carried out, based on various sources (mainly local newspapers).

RESULTS

The results of combining landslide and rainfall data are represented in the plots of Fig. 2. In such a representation the annual maxima of different durations relative to the same date are joined by a line.

In the plots the red lines represent rainfall that potentially activated landslides (among the ones present in the collection), while the green ones represent rainfall not triggering landslides.

From the plots it can be noted a wide scattering of the rainfall data, both for the "positive" (red, landslides) and the "negative" (green, no landslides) sets. Also there is a wide interval in which both cases are frequent, even though there are definite differences between the minimum values of rainfall relative to the two cases. These results may be in part due to deficiencies of the data collection (such as distance between the rain gauge and the area hit by the landslide event, for which low values of rainfall are associated with landslides), but also corroborates results obtained by other researchers (cfr. BERTI *et alii*, 2012), that show that thresholds calculated with reference solely to the case of rainfall events triggering landslides are of questionable reliability and may give erroneous warnings.

Maximization of the objective function leads to the rainfall thresholds shown as thick dashed lines in fig. 2, for various values of the ratio *w* (1, ½ and ¼).

A validation analysis has been also carried out (details are omitted for the sake of brevity), applying the thresholds to a 10 minutes temporal resolution rainfall series measured by rain gauges nearby the studied areas. The best validation results have been obtained for the threshold of 99 mm in 3 hours, for the Peloritani Mountains case, and of 92 mm in 6 hours, for the Erei Mountains case.

CONCLUSIONS

The results obtained from the application of the proposed methodology to the two areas most prone to landslides in Sicily (Peloritani and Erei Mountains), seem to indicate a significant

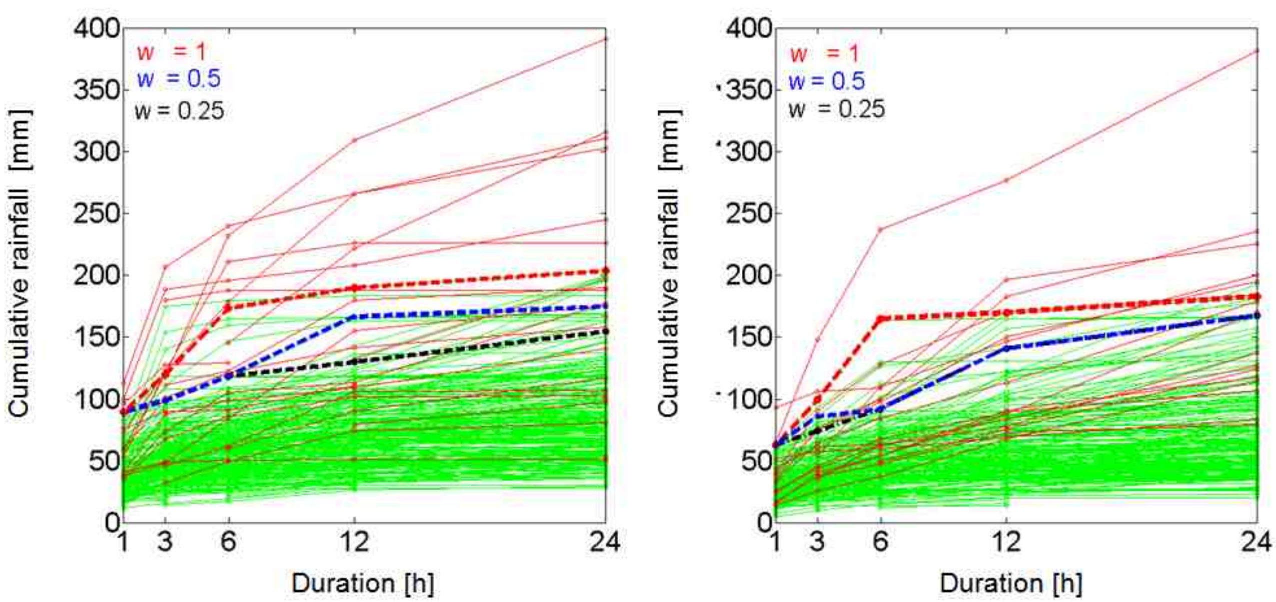

Fig. 2 – Results of the combination of landslide and rainfall information. Thick dashed lines represent the early warning thresholds derived for various values of *w*; Peloritani Mountains (left) and Erei Mountains cases.

information content of the historical data used for the purpose of the analysis, and the actual possibility to identify rainfall thresholds for landslide early warning.

Nonetheless, the traditional shortcomings of data-based models (empirical approach) are highlighted by the results of the proposed methodology, that corroborate the fact that thresholds derived on the basis of both the rainfall events that triggered and not triggered landslides are more reliable than the ones based only on the former.

Including antecedent rainfall in the methodology, through the use of daily rainfall data, is the subject of ongoing research.

Debris flows events in the Messina Province: non structural hydrogeological risk mitigation measures

L.M. STANCANELLI (*), C. LA ROCCA (**), R.E. MUSUMECI (*), V. NICOLOSI (**) & E. FOTI (*)

Key words: *risk map, debris flows, case study.*

INTRODUCTION

The Messina Province is located in the North-eastern part of Sicily Island. It is characterized by the presence of the Peloritani and the Nebrodi Mountains, facing the Tyrrhenian and the Ionian Sea respectively. The geomorphology is characterized by river valleys with large hillslope angles (in the range 30°- 60°) and catchment basins of small or moderate extensions (in the range 0.5 km^2 - 12 km^2) (Figure 1). Within the entire area the soil is composed by metamorphic material, which is easy to be eroded thus forming debris flows, also due to the semi-arid climate that determines high intensity rainstorms of short duration.

During the last three years, the Messina Province has been struck by three different severe alluvial events (Figure 1) which caused several fatalities and significant economic losses.

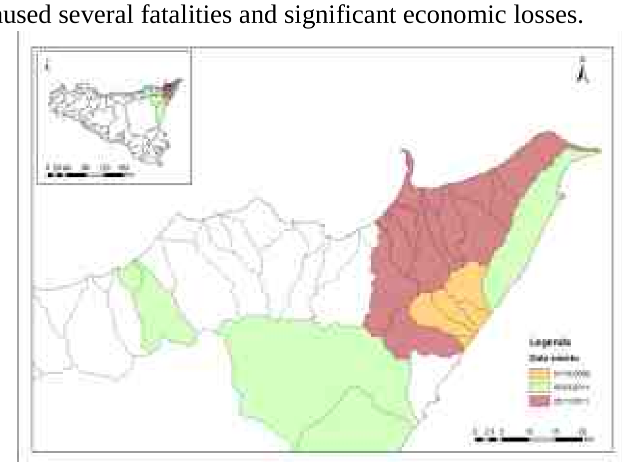

Fig 1 - Catchment basins hit by alluvial events in the Messina Province during the last three years (2009-2011)

(*) Dipartimento di ingegneria Civile ed Ambientale, Università degli Studi di Catania, Italy

(**) Dipartimento Regionale della Protezione Civile della Regione Sicilia, Servizio Provincia di Messina, Messina, Italy

On October the 1st 2009 a severe rainstorm struck the South district of the Messina Province. In that case in an area smaller than 60 km^2, more than 600 debris flow events occurred in a few hours, which resulted in 37 fatalities and damages to public and private structures. The intense rainstorm interested the municipalities of Messina, Itala and Scaletta Zanclea; one of the most damaged villages was Giampilieri (Figure 2a).

Moreover during February-March 2011 heavy rainstorms hit almost the same area, involving in such a case a wider territory, on both sides of the Ionian and the Tyrrhenian of the Messina coast. Several shallow landslides caused damages to transportation and public and private buildings.

Fig 2 - Images of the alluvial events: a) heavy damages in the urbanized area of Giampilieri during the alluvial event of 1st October 2009; b) bridge collapsed in Barcellona Pozzo di Gotto town during the alluvial event of the November 2011.

A more recent event is the one which happened the 22nd of November 2011, when an area more than 400 km^2 wide was damaged. The most damaged villages were Barcellona Pozzo di Gotto and Saponara, where 3 fatalities occurred. Also in this case several damages to infrastructures have been observed, in particular related to the traffic transportation system (Figure 2b), hydraulic structures, mainly sewage system and buildings.

Alternative approaches, reconstruction options, recovery strategies and different possible designs of structures for mitigating the hydrogeological risk were the focus of technicians, local administrations, public body representatives, civil defense authorities and population stakeholders during the months that followed the disasters.

With particular reference to the event of October 2009, the challenge for technicians was to improve the resilience of the town reducing the vulnerability to a reasonable level through structural and non-structural risk mitigation measures such as hydraulicarrangment of the hydrographic network in the urban context and the drafting of a color-coded hydrogeological risk map of the towns.

The decision making process has been carried out always involving the civic committees in order to proceed with technically feasible, economically sustainable, environment-friendly, largely accepted choices.

It is worth pointing out that non-structural mitigation measures such as population alerting systems made through the use of SMS, horns or loudhailers partially lose their efficiency due to the small dimensions of the basins involved during the event, that are characterized by a very fast hydrologic response to severe meteorological events.

NON STRUCTURAL HYDROGEOLOGICAL RISK MITIGATION MEASURES

During the emergency stage, initially in order to favour a slow recovery to normal conditions for the population, a strategy based on non-structural hydrolgeological risk mitigation measures has been carried out. Color-coded hydrogeological residual risk maps have been drafted for all urbanized centers hit by the event. Figure 3 reports the first release of the map of Giampilieri. Four colors have been used to delimitate areas at a block of flats scale resolution. The following meanings are associated with colors:

RED – areas pertaining to river/streams (hydrologic) or to landslides (geomorphologic), even not directly impacted by recent events. In these areas structures (i.e. buildings) and/or infrastructures (i.e. streets) have to be moved to safer areas. After an accurate in-situ verification buildings falling on these areas have to be demolished.

PINK – areas involved by hydrogeological instability, areas close to areas involved by hydrogeological instability, areas where remain clear conditions of hydrogeological risk that cannot be solved by local interventions, areas where are present structures (i.e. buildings) and/or infrastructures (i.e. streets) which increase or can increase local conditions of hydrogeological risk. Within these areas delocalization and demolition of buildings are not excluded.

YELLOW – areas involved by hydrogeological instability, areas close to areas involved by hydrogeological instability, areas where clear conditions of hydrogeological risk remain that have to be locally investigated and can be solved through geotechnical or hydraulic local interventions. Within these areas, buildings are not immediately livable.

GREEN – areas not directly involved by hydrogeological instability and where are no present clear conditions of hydrogeological risk. Buildings can be declared livable after an accurate in-situ verification also considering the working conditions of water, sewer and electric networks and the safeness of the ways of access.

Fig. 3 - Color-coded hydrogeological risk map of Giampilieri Town, developed using a speditive approach.

In particular two different methodological approaches for drafting such maps have been developed: a speditive approach based on uncertain data collected during the first phase of the emergency and a more sophisticated one validated through a numerical model.

The speditive approach takes into account preliminary analyses based on on-site surveys, rough geomorphologic data collection, hydraulic streamflow network studies and effects on infrastructures, leading to a colour-coded risk map. While the more sophisticated approach makes use of the two-dimensional commercial model FLO-2D (O’Brien, 2007), which is physically based and takes into account the momentum and energy conservation of flows (Figure 4a). Hyperconcentrated sediment flows are simulated considering a monophase approach, based on empirical quadratic rheological relation developed by O'Brien and Julien (1985). More detailed information about this rheological model can be found in O'Brien et al. (1993). The model can be used to predict areas potentially endangered by debris flows. In particular, FLO-2D simulations have been run in order to analyze debris flow propagation and deposition inside the Giampilieri village, which allow to define and validate the vulnerability analysis of the investigated sites (Figure 4b).

a) b)

Fig 4 - Images of vulnerability map for Giampilieri village: a) developed using FLO-2D; b) comparison between FLO-2D results and these coming from the speditive approach.

CONCLUSION

The Messina Province is an high risk of debris flow phenomena prone area. The extension of the area involved by such phenomena and also the presence of small basins makes non-structural measures more suitable in order mitigate hydrogeological risk of the urbanized areas.

In particular, in the present paper it has been presented a methodology for mitigating the hydrologeological risk by the drafting of vulnerability maps particularly powerful for the implementation civil protection policy. The vulnerability map has the aim of indicating the more dangerous places inside the urbanizated area.

They have been developed using two different approaches. The first one based mainly on site-surveys and the second one making use of a propagation debris flow model.

In conclusion it is important to point out that the maps have been designed as something in continuous evolution that has to be permanently updated on the basis of the progression of more time-consuming structural mitigation measures.

ACKNOWLEDGMENTS

All consultants of the OPCM 10 October 2009 n°3815 are greatly acknowledged, for the support demonstrated also for the provided information.

We would like to thanks the Public Civil Engineering Works Office of Messina Region and the Department of Civil Protection of Sicilian Region for providing important data such as the digital terrain model.

LEWIS Project: an integrated system of monitoring, early warning and mitigation of landslides risk

P. VERSACE (*),G. CAPPARELLI (*), S. LEONE (*), G. ARTESE (**), S. COSTANZO (***), P. CORSONELLO (***), G. DI MASSA (***), G. MENDICINO (*), D. MALETTA (*), F. MUTO (°), A. SENATORE (*), A. TRONCONE (*), E. CONTE (*) & D. GALLETTA (°°)

Key words: *early warning, landslide, monitoring.*

GENERAL FEATURES

The LEWIS (Landslides early warning integrated system) project is aimed at developing an integrated, innovative and efficient solution in order to solve the risks caused by those landslides that can interfere with infrastructure.

The research project was submitted for financial support in the framework of the Multi -regional Operational Programme 2007-13: Research and Competitiveness funded by the Ministry of Research (MIUR) and co-funded by the European Regional Development Fund.

The final goal is to timely identify the potentially dangerous landslides and to activate the necessary safeguard measures in order to avoid and mitigate the consequences for the population, including information delivery.

The approach to the problem corresponds to a "systemic logics" (Figure 1) where each developed component (monitoring arrays, telecommunication networks, scenario simulation models, data acquisition and processing centre, traffic control centres) foresees different interchangeable technological solutions to maximize the operational flexibility.

The final system may be configured as a simple to complex structure, including different configurations to deal with different scenarios. Specifically, six different monitoring systems will be realized: three "point" systems, made up of a network of locally measuring sensors, and three "area" systems to remotely measure the displacements of large areas. Each network will be fully integrated and connected to a unique data transmission system. Standardized and shared procedures for the identification of risk scenarios will be developed, concerning the surveys to be carried out, the procedures for each type of on-site testing and guidelines and dynamic templates for presentations of results, such as highway risk maps e.g.

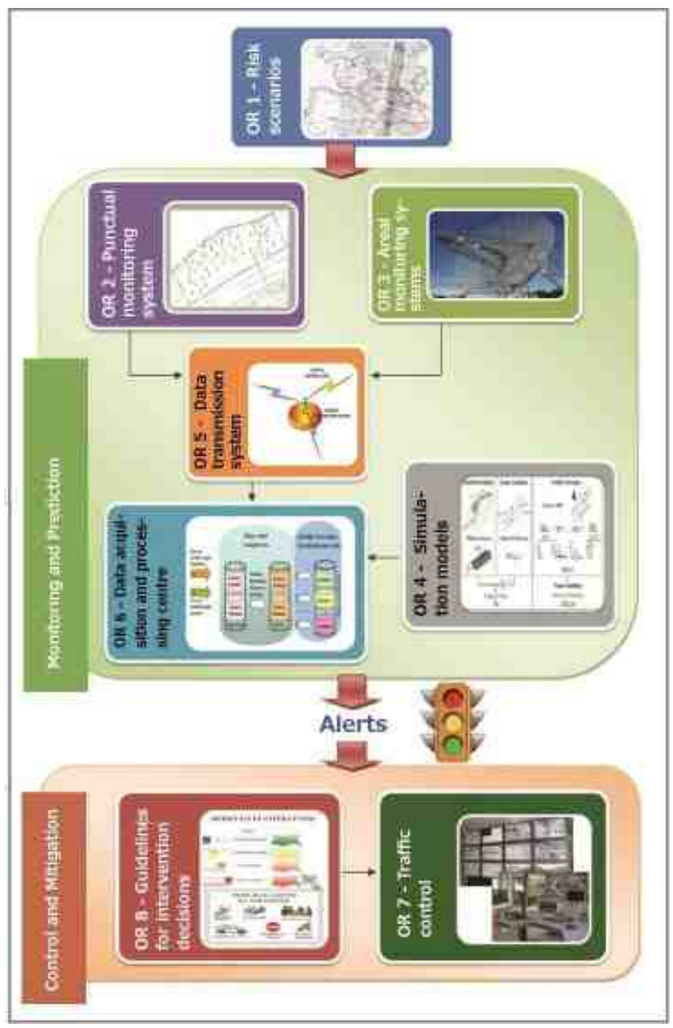

Fig. 1 – The LEWIS Project plan.

The setting up of data acquisition and processing centre and traffic control centre are the core of the integrated system. The

(°°)Società Autostrade Tech, Roma

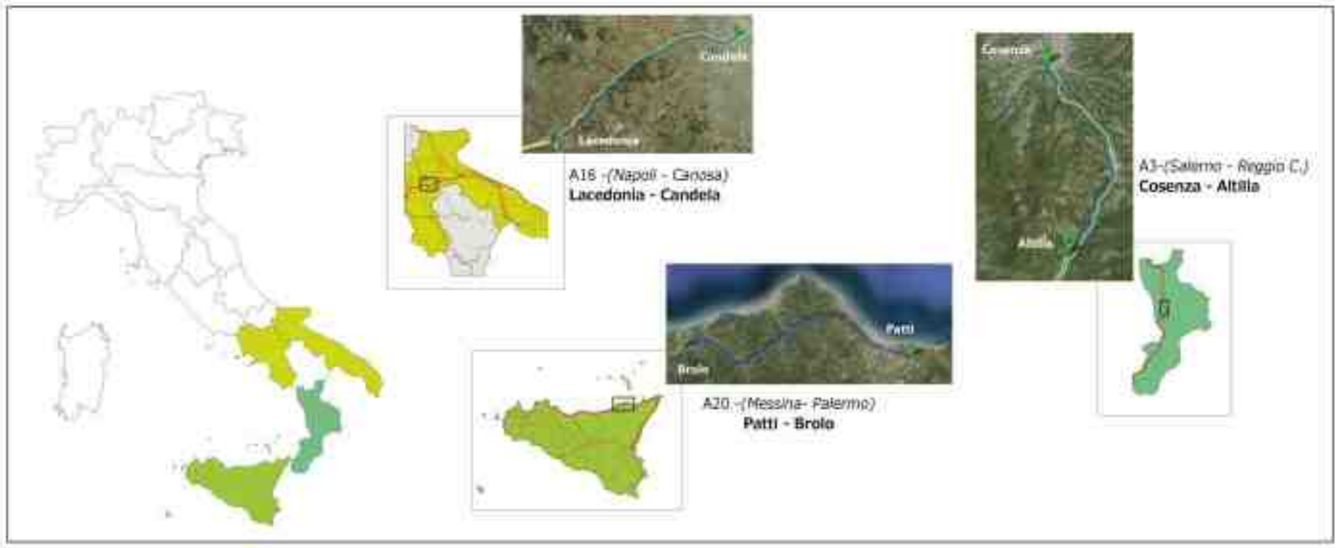

Fig. 2 – Site test in the regions of Puglia, Calabria and Sicily where the system will be experimentally validated.

DAC (data acquisition center, newly designed) will acquire and process data varying in intensity, dimensions, characteristics and information content.

The Traffic Control Center (TCC) is meant to integrate the scientific and the management aspects of hydrological risk monitoring and early warning. The overall system is expected to benefit of the development of new, advanced mathematical models on landslide triggers and propagation. Triggering models will be empirical or hydrological, represented by simple empirical relationships, obtained by linking the antecedent rainfall and the landslide time occurrence, and complete models identified through more complex expressions hat take into account different components as the specific site conditions, the mechanical, hydraulic and physical properties of soils and slopes, the local seepage conditions and their contribution to soil strength.

Upon integration, the system will be experimentally validated and demonstrated over ca. 200 km of three highway sections, crossing the regions of Campania, Puglia, Calabria and Sicily, as showed in Figure 2.

Teaching Geography Outdoor. The Case of Ce.P.E.A.

GIANFRANCO BATTISTI (*)

Key words: *Field Lesson, Wandering Lesson, Human Geography, Urban Geography.*

Human geography, although classified by the Ministry of Education among the humanistic disciplines, shares with natural sciences the tradition of field activities as a fundamental experience in the teachers' education. Owing to the lack of time and money, not to mention the willingness of teachers, nowadays this practice is rather disused; nevertheless it is still considered of paramount importance in all fields of the discipline, i.e. the cultural, economic, political and social ones. For this reason, every scientific meeting ends with a field excursion aimed at introducing foreign colleagues to the most noteworthy characters of the geographical region investigated by the organizers.

We all agree on the fact that studying geography only through books and maps is inadequate. Neither can lectures and workshops, even if carried out through multimedia instruments, succeed in completing the task. Between the oral description of whatever geographical phenomenon, even if with the help of images (printed or projected on a screen) there is the same difference existing between the advertising of an ice-cream and its actual flavour. Moreover, scientific knowledge means the capacity to recognize and, as we all experience, our ability to re-cognize is linked to a previous knowledge (just like the biblical meaning of the term).

The field lesson is precisely the opportunity to transfer this basic experience; the time (and the place) when under the master's guide we learn how to learn - and therefore to teach - thus acquiring the knowledge through the whole of our senses. Learning through discovering, a guided but always ineherently individual experience. By shareing the experience, the learner acquires at the same time the concurrent capacity to lead other pupils on the same formative path.

Inside a classroom, the key question lies in the sensory limitations of the proposed models (no matter if graphic, icononic or mathematical ones) in comparison with reality.

This is particularly true for geography, since the phenomena it considers are intrinsecally clusters of analytical phenomena studied by other disciplines.

First of all we must consider the dimensional shrinkage, or better, the problem of scale (think at the difficulty to correctly read the maps). There is also the narrowness of the field of vision, linked both to the perspective chosen in the representation and the shooting angle of the camera. The vision is always limited, because is "commended" (or chosen) by the teacher, who is interested in focussing the attention of his audience towards the places and details considered to be the most deserving.

The rest of the scene is generally neglected, but the rest in our case represents the context where the different phenomena are framed. This is of particular relevance for geography (both physical and human), but also for applied disciplines like land-use planning the position in the wider context is a fundamental point of view.

At the end, in the class-room the teacher must adjust his freedom to the timing and the spaces available, where the transmission of knowledge is institutionally grounded. These constraints are in conflict with the freedom of the learner too, who often wants to look farther than the teacher, to cast a glance towards other directions. In doing so he may enrich himself, working out interests and questions sometimes trivial but never useless. The process of learning is indeed the product of the teacher's activity, but it starts only when the learner's mind has been put in the condition to move into action.

To this purpose, the teacher is required to have a specific preparation. This is partly of disciplinary nature, partly requires a previous organizational activity, aimed at easing the field activity to the teachers.

As an example, we highlight the experience gained in Trieste during the 90's, at the Permanent Centre for Environmental Education (Ce.P.E.A.). It was a joint venture promoted by the provincial education superintendency, the municipal administration and the Department of Geographical and Historical Sciences, University of Trieste, with the cooperation of the Association of Italian Geography Teachers (A.I.I.G.). In Italy the university curricula for schoolteachers were at their beginning, so the author, together with Dr. M. Stoppa, prepared some training courses for teachers and university students. Two titles among others: *The Environment Tells - Tell the Environment, A city to live in - Understanding in order to Manage.* For each course a questionnaire was produced, useful to the introductive check-up of learners, as well as a program of field trips.

(*) Di.S.U., University of Trieste; e-mai: gbattisti@units.it

Paper prepared within the research activity furthered by the P.I.D.D.AM. under the aegis of CIRD, University of Trieste.

Fig. 1 – Trieste. A panoramic view from the slopes climbing up to the highland.

Concerning the said curriculum in urban geography, four routes were selected in the Trieste built-up area: the main canal area in the so-called *Theresian town*, the panoramic funicular to the karst village of Opicina, the new industrial zone, the old and new free port facilities.

A working form was produced for each of these routes. It began with the technical notes (time required, type of route - pedestrian, by pullman. etc. - gathering point, entry permissions, educational goals, possible scientific support, i.e. the intervention of a geologist). The second part contained the essential information (borders and type of the area to be crossed, prevailing functions, urbanistic models, noteworthy architectural elements, main land-use transformations in and outside the area, synthetic reading of the selected processes). The form ended with normative and bibliographical references.

Fig. 2 – Old factories bordering the canal in the centre of the industrial zone.

Glaciers one-time

A century of climate change on glaciers of Italy

One popular project with direct involvement of the society that becomes protagonist and share in research

CHRISTIAN CASAROTTO (*)

Key words: *photographic comparison, glaciers, research and society, enhancement mountain environment.*

INTRODUCTION

Alpine glaciers are of great importance in the eyes of climate, economy, society and energy studies. They are also an element of the alpine landscape that has long fascinated researchers and explorers going to high altitudes. At present we must recognize that during the last century the extent of alpine glaciers has been halving. This highlights the importance of collecting scientifically valid evidence involving the citizenship in the development of a popular scientific project, which, among its objectives, aims to make the society conscious of the glacial retreat in action and to quantify the changes in the mountain landscape.

The project has been proposed and publicized to the whole community, in order to involve everybody in a research program. All are invited to take photographs of the modern Italian glaciers with the exact points of view of historical photographs, and to make photographic comparisons. The photographic comparisons in fact are the basis to carry out comparative studies on the health of our glaciers, seen as valuable indicators for the assessment of climatic conditions and their evolution over time.

With the aim of encouraging the community to approach, re-discovery and develope the mountain environment, we didn't give detailed information relating to the photographed glaciers; so the citizens are encouraged to start a phase of study, with important social implications, concerning the identification of the glacier and the location of the place from which to take the photo.

The project *Glaciers one-time* is characterized therefore by a strong involvement of society in the world of research, to the enhancement of the Italian Alps, as an incentive to attend and rediscover the mountain, transmit to the society the meaning and importance of research, and ensure that the research becomes an important process useful for the growth of the individual and the community.

The choice of the Italian glaciers is carried out in collaboration with the Comitato Glaciologico Italiano, involving all regional and provincial organizations and institutions that carry out glaciological activities (Fondazione Montagna Sicura, Servizio Glaciologico Lombardo, Servizio Glaciologico Alto Adige, Comitato Glaciologico Trentino, ARPA Veneto, Unione Meteorologica del Friuli Venezia Giulia).

The important institutional network so has the goal to cooperate together for the promotion of historical photo archive, the promotion and dissemination of research within the society, the enhancement of the mountain environment and of tourism activities, the understanding of the landscape changes due to retreat of the glaciers.

In detail, the operational phases of the project *Glaciers one-time* were:

1 - Identification of the national network. The Museo delle Scienze, the project leader, launched a capillary communication directed to organizations and institutions, public and private, in various capacities, operating within the context of the Alps and involved in glacier monitoring.

2 - Identification of the Scientific Committee. With the collaboration of Carlo Baroni (University of Pisa), Claudio Smiraglia (University of Milan) and subjects related to the institutions of the national network a Scientific Committee was established with the task of validating the scientific aspects of the

(*) Museo delle Scienze, via Calepina 14 - 38122 Trento.

Project co-funded by the Comitato Scientifico Centrale del Club Alpino Italiano, under the patronage of the President of the Italian Republic.

With the participation of Comitato Glaciologico Italiano.

Coordination of the Scientific Committee: Carlo Baroni, Claudio Smiraglia, with Fondazione Montagna Sicura, Servizio Glaciologico Lombardo, Comitato Glaciologico Trentino, Servizio Glaciologico Alto Adige, ARPA Veneto, Unione Meteorologica del Friuli Venezia Giulia.

Sponsorship of Società Geologica Italiana, Società Geografica Italiana, Collegio Nazionale delle Guide Alpine, ENEA, CNR, Accademia della Montagna del Trentino, Trento Filmfestival della Montagna, Ministero dell'Ambiente del Territorio e del Mare, Ministero dell'Istruzione dell'Università e della Ricerca.

Fig. 1 – The Adamello Glacier as seen in 1903 and how it is today. From the photo comparison we may extrapolate date concerning the glacial retreat in the last century.

initiative and the qualitative factors to extrapolate through photographic comparisons.

3 - Identification of a Mountaineering Committee. The Museo delle Scienze identified, within the mountaineering world, two major figures in the field of the mountains to represent the project: Fausto De Stefani and Michele Comi. The two climbers have simbolized respectively the historic and modern alpine photography, with a dialogue concerning the changes in mountain climbing, or "of going to the mountains". Mountain climbing is in fact a practice following the modifications in the high-mountain landscape.

4 - Selection of historical photographs and their widespread national circulation. The Museo delle Scienze involved stakeholders in the institutional network, leading them to enhance the photographic archives and historical images, with reference to some of the most significant Italian glaciers, can provide qualitative data of changes in the landscape. The photographs, selected to cover uniformly all over the Alps, have published on the websitewww.ghiacciaidiunavolta.it

5 - Recognition of places. The society didn't suggest the pointers, mountains, glaciers and valleys depicted in the photograph. The project allowed the discovery of the territory retracing the paths walked by the ancient photographer to take, in the same place, the same snap shot. This was useful for promoting the re-discovery and development of the mountain, starting a process of socialization leading to the identification of the place from which to take the photo.

6 - Forwarding of the produced photographs. We offered the opportunity to take photographs during the entire summer 2012. The photographic material was to be sent, via the website, to the Museo delle Scienze who files the photos with information on the author's, date and place of capture.

7 - Analysis, evaluation and selection of the best photographic comparisons. The Scientific Committee is conducting the appropriate assessments to extrapolate the best pictures. With this selection the Committee is working to extract, through photographic comparison, the changes in landscapes and portraits of the glacial retreat.

Fig. 2 – The website of the project *www.ghiacciaidiunavolta.it*, hosting the photo gallery and allowing the mailing of the photos produced during the summer 2012.

8 - Publication of the material. All the best pictures are shared within the network and posted online to make them available to the entire community that can see and rediscover the importance of their work. With the contribution of the Società Geologica Italiana, a publication will collect the best photographic comparisons with qualitative / quantitative analysis and geological and geomorphological descriptions of some routes to the "discovery of the glaciers". A DVD and / or traveling exhibition may also be created.

The purpose is to disseminate the valuable material contributing to an epochal debate. The photographic comparison of alpine glaciers, portrayed in historical times and today with the same frame and location, documents a strategic issue in an endangered planet from which depends the safety of future generations. The glacier is in fact our wealth and the development of mankind cannot in any way be separated from its conservation. A century of climate changes in the Alps is a long part of human history that we can trace back, rediscovering the charm of the alpine landscape and its greater glaciers in the past.

The Discovery of Landscapes Based on Geological Boundaries. A Study Visit in the Regional Reserve of Rosandra Valley (Trieste)

GIOVANNI GIURCO (*)

Key words: *Didactics of Geosciences, First Grade Secondary School, Study Visits, Protected Areas, Friuli-Venezia Giulia.*

The new first grade secondary school is greatly interested to get over a layout still linked to the traditional classroom front lesson. To this regard, the study visits on the ground represent particularly efficient experiences towards significant development of multidisciplinary competences, unavoidable also on the motivational side, to enhance the learning of geography and natural sciences.

Usually, even if not by necessity, study visits are integrated in a wider range of workshop plans, mostly markedly interdisciplinary, lasting four months periods. For this reason, they must also be carefully planned and designed, through the formulation of a detailed action plan, specific for each one of the disciplines involved. "Teaching on the field" is, therefore, a complex and demanding activity at the same time, stimulating and fascinating, undoubtedly crucial for a significant learning of geosciences.

The didactic experience presented in this paper was conceived for a target group including 20 students of various classes in the three-year curriculum of the first grade secondary school, thus operating on a vertical perspective. The activity has been realized in the first decade of March, because the reduced vegetation covering allows easier observations of the peculiarities - both morphological and geological - of the territory.

We singled out the "*polje* of ice-houses", located near the little settlement of Draga St. Elia (near Trieste), within the regional natural reserve of Rosandra valley. Although located in an apparently marginal area of the Reserve and therefore much less known to the visitors than the nearby Rosandra valley, it is an extreemely interesting place for the contiguous presence of an anthropic and a geosite of high interest from a cultural and didactic point of view.

The geosites positioned in an environment characterized by the presence of a geological boundary between litotypes of different permeability (limestone and flysch), allow the students to launch into captivating discovery of the layout of river-karstic transitional landscapes and their characteristic landforms.

The study visit has been properly subdivided into eight steps, during which the students have carried out mainly workshop activities.

The first phase required a bus transfer to reach the site, the teachers handed out to each student a didactical package containing cartographic excerpts concerning the territory and a field book to be used in the outdoor workshops. They divided the students into working groups, operating in competition (particularly during phases 2 and 3) or sinergically (mostly in phases 4-7). Logistic information have also been given about the operations to be dealt on site by the different groups.

Phase 2 involved advancing on the cart roads and the tracks connecting the nuclear settlement of St. Lorenzo (starting point) and the site to be investigated. The path wounded up in a karstic plateau.

Along the way the students performed orienteering activities, using cartographic excerpts, properly enlarged, from the Regional Technical Map 1:5,000. The learners have been invited to single out and map the outcrops, collect samples, make the main macroscopic observations about the calcareous lithotypes, learn how to measure the attitudes by means of a geologist's compass, and tabulate the collected data.

Phase 3 began when the closed catchment basin was reached. The learners have been stimulated to measure themselves against analytical observations from panoramic places. The themes were the forms associated to the two lithological domains in the areas (the calcareous and the marley-sandstone one) as well as the

Paper prepared within the research activity furthered by the P.I.D.D.AM. under the aegis of CIRD, University of Trieste.

Fig. 2 – A pond where the ice was quarried from the depression, which is still collecting the meteoric waters, was made by removing the materials of colluvial origin coming from the degradation of marley slopes and dykeing the edges to increase the volume.

Fig. 3 – Remains of an ice-house, where the ice forming in Winter in the nearby ponds was deposited and conserved. The ice was sold in Summer before the development of modern refrigeration systems. Obtained from materials of colluvial origin, the man-made facility was made of limestone.

morphologies shaped on the contact between the two lithotypes, not forgetting the characters of the corresponding vegetation landscapes and the different land use forms.

The learners have been invited to describe the observed objects, to formulate hypotheses and outline possible interpretations. Adequate time has been devoted to the analysis of the landforms on the slopes.

Phase 4 was reserved to the study of a closed depression. Once impermeabilized, it hold a pond from which in Winter people used to pull out iceblocks that were preserved in the nearby ice-house. The learners have been stimulated to distinguish the emerging lithotypes and discover how a colluvial sheet actually covers the contact between the limestones and the more recent marley-sandstone strata.

Phase 5 was dedicated to examining the anthropic site characterized by a juxtaposition of ponds and ice-houses. The learners have been invited to interact with the teachers in a progressive discovery of the systems of water collecting used in the past by the rural populations, with the peculiar building techniques, the way of use, the forms of potential recycling. The teachers provided operative suggestions finalized to restore the site of anthropic interest, requested to carry out the didactical activities to be developed at school.

During Phase 6, the learners have reached the bottom of the closed depression, and went down a track following the main catchment drain feeding the basin. During the itinerary precise observations were made about morphology and geology (lithological boundaries, side dynamics related to slopes of likely neotectonic interest, springs, characters of erosional trenches, ichnofossils inside the sandstones, remains of hydraulic fittings of rural interest, terracings, plant landscapes associated to the different lithotypes, conditions of environmental dangerousness).

In Phase 7 the learners undertook, with the help of the teachers, a reconnaissance of the bottom of the *polje*, with particular attention to the colluvial deposits, the distribution of water-scooping points (alluvial doline, swallow-holes) also with particular reference to the organization of the ephemeral drainage network.

In Phase 8 the group set out for the settlement of Draga St. Elia. There further observations were made on phenomena like the regression of swallow-holes and the morphology of doline.

The students got on the school bus that carried them back to school. During the activities each group had compiled its own noteboock, collected rock samples and documented through digital cameras the outstanding physiographic features of the landscape. The materials so produced have been used during the consolidation activities later performed in the class room.

The Discovery of Mineral Resource. A Geo-Science Itinerary for Primary School

ROSSELLA LA PORTA (*)

Key words: *Workshop Didactics, Geosciences, Mineral Resources, Primary School, North East of Italy*.

The complex and delicate relationship between man and natural resources is a subject of great interest, on which the school is called to focalize its didactic activity. The territory is indeed a container of resources: the students ought to be helped to ponder it and guided to discover their value and the related problems from the perspective of sustainable development.

Among the opportunities suited to this purpose there are particular facilities - the open-air museums - established to enhance entire regions and the resources they offer. Of particular interest are the museum complexes oriented to revise and protect divested mines. They allow the visitors, through a masterly preservation of the culture and history linked to this activity, to identify the typology of activities once carried out, thus becoming places of evidence and collective memory.

From a didactical point of view, they appear of extreme interest since they exploit the great educational potential both of the museum and the territory. Actually the museum, through the direct involvement of the school world (see f.i. the organization of guided routes inside and outside the museum) qualifies itself as a specific environment devoted to meaningful learning.

The restoring and historical reconstruction of the environment - the mines - set the conditions for an emotional sharing on part of the students. They play an active role, living unique and stimulating experiences that lead them, through playing and discovering, to the self construction of knowledge.

Several are the activities that may be developed inside the museums and, since they stimulate the comparison, the formulation of hypotheses and the discussion in a highly motivating and stimulating environment, they foster not only the cognitive side of the learning process but also the sentimental and relational one. We therefore believe that a museum experience ought to become an integral part of didactical planning, especially from a multidisciplinary point of view.

(*) Scuola primaria "C. Collodi", Istituto comprensivo "Iqbal Masih" - Trieste, e-mail: io_pjoe@virgilio.it

Paper prepared within the research activity furthered by the P.I.D.D.AM. under the aegis of CIRD, University of Trieste.

It is obvious that it may be integrated in a wide-ranging educational path rooted in a workshop didactics, seen as a methodology aimed at developing competences and at the same time realizing the knowledge and know-how concurring to the development of the students' personality.

In this light we have decided to plan a didactical action concerning mineral resources, proving that, notwithstanding its apparent complexity, it may be proposed to the pupils of the last year of primary school. It is composed of practical and group activities, to be performed at school and on the field, in order to facilitate the understanding of the contents and, moreover, raise interest and motivation towards learning.

The theme chosen is of particular interest on the didactical side; considering the extent of the knowledge involved, it may be proposed to the children in a multidisciplinary perspective, drawing in disciplines like geography, history and natural / experimental sciences as well as environmental education.

Various are the subjects to be treated: on one hand mining, with knowledge included in the domain of geographic-scientific disciplines, on the other the analysis of the human characters of life in the mines and in the mountains at large, always difficult and often extreme.

Other themes that may be treated concern the environment, i.e. pollution and environmental disasters produced by mining over time. We can help the learners to realize the importance of preserving the environment and its natural resources.

This didactical proposal - lasting 90 hours in all – is articulated into some workshop activities to be previously developed at

Fig. 1 – Outline of the educational path.

school, finalized to allow the students to acquire the mineralogical and geographical knowledge requested to face up more consciously the educational tour that is the core of the project. The experience shall be later worked on again in a further workshop centred on a reflection concerning the respect and the exploitation of the cultural and environmental assets of the considered territory.

The educational tour - planned to last 6 days - files through a motivating and enriching itinerary that allows to read each subject in a logic and sequential way, growing in relationship and complexity. The selected case studies allow the building of a meaningful educational path, thanks to the variety of didactical stimuli offered by the areas considered throughout Friuli-Venezia Giulia, Trentino-Alto Adige and Veneto (Fig. 2).

The case of Masseria is emblematical, among other things, of the didactic potential of the proposed places. Actually the museum area, located in Val Ridanna (BZ), through the visit of the mine in Ridanna-Monteneve, allows to deepen the knowledge of the mining world, with special attention to industrial archaeology. The mine museum of Ridanna-Monteneve, indeed, is no traditional museum but an entire massif with exceptional facilities and machinery still perfectly working. Here it is possible to penetrate the world of mines, directly experiencing the hard work of the miners engaged in digging mineral out of the underground.

The whole productive chain is still intact, so it a close observation of the equipment is possible. It is a real travel back in time to discover the main techniques of ore exploitation used over the last eight hundred years. People can also put themselves in the miners' place and experiment with darkness, cold, smell, dust and noise which the miners had to live with daily.

For this reason - in addition to the closeness to the Austrian territory, an aspect of particular interest in the perspective of a transborder didactics - manifold are the educational activities that the teacher may offer to the learners. Among these it is worthwhile recalling the visit to the ore upgrading plant, still perfectly operating.

It is a very stimulating experience; the students can understand and get a live look on how the ore was separated from the gangue as well as appreciate the evolution in digging techniques in time and observe some of the tools in operation.

Stage 1	Stage 2	Stage 3	Stage 4
Cave del Predil	*Masseria*	*Valle Imperina*	*Val Resia*
The ore are mined. General issues, dangers and importance of mineral resources in the local economy.	Once dug out, how was the mineral processed? Visit to an upgrading plant and introduction to the environmental problems linked to mining.	Next phase in ore processing: smelting. Visit to furnaces and investigation of the heavy fall-out of mining in the environment.	Naturalistic excursion in the Julian Alps Natural Park. The discovery of a different kind of mineral resources, oil shales.

Fig. 2 – Outline of the proposed itinerary.

Fig. 3 – The Museum area of Masseria (BZ).

In the museum halls, moreover, a wide relief map allows to explain to the children the structure of the impressive ore conveyor plant, based on a complex system of inclined and haulage planes.

Of great impact is the excursion in the bowels of the mountain, that is the discovery of the mine in a literal sense. Starting from the "Poschhaus" gallery at 2,000 meters above sea level, after a run of about 3,5 kms onboard the old narrow gauge train of the mine, a real eventful journey begins. Running through wide tunnels, inclined planes, pits (sometimes occupied by underground watercourses), the students can become fully aware of what working in a mine really is. Equipped with rock drill and mallet the children can also measure themselves with digging the ore from the still existing veins and carry home their "treasures".

The teacher can use the case of torrent Ridanna - which remained devoid of any living organism during more than 20 years owing to the spilling of chemical reagents used to separate metals - to stimulate the learners to reflect about the environmental impact of the mine. Is mining a polluting activity? May it endanger the environment? and in general, which are the sources of pollution caused by man's activity?

Another opportunity is underlying the importance of monitoring natural ecosystems by means of some parameters of the state of the environment. In the case of water, which are these parameters? How is sampling made? Which kind of analysis can be carried out?

It could be useful to propose a workshop activity on the field - to be developed through appropriate kits for the analysis of water - aimed at deepening some of these subjects and making the students understand the importance of water as a resource.

In short, we believe that manifold activities can be performed in the selected museum areas. They can lead to a fuller understanding of the complex relationships between man and the resources of a territory. So students can consider the reality from different points of view and learn it in a meaningful and contextualized way. When involved in this kind of workshop itinerary the students will be able to dynamically perceive the close links existing between a territory and the economic and cultural processes and analyze man's on the environment, thus understanding the importance of its preservation.

Field Activities in the Training of Teachers

MICHELE STOPPA (*)

Key words: *Didactics of Geosciences, Didactic Research, Initial Education of School Teachers, Teachers' Training, Territorial Didactics, University Didactics.*

If adequately prepared and harmonized to the different training offers, didactical activities on the ground, carried out in direct contact with the real territory, pay a not marginal contribution to the learning of geosciences. They actually allow the consolidation and contextualization of learning, thus overcoming the fragmentation of the different curricula.

THE NEED TO TRAIN TEACHERS

The territory-based didactics represents a valued opportunity for students, yet its quality depends on the command of specific competences on part of their teachers. These must in fact be able to control its complexity with full awareness and in a reliable way so as to guarantee its educational effectiveness.

As a consequence, the activities on the ground give a professional training also to the initial education of the future teachers involved in the various teaching processes - learning of geosciences in the schools as well as their preconditions, perspectives and goals - which are rather different from those requested of a professional geologist.

The curricula drawn up for the training of teachers, therefore, ought to take into account a systematic recourse to initiatives of territorial didactics. These must of course make reference to and be founded on the basic themes from the school curricula, developing them with a particular attention both to the information function (contemporary consolidation of theoretical learning) and the professional one (methodological training).

Moreover, it is of paramount importance to offer courses in Applied Geological Survey. By mixing together topics pertaining to the multidisciplinary field of geosciences (especially geological survey) and didactical topics, this would make it possible to provide the teacher with the specific competences required to plan and carry out a didactics on the ground, that is one tailored to suit the different learning material required at each school level.

THE DIFFERENT TYPES OF TRAINING

Some of the field activities (lessons on the ground, wandering lesson, study visits, study tours etc.) aim at giving the possibility to acquire and consolidate learning, promote multidisciplinary competences (territorial workshops, didactical excursions, survey campaign) or professional teaching-related expertise (geological survey campaigns applied to the didactical planning of territorial curricula). For obvious reasons, activities of this kind are only suited to numerically limited target groups.

Lessons on the ground (limited in time) aim at studying a phenomenon restrained within a well-defined area (for instance an outcrop, a stratigraphic sequence, the segment of a river bed, a geotope). The territory becomes thus a sort of virtual classroom and the lesson must be adjusted to its characteristics. It cannot absolutely be the repetition on the ground of a traditional front lesson held in a classroom.

Bad weather (cold, hot, rain, wind etc.) as well as an excess of vegetation or disturbing biological activity (insects, for example) may give rise to objective difficulties that can be partly overcome using adequate clothing or resorting to other solutions (an umbrella can enable a student to take notes even under the rain). The teacher has to consider the manifold stimuli conveyed through the context, which may cause a diminution of attention on part of his students but may also be adequately used to rouse their interest and support their motivation.

Long monologues are to be avoided and the appropriate comments must be very short, sharp, contextual, selective, formulated in an interactive, dialoguing way. Teachers must absolutely avoid handling not contextualized general subjects, more suitable for the classroom - a place surely more comfortable even if less pleasant.

The easy access to the chosen site as well as the practicability of the routes and the time required to reach it are to be checked in advance. The most appropriate means of transport must be carefully selected. Making of records, data, photo taking and sampling operations as well as the mapping of the info collected should be encouraged. Proper educational aids must also be prepared in advance and handed out on the spot. A voice amplification device can prove very useful.

Wandering lessons are an organic sequence of lessons on the ground, delivered at various points of a thematic / integral itinerary prepared *ad hoc*, consistent with the pursuit of formative goals. The locations could be panoramic sites, very useful to have a close look at morphology, stratigraphy and tectonics, or places

---

(*) Dipartimento di Matematica e Geoscienze, Università degli Studi di Trieste, e-mail: michele.stoppa@dsgs.units.it

Paper prepared within the research activity furthered by the P.I.D.D.AM. under the aegis of CIRD, University of Trieste.

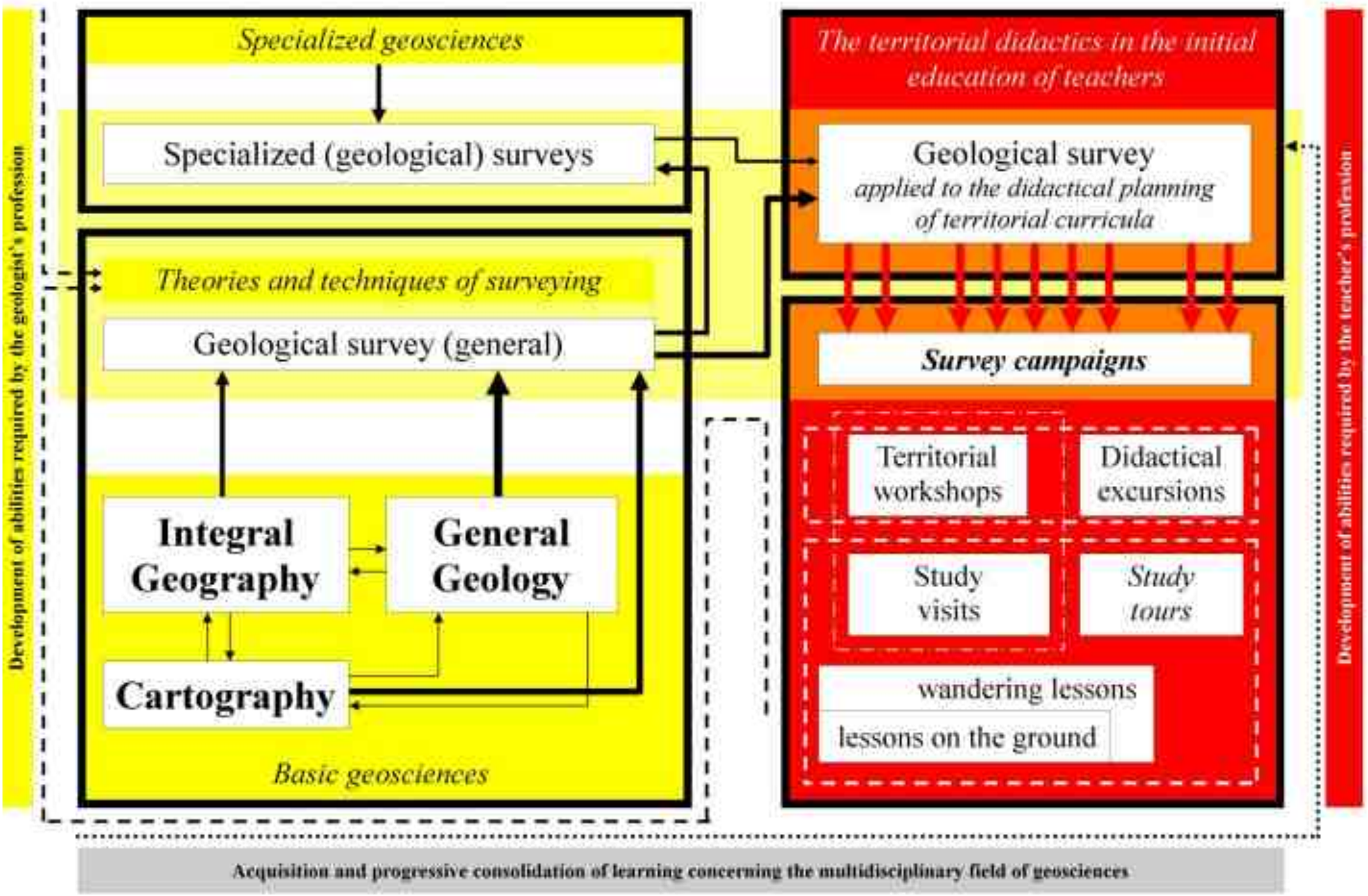

Fig. 1 – Typologies of territorial didactics for the teaching of geosciences.

of peculiar relevance for geomorphology, petrology, sedimentology, palaeontology, etc. They actually follow the traditional methodology used during one-day *study visits* as well as during longer *study tours.* These latter, as norm, include activities to be performed in museums, working centres inside protected areas or often indoor workshops, that is not exclusively on the ground.

The logistics (including means of transport, travelling times, planned stops, overnight accommodation etc.) is not to be underestimated. Study visits and study tours have mainly an informative character and are based on the discovery of something more than the analytical exploration in detail. Their aim is in fact to stir up interest and consolidate, inside the context, all the knowledge previously acquired in the classroom. They avail themselves, as a norm, of a interdisciplinary team of teachers supported by experts in the sector.

Didactical excursions resemble *study visits* but their aim is the detailed exploration of a territory. This is carried out mainly on foot, in a not too wide area, also advancing in rough courses or even out of track, for example along the bed of a torrent. This is sometimes dangerous, as rough areas may present risks of different nature (geological, morphological, biological or anthropic).

Activities of this kind are characterized by the habitual visiting of the study area, so as to obtain a stratified multisectorial analysis of its peculiarities. The same territory must be covered repeatedly under different seasonal and weather conditions, not only to discover the places as a whole but also to analyze details and recognise the starting up of the ephemeral dynamics.

Generally these initiatives are part of much longer workshop itineraries with a wider scope. Between two consecutive ground activities, but also at the beginning and at the end, it is necessary to activate targeted educational trips, needed to prepare for the next field activity or systematize it once back in the classroom.

In *territorial workshops* the territory becomes a real virtual laboratory. Within them teachers may propose practical activities requiring a gradual involvement of the students in the heuristic procedures of geosciences. This time its it the “impact strategy” which is privileged with regard to the territorial complexity, mellowed at first by educational remarks. These are later to be followed by comments aimed at stimulating the learners and support them in the introduction to scientific research. The final step is the enforcement of the *Delphi Technique* in its *territorial* version. It requires to alternate personal work done by the students first in pair, then in a (restricted or enlarged) group, mediated and systematized by the teachers’ team. These activities are mainly oriented to the development on part of the students of autonomous ways to implement the knowledge acquired.

The geological survey programmes fall within this scope, but they are mainly vocated to the education and training of the professional geologist, more than of the geosciences teacher.

THE "DIDACTIZED" TERRITORY: A VALUABLE RESOURCE

Despite the care given to the education of teacher able to implement territorial activities, we cannot forget the problems encountered by the majority of teachers in nursery and primary schools. They have not graduated in geological sciences, as is unfortunately also the case of many who teach "integrated sciences" in secondary schools.

This makes the didactics on the ground rather troublesome on account of the teachers' limited competences in geosciences, inadequate to face the complexity characterizing a given territory. To solve the problem the teacher may take advantage of the expertise of university teachers, professional geologists and museum staff. They can offer a factual contribution to a joint planning of the educational activity and, according to their competence, also implement the didactical intervention.

A decisive contribution to the teachers' work may also come from the so-called "didactized" areas. Both in Italy and abroad, these are places of geological relevance, included in protected areas or near museums, which offer a variety of scientific, logistical and didactical support. In some places there are didactical facilities or other facilities suitable for the purpose (for example open-air multipurpose classrooms, which can be adapted to meet different didactical requirements).

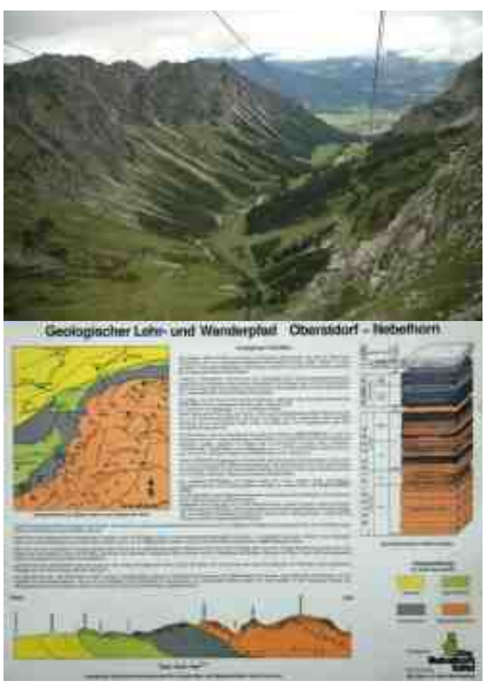

Fig. 2 – The *Geologischer Lehr- und Wanderpfad Oberstdorf-Nebelhorn* in the Allgäuer Hochalpen (Bavaria, Germany).

They guarantee moreover the appropriate accessibility through safe and easily practicable roads. In some cases there are also means of transport (narrow gauge trains, funiculars and the like) that enable not only to reach in a short time the most interesting geological sites but also to look at them from appropriate perspectives, thus reducing the fatigue which inevitably diminishes learners' attention.

In particular, they offer fixed or movable teaching aids, allowing sometimes a sectional thematic view, others an integral stratified multiperspective reading according to the characteristics of the ground. These aids support the generalist teacher and may be used at a later stage to undertake successful in-depth studies.

Fixed aids, conveniently located at panoramic spots or in places of particular interest along the geological route, have a popular character and spread geological culture in society at large, allowing a deeper knowledge of the territory. On the other hand, they do not always take in account the variety of stimuli that only the mediating activity of a teacher can organize so as to really enhance the cultural and motivation level.

The role of geological outing to face visual impairment: the experience of Museo delle Scienze of Trento

ROSSANA TODESCO (*), CHRISTIAN CASAROTTO (*), PAOLO FERRETTI (*), FERDINANDO CECCATO (**), DARIO TRENTINI (**), IRENE MATASSONI (**), GIANFRANCO CAINELLI (***) & VALERIO VALENTI (°)

Key words: *geological pathway, visual impairment, blindness, tactile manipulation, disability, Trentino.*

ABSTRACT

The Museo delle Scienze through a network of partnerships with organizations working on the safeguard and research in the disability field (Istituto per la Ricerca, la Formazione e la Riabilitazione and Unione Italiana dei Ciechi e degli Ipovedenti) and the design of natural pathways (Azienda Forestale e Provincia Autonoma di Trento), inaugurated on september 2012 an educational pathway that highlights the geological peculiarities of Trentino. This didactic geological pathway is the culmination of a project, that began on may 2011, with the aim of involving blind and visually impaired people to geological sciences as to reduce their disability and make the naturalistic issue more accessible and actual.

The project took place in three steps:

- training for museum staff involved in the project: documentation and testing on sensory disability museology; studying on visual disability;
- planning and implementing several geological-naturalistic workshops on the field and inside of the museum;
- planning and carrying out of geological educational pathway.

To carry out this geological pathway we have learned how the visual deficit or blindness affects mobility, orientation and personal autonomy and last but not least, on outside information, understanding that to this purpose it is necessary to follow an itinerary from particular to global.

We treated these issues with the support of a qualified staff during several naturalistic activities on general themes like “rocks, fossils and minerals”, “the seasons”, “the life in woodland”; and specific themes like “geological resources of Trentino” or “the prehistoric reptiles of the Dolomites”.

The activities are calibrated according to the age of the people, the blindness onset, the patology of visual impairment and the presence of other disabilities.

Our project involved blind and visually impaired (with different pathologies - glaucoma, maculopathy, pigmentary retinopathy, cataract, visus < 3 -) with ages ranging from 5 to 80 years, including people who were borne blind and people who lost the sight in their infancy, in youth or in mature age.

The people involved have shown interest in the activities, increasing their capacity of tactile manipulation and mobility in environments far from the everyday contexts.

The geology, in these project, has been the vehicle to pull down physical, psicological, environmental and cognitive

barriers that follow the acute visual impairment, with the aim to reduce disability obstacles and to facilitate the integration into the cultural fabric.

Discovering an Open-Air Geological Workshop. The Regional Natural Reserve of the Rosandra Valley near Trieste

SONIA TRENTO (*)

Key words: *Didactics of Geosciences, Environmental Education, Sustainable Development, Territorial Didactics, Primary School, Protected Areas, Friuli-Venezia Giulia.*

The educational project outlined here has been inspired by several ministerial instructions aimed at stimulating schools to develop experiences of watching and direct learning of the natural environment. This especially through study visits in the protected areas. In particular, the directions contained in the *Guidelines to Environmental Education and sustainable development* (dated December 9, 2009) have been taken into account.

The need for a more specialized handling, framed within areas highly related to an interdisciplinary learning, has suggested to work out a stimulating educational project for the final two-year course of primary school.

The goal is to acquire on the field solid geological knowledge of a peculiar landscape, the Regional Natural Reserve of the Rosandra Valley (Trieste). The protected area, located in the south-eastern corner of the Province of Trieste, contains a spectacular active Karstic valley, highly tectonized and deeply carved in the calcareous lithotypes by an allogenic stream coming from the Slovene territory (Fig. 1).

The decision to deepen the knowledge of the lay-out and the morphogenetic dynamics giving life to the territory involved the formulation of an articulated educational package. This must be properly developed by a coordinated team of teachers of subjects ranging from geography to natural and experimental sciences, able to correctly and effectively handle geological themes on the field, if necessary with the appropriate cooperation of experts, thus favouring the achievement of an acceptable planning target, for instance the organization of a photo show.

To this purpose, we have singled out in advance a series of learning goals - to be implemented with caution, given the complexity of the environment considered - outlining specific fields of geo-scientific knowledge, expressed in *methods*, *languages* and *sustainable behaviours* (Fig. 2).

Inside the educational package *Arrangements and dynamics of the karstic landscape, exploring Rosandra Valley,* five educational units have been planned, aimed at handling specific key competences such as *locating*, *exploring*, *identifying*, *analyzing* and reliable *behaving*, to start with the development of the basic competence of *observing* (Fig. 2).

In the training dynamics various educational conditions have been considered, for instance when the concerned teacher either *transfers the knowledge directly in a logic and coherent way* to the learners or, in alternative, *prepares stimulating experiences of information discovery in an autonomous way or in a group.*

It is advisable to propose the essential survey methods (very simple ones, given the age of the pupils) concerning the main environmental characters as well as to enforce the strategies consistent with a macroscopic analysis of rock samples and an organic and systematic reprocessing of the collected data. The teaching team shall organize at this point interesting practical activities centred on the simulation of given procedures.

Practical simulations are to be realized individually or in cooperation, resorting if necessary to efficient educational aids (explanatory sheets and guide books). Special attention has to be paid also to some basic techniques of expression and representation, to promote in the learners a progressive acquisition of the multiform language of geosciences.

At the end, we take the opportunity to promote positively *sustainable behaviours.* Only through the correct understanding of the interdependencies linking the components of an environment is it possible to infer the importance of a reliable and respectful behaviour. The teachers are therefore invited to propose at the same time experiences oriented to *the study of the systemic*

Timing of river incision and speleogenesis in the Tacchi area (Central-East Sardinia)

JO DE WAELE (*), FRANCESCO FERRARESE (**), DARRYL E. GRANGER (º) & FRANCESCO SAURO (*)

Key words: *Cosmogenic burial dating, cave levels, knickpoint retreat, river capture, Plio-Quaternary*

INTRODUCTION

Underground voids are important repositories of old surface sediments that have washed in, often preserved in alcoves or under protecting flowstone deposits. These chemical and physical deposits, or the fossils they contain, can be dated and give minimum ages of the voids in which they occur. The altitudinal development of cave systems, composed of subhorizontal levels interconnected with vertical shafts, often reflects base level changes, in turn triggered by tectonic movements and/or landscape evolution (river or glacial erosion, sea level changes). These levels of karst development can be correlated to planation surfaces and river straths, allowing to have a relatively good idea of the base level lowering over small areas (ANTHONY & GRANGER, 2007).

In this research, the sediments of four inactive caves in the Taquisara valley have been studied and were dated using cosmogenic nuclides. The DTM of the area has highlighted some prominent geomorphological features, such as river captures, abandoned thalwegs, and planation surfaces. A 3D analysis of the caves and the planation surfaces has also been carried out to determine the local base level stillstands. This research allows some preliminary conclusions to be drawn on the geomorphological evolution of this part of Sardinia.

STUDY AREA

The karstic Taquisara valley is situated South of the Gennargentu mountains in the central-eastern part of Sardinia.

It flows from NE to SW and is developed between altitudes of 780-700 m a.s.l.. The valley dissects the Jurassic carbonate table mountains Tacco of Ulàssai and Taccu Isara and almost reaches the Palaeozoic basement (Fig. 1).

Towards the NE and SW of this area the drainage network has incised very deep and steep valleys into the Palaeozoic basement rocks, Pardu and San Girolamo rivers respectively. From an analysis of topographic maps it is obvious that Rio Pardu was captured by Rio Pelau. Drainage area of Riu Pardu upstream from the capture elbow is 44.78 km^2. An abrupt change in the river gradient, identifiable as a knickpoint, is located around 10 km upstream from the capture point at 550 m a.s.l.. The palaeo Riu Pardu – named Riu Quirra - continues towards the SE 165 m higher, with wind gap at Genna 'e Cresia, at 290 m a.s.l..

Many caves are known along the borders of the valley, mainly characterized by subhorizontal passages often partially occupied by stream sediments (DE WAELE *et alii*, 2005).

These watertable caves are situated at different heights along the valley borders, especially at elevations of 775 m, 815-830 m , 850-870 m and 930-950 m a.s.l. on the SE side and 900 m and 950-955 m a.s.l. on the NW side.

COSMOGENIC DATING OF CAVE SEDIMENTS

Burial dating of cave sediments with ^{26}Al and ^{10}Be allows to give minimum ages of cave passages ranging from about 100,000 years up to 5 Ma (GRANGER *et alii*, 2001; GRANGER & MUZIKAR 2001). Cave sediments have been carefully mapped and samples were taken in the summer of 2005.

AMS measurements were made at PRIME Lab. Beryllium-10 was measured against a standard derived from NIST, but the values reported in Table 2 have been adjusted to match the standard of NISHIIZUMI *et alii.* (2007). The ^{10}Be meanlife used in calculating burial ages is 2.005 My (KORSCHINEK *et alii.*, 2010).

The cosmogenic results indicate that all of the cave sediments have similar ages, and their burial dates at least to the Late Pliocene (Table 1). The upper cave levels would thus be older tha 2 Ma.

Cave	$[^{26}Al]$ (10^3 at/g)	$[^{10}Be]$ (10^3 at/g)	Burial date (My)
Genna'eUa	50.3 ± 10.2	27.9 ± 4.5	2.74 ± 0.47
Serbissi	60.8 ± 10.7	7.6 ± 0.8	Insuff. depth
Bulverera	23.3 ± 5.2	10.9 ± 1.7	2.40 ± 0.50
Su Coloru	38.0 ± 27.0	20.5 ± 2.7	2.70 ± 1.13

Tab. 1 - Cosmogenic $^{26}Al/^{10}Be$ burial ages of cave sediments

PLANATION SURFACES, CAVE LEVELS AND VALLEY MORPHOLOGY

Topographic maps in scale 1:10,000 have been used to construct a DTM of the entire region enveloping the Tacchi of Isara, Ulassai, the minor ones of Tisiddu, Troiscu and Ungul'e Ferru from the upstream Riu Pardu valley up to its capture by Riu Pelau and its ancient Rio Quirra valley. Accuracy of this DTM is 10 m.

The slope map (Fig. 2) shows the main dolomite table mountains and their almost vertical outer cliffs, but also highlights the large planation surfaces on these plateaus (white areas in Fig. 2). The major of these surfaces (A in Figure 5) on the biggest table mountain (Tacco of Ulassai) has a dendritic pattern and is probably related to an ancient drainage system and develops between altitudes of 810 and 750 m a.s.l. The main planation surface on Taccu Isara develops between altitudes of 900 and 870 m a.s.l., similar to another surface clearly visible on the northern part of Taccu di Ulassai at the same altitude (B in Figure 2). The smaller table mountains also have typical planations surfaces, located at 875, 740 and 770 for Monte Tisiddu, Troiscu and Ungul'e Ferru respectively. A general 3D analysis of these surfaces confirms the general trend of decreasing altitude from NE to SW (Fig. 3).

Also caves are developed at certain altitudes, with horizontal passages not related to lithological factors and reflecting local base level stillstands (Fig. 3).

The tacchi area is dissected by the deeply cut Riu Pardu valley that flows in a NNW-SSE direction following a major

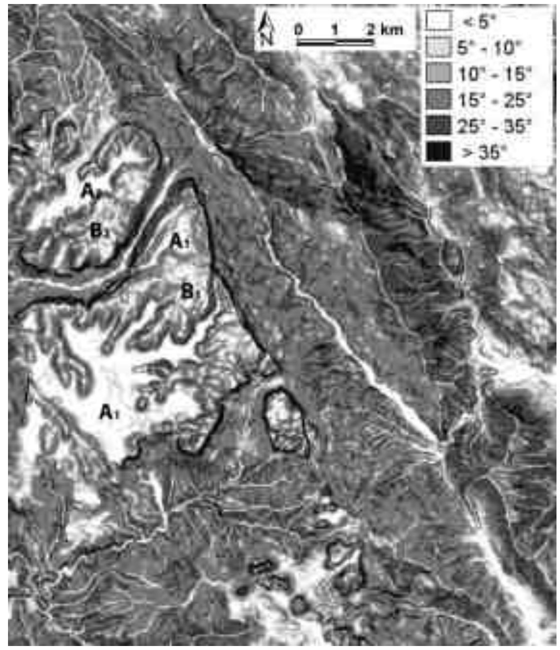

Fig.2 – Slope map of the study area

Tertiary fault (Fig. 1). Downstream, the river has been captured and turns abruptly eastwards at Genna 'e Cresia, changing name into Riu Pelau, and then flows into the Tyrrhenian Sea close to the village of Cardedu. At Genna 'e Cresia the abandoned Riu Pardu valley continues southwards and takes the name of Riu Quirra (Fig. 1).

Today the Taquisara valley flows towards the southwest and hosts a temporary rather unimportant streamlet. Its size cannot be explained by the present day configuration. Taquisara's drainage basin almost certainly extended far beyond the actual outcrop of Jurassic limestones, and comprised the Palaeozoic basement rocks of what is now the northeastern flank of Riu Pardu.

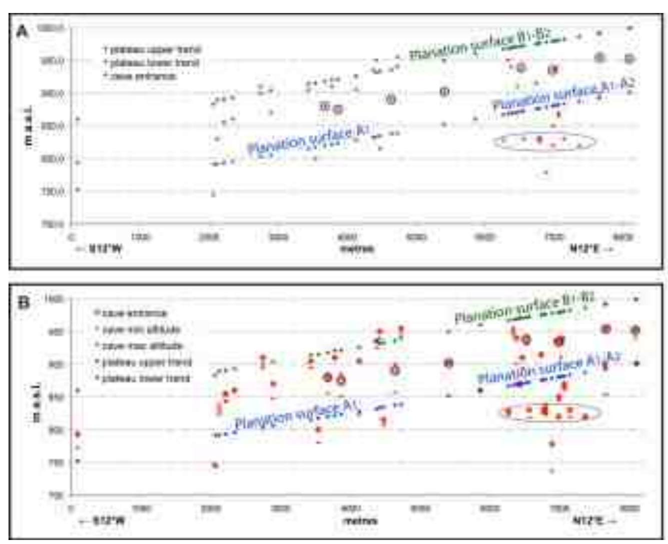

Fig. 3 – Planation surfaces and caves

DISCUSSION AND CONCLUSIONS

Cosmogenic dating of cave sediments in the Taquisara valley have shown these caves to be older than 2 My. The valley, according to these dates, appears to have achieved its actual shape already during the Late Pliocene (2-3 My ago).

The size and morphology of the highest – first level – caves (Serbissi, Genna 'e Ua, Lioni, Taquisara, etc.) suggests them being formed in a more humid climate, with higher rainfall values. The rivers that formed them were able to transport, probably during floods, also cobbles of several cm in diameter. To these first level caves also belong Orroli, s'Armidda, Foxi 'e s'Abba, and Su Marmuri caves. The second level (Bulverera) and third level caves (Coloru, Lancia etc.) are much smaller in size and appear to have formed by smaller underground rivers, as confirmed by the much smaller grainsize of the trasported sediments. The extension of the third level of caves suggests this phase to have lasted longer, although the size of the caves is an indication of lower rainfall rates. Their development at a more or less constant level (around 830 m a.s.l.) is indication of a local base level, almost surely the Taquisara valley. Today active caves are located around 200 m below the highest level caves, more or less 20-30 m below the present thalweg. The Taquisara valley has witnessed four major incisions of 50, 30, 40 and 80 m respectively. Cosmogenic dating, however, was not able to resolve these incision periods, that must have happened before the onset of Quaternary.

Also the large planation surfaces present on the Tacchi, relative to at least two main erosion stages, must be older than 2 My. The highest surface is surely much older, and so are most of the large-sized highest caves. This surface and these caves might well be Pliocene or even Miocene in age.

The deep valleys such as Rio San Girolamo and Riu Pardu, instead, are younger than the Taquisara incision, and have formed in the last 2 million years.

Riu Pardu has clearly been captured by Riu Pelau, and the altitude difference between the wind gap (today's Rio Quirra) and the present thalweg at the capture elbow is around 165 m. Considering a mean river erosion rate of 0.2-0.4 mm y^{-1}, based on studies carried out in Corsica (FELLIN *et alii*., 2005; KUHLEMANN *et alii*., 2008) this capture might have occurred in a period between 400-800 ky. Considering the weak nature of the incised bedrock (phyllites) and the sudden lowering of base level over more than 150 metres, erosion might have been faster by an order of magnitude.

Since the capture occurred, the knickpoint has retreated approximately 10 km upstream. With an average knickpoint retreat velocity of 0.1-0.2 m y^{-1}, similar to what has been measured in an Appalachian fluviokarst (ANTHONY & GRANGER, 2007b) or in Mediterranean rivers (LOGET & VAN DEN DRIESSCHE, 2009) of similar size and with similar rainfall and hydrological behavior, this would suggest the capture to have occurred between 50 and 100 ky.

From these preliminary data the present landscape of Central-East Sardinia, with its isolated table mountains (*Tacchi*), resting on the Palaeozoic basement, seems to have started forming during Late Tertiary, with a major incision rate during the last 2 My. The capture of Riu Pardu by Rio Pelau might have occurred around 100 ky ago. Further research is needed to confirm these dates and to relate these events to the incision of other main rivers of the region, that according to these preliminary data appear to be less than 2 My old.

Land-management and planning in karst areas: the Ligurian case-study (Italy)

F. FACCINI (*), A. BENEDETTINI (**), M. FIRPO (*), L. PERASSO (**) & F. POGGI (***)

Key words: *Speleology, Karst areas, Hydrogeology, Liguria, Italy.*

INTRODUCTION

Karst landscapes represent an important facet of the Earth's geodiversity, and one of major management significate. The relevance of cave and karst is well known; in addition to the importance of retaining examples of karst landforms and landscapes as part of strategy to safeguard global geodiversity, a number of economic, cultural and scientific values may be present in karst areas (IUCN WCPA, 1997). Agriculture, forestry, water management, limestone extraction and tourism are usually the most important forms of economic activity in karst areas. A wide variety of scientific values exists in karst environments. In terms of earth sciences, karst offers bedrock geologists clear exposures of lithological units, geological structures and minerals. Geomorphologist derive insight into landform evolution and climate change over broad areas from the morphology of particular caves and the study of cave sediments. Some karst are important for spiritual, religious, aesthetic, recreational and educational reasons.

Cave and karst are especially vulnerable, probably more than most other land resources. It's fundamentally important to recognize that the proper protection of caves and karst is not just a matter of preserving interesting, beautiful or scientifically interesting natural features. In most cases, protection has far-reaching environmental implications which in turn generate significant economic impacts. In particular proper management of karst is an essential element of water resources management.

The Regional Law No 14/1990 fundamentally contributed to the understanding, development as well as protection of the karst ecosystem (Faccini et al., 2011). Furthermore it allowed the identification of regional karstic areas as well as the drawing of the related rules concerning land planning and management. The law has been established the regional cave cadastre, whose management and update are entrusted to the Ligurian Speleological Delegation, the federative association of most of the ligurian speleological groups.

The new Regional Law No 39/2009, also concerning geodiversity, has stressed the importance of karst aquifers protection: an updating of the karst areas map, in force today, is required to this purpose. Infact, these areas will represent an essential layer of the Water Protection Master Plan.

As a result of speleology activity a great number of new cave in Liguria was found and explored in the last twenty years, resulting in cave cadastre developing and updating into a brand new geodatabase (AA.VV., 2006).

The result of CARG project has improved the national geological mapping: as an obvious consequence of this process, the activity of revision of regional karst system boundaries, nowadays in progress, will benefit of a fundamental basic input information.

THE LIGURIAN KARSTIC AREAS

Karst areas denote a peculiar morphology, characterised by individual landforms and landscapes, that in large measure are the product of rock material having been dissolved by waters to a greater degree than is the norm in most landscapes. In strict sense karst refers any area which has been shaped by solution processes.

Regione Liguria has identified 39 karst areas with hydrogeological, environmental and landscape importance; altogether, they cover an area of about 350 km^2, around the 6% of the entire region (Fig. 1).

The definition of karst areas boundaries has allowed the achievement of some important goals: a) the protection of areas with relevant hydrogeological and geomorphological importance, ensuring the ecosystem through specific rules, with particular emphasis on urban, quarries and waste disposal planning and management; b) the institution of the regional cave cadastre, permanently updated thanks to the activity of speleologic groups; c) the management of caves and karst areas use, also including geographical and hydrogeological study, with particular regards to underground drainage systems.

Twenty years after their first mapping, in application of the Regional Law No. 14/1990, karst areas represent a starting point both for the maintenance of the ecosystems and the Ligurian landscape.

Verruga.

In consequence of the improvement achieved both from the field activities carried out by the speleological groups and from the progress of the above mentioned CARG project, some important issues requiring a careful evaluation can be highlighted; a) the cross-correlation between the boundaries of the 39 karst areas, today in force, the Ligurian tectonic units and the cave cadastre outlines that some of the karst areas, from a lithological point of view, seem to be characterized by parakarst phenomena (eg. IM2, IM3 and SV18), since they are not overlapping soluble rocks units; b) a lot of caves are located outside karstic areas (eg. the well-known caves in the Mt. Antola Flysch).

Moreover, with the purpose to define better conservation rules with regards to water reservoirs, the new regional law on karst areas requires a distinction between recharge zone (diffuse or concentrated infiltration) and spring zones.

With the aim to fulfil the tasks defined with the new regional law, this paper will discuss the followed methodology in order to update karst areas mapping. A summary of the obtained results after more than two decades from the issuing

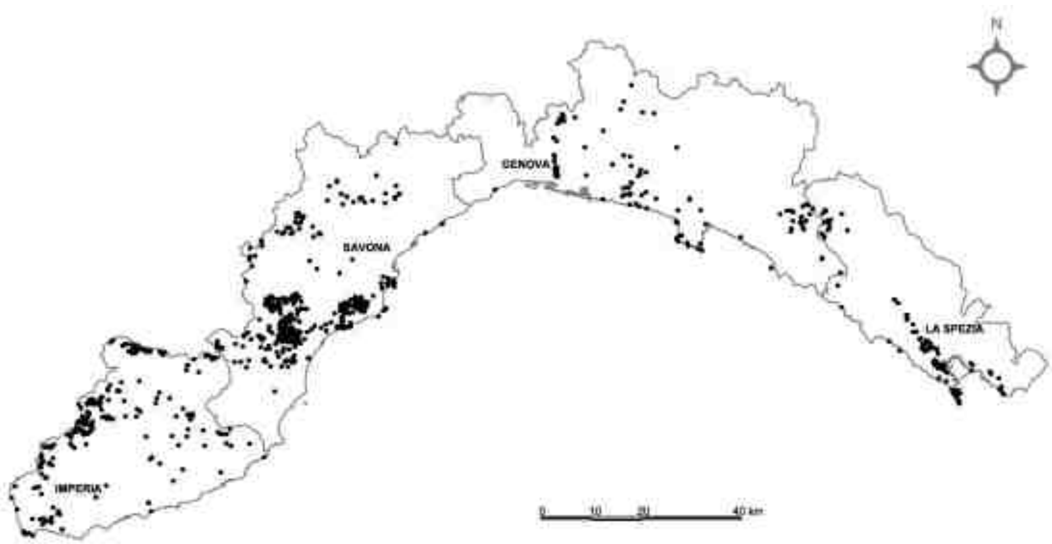

Fig. 2 – Caves location based on Ligurian Speleological Cadastre

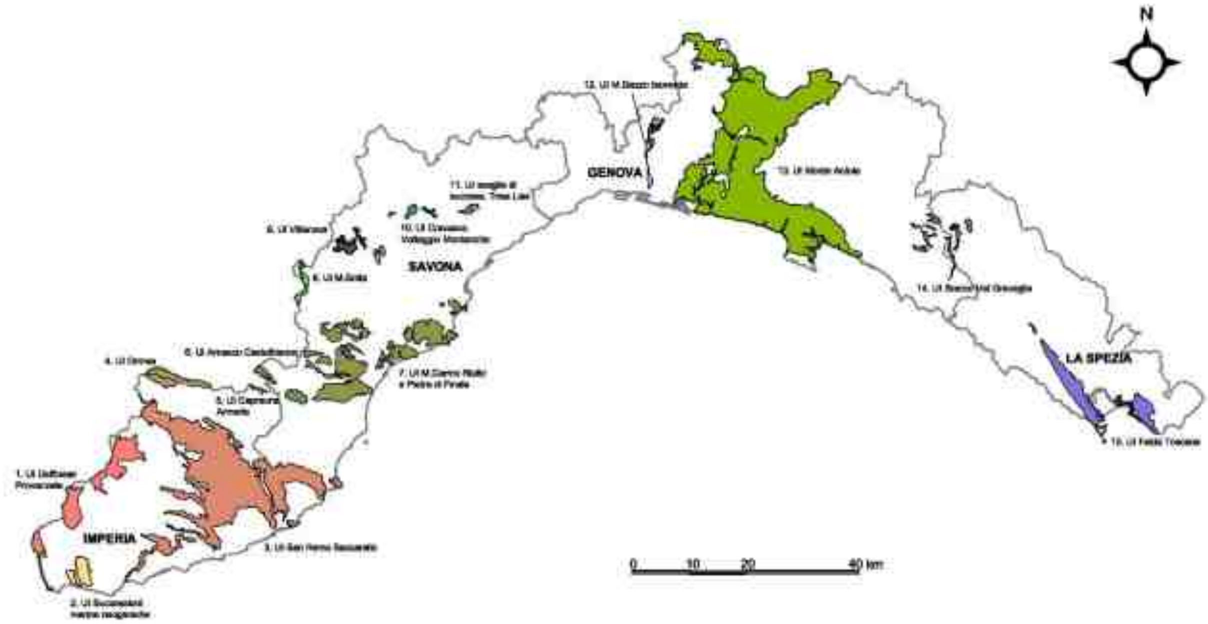

Fig. 3 – The Ligurian karst areas divided in hydrogeological-tectonic Units.

of the regional rules regarding speleology, will be provided as well.

The mapping activity will be carried out through a GIS platform, adopting as topographic base the regional map at 1:10.000 scale.

The starting point is represented by caves cadastre (Fig. 2); the first step towards the redefinition of karst areas can be obtained through the introduction of information layers concerning soluble rock formations, that can be provided by the regional CARG data base. This redefinition will be divided into a first level according to the hydrogeological tectonic units and a second level according to its geographical location.

The main karst areas ("Hydrogeological Unit") can be pointed out from the preliminary cross-relation between actual karst boundaries and Ligurian tectonic units (Giammarino et al., 2002), and can be defined as follows (Fig. 3): Delfinese-Provenzale, S. Remo-Mt. Saccarello, Ormea, Caprauna-Armetta, Mt. Carmo-Rialto, Trias-Lias scales connected to Voltri Group ophiolite massif, Cravasco-Voltaggio-Montenotte, Mt. Sotta, Arnasco-Castelbianco, Villanova, Mt. Gazzo-Isoverde, Bracco-Graveglia, Tuscan Nappe, Rock of Finale.

These new hydro-tectonic units will be then better contoured and furtherly divided, according to lithology and geomorphologic features (sink-hole, swallow hole, polje, caves distribution), also distinguishing the recharge areas (diffuse or concentrated) from the karstic spring zones. This last activity is directly required by the guidelines stated by the new regional law, which plans to define a peculiar regulatory regime modulated on the intrinsic vulnerability of the different areas, to ensure better protection of karst systems and its aquifers,.

A new methodology for the analysis of morpho-structural data of karstic caves in the Alburni Mountains of southern Italy

E. GUEGUEN (1,2), S. CAFARO (3), M. SCHIATTARELLA (4) & M. PARISE (5)

Key words: *Alburni Mountains, Karst morphology, Southern Italy.*

INTRODUCTION

The Alburni Mountains, in the area of the Cilento and Vallo di Diano National Park (Campania region), represent the most important karstic area of southern Italy with about 273 registered caves, including some important show caves (Grotta dell'Angelo Cave at Pertosa, CP 1, and Castelcivita Cave, CP 2; PARISE, 2011). The carbonate massif has been the goal of many speleological exploration campaigns since the early '70s. However, its geological and hydrogeological setting, and the karstic evolution as well, are still poorly known; even the most recent studies are mainly based on surface data analysis. However, in the last years new active speleological exploration campaigns led to the discovery of new caves and to a better knowledge of those already known.

Aim of this work is to investigate the relationships between geological structures and cave development in the Alburni Mountains on the basis of new surface topographic data, underground topographic data from the Campanian register of caves and original geological data using a new geomorphological approach based on cumulative curves of geological and geomorphological data (GIOIA & SCHIATTARELLA, 2010).

GEOLOGICAL SETTING

The Alburni Mountains are mainly built of Mesozoic-to-Cenozoic carbonate rocks of the Alburni - Cervati Units belonging to the Campania - Lucania carbonate platform (D'ARGENIO, 1974). They represent a huge 1500 m thick, southward dipping, monoclinal structure, which is locally overlain by Tertiary flysch units trapped in half-graben basins .

The massif is limited to the NW by an important normal fault zone, whereas towards the NE it is limited by a complex fault system linking the Alburni Mountains to the Monti della Maddalena structure across the Auletta basin and the Vallo di Diano valley.

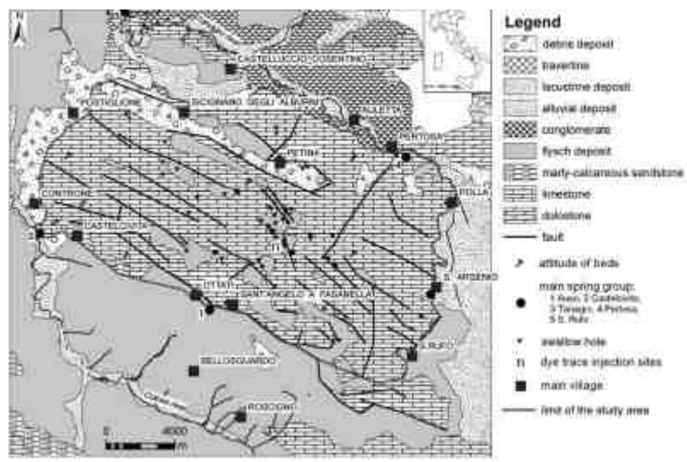

Fig. 1 – Geological sketch map of Alburni Mts (after DUCCI, 2007)

The entire massif is structured by a regional scale NW-SE trending trans-tensional fault systems delimiting the half-graben basins, and offset by roughly N30° and N70° trending faults (BERARDI *et alii*, 1996). A minor E-W trending fault population has been observed during some underground surveys (SANTANGELO & SANTO, 1997).

The Alburni Mountains is also one of the more important hydrogeological structures of the Campania region (CELICO *et alii*, 1990, 1994) but its actual groundwater circulation is still poorly known mainly due to the lack of complete detailed studies on this complex karstic system.

DATA ANALYSIS

During this study we performed a geomorphological and structural analysis using both aerial photography and the 20m resolution Digital Elevation Model provided by the Italian Ministry of Environment.

Then a geological survey was conducted within and outside a set of selected caves to collect new original structural data. A

(5) CNR, Istituto di Ricerca per la Protezione Idrogeologica, Bari.

morphological study was also performed on the plan maps (Fig. 2) of the caves provided by the register of caves from Campania, managed by the Campanian Speleological Federation (DEL VECCHIO, 2005) in order to identify the prevailing directions of cave development.

We have divided the selected caves into three subsets according to the different structural sectors identified in the Alburni massif (NE sector, central portion, and NW sector) in order to compare the directions observed on the topographic cave surveys to the structural directions measured both on geological maps and in the carbonate rock mass at the outcrop scale.

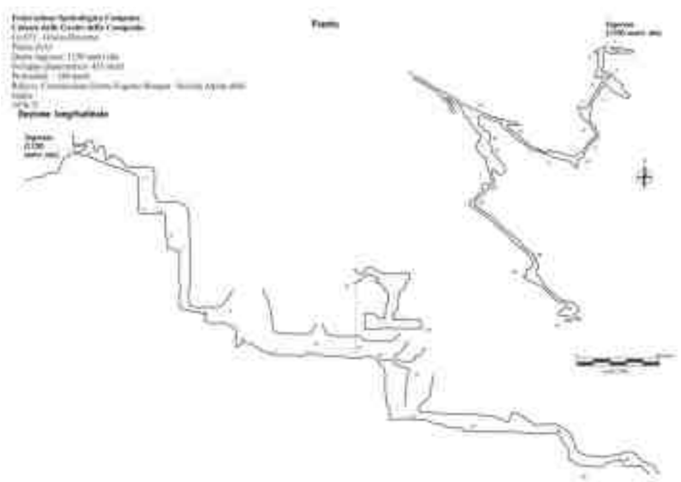

Fig. 2 – Topographic survey of the Grava d'Inverno Cave, CP 672 (data after the register of natural caves of Campania, managed by the Campanian Speleological Federation).

Rather than displaying the collected data on the commonly used diagrams (i.e. rose diagrams, histograms, etc.), the cumulative curves method, described by GIOIA & SCHIATTARELLA (2010), was chosen to compare the different sets of data. The method was originally used by the Authors for comparing geomorphological parameters of streams and river valleys, but it is suitable to analyze numerous sets of data. Its main advantage consists in the possibility to plot a large number of different data on the same diagram allowing a clear and quick correlation between the different curves as shown in the figures 3 and 4.

In particular, figures 3 and 4 show how the development of some caves (Polla cave, CP 4 in fig. 3 and Grava d'Inverno cave, CP 672 in fig. 4) mimics the pattern of the regional structural directions whereas other caves appear to be mostly controlled by local structural directions (Grotta dell'Angelo, CP 1 in fig. 3, Gravacine cave, CP 476 and Piani di S. Maria III cave, CP 472 in fig. 4).

CONCLUSIONS

The first result of this work is that cumulative curves have shown to be a powerful analysis tool for comparing different sets of data. The study has also confirmed the existence in different sectors of the massif of different families of caves.

Finally, the development of the caves is not only controlled by the main direction of regional structures at the scale of the entire massif but also by local structures that in some cases play a major role.

Geological controls in the development of palaeo-karst systems of High Murge (Apulia)

E. GUEGUEN (1, 2), W. FORMICOLA (2), V. MARTIMUCCI (2), M. PARISE (3), & G. RAGONE (2)

Key words: *karst, quarry, human impact, speleology, Apulia.*

INTRODUCTION

In the Minervino Murge territory (Apulia) a large limestone quarry has destroyed for years several caves. Notwithstanding the efforts by cavers to explore the underground environment, aimed at documenting and safeguarding the precious subterranean karst landforms, the quarry kept working for a long time, until in 2005 an inquiry was conducted at the site. Following the end of the quarrying activities, it was eventually possible to fully document the karst values of the area, which presents at least six caves of great interest for reconstructing the karst history of this sector of Apulia.

GEOLOGICAL SETTING

Minervino Murge is located in the High Murge plateau, one of the most interesting areas of the Apulian karst (SAURO, 1991; PARISE, 2011). The High Murge is limited by step-like scarps, more evident on the south-western edge, whilst the north-eastern margin occurs through a series of small scarps and intervening benches. As interpreted by SAURO (1991), the plateau was an island in the Plio-Pleistocene sea, and the karstic processes began in the area not later than the upper Miocene. Landscape in High Murge is very articulated, with remnants of fluvio-karst landforms and several karst features (valleys, dolines, caves). Wide areas of High Murge are marked, in particular, by the presence of dolines, both as individual features and as coalescent landforms, giving origin to more complex depressions.

Cretaceous limestones characterize the landscape, in sub-horizontal bedding. These rocks have been affected by at least two phases of karst, that led to filling of the palaeo-caves by terra rossa and bauxite deposits. Many quarries in the Cretaceous limestones have been opened in this area starting from the 1950s, and the areas of extraction have progressively increased since then (PARISE & TROCINO, 2004).

In many occasions the effects of human activities resulted in Apulia to produce severe changes to the karst ecosystems with serious negative effects (PARISE & PASCALI 2003, CALÒ & PARISE 2006; NORTH *et alii*, 2009). Quarrying is probably the activity producing the worst impacts on the natural landscape: development of quarries causes immediate, sometimes irreversible, changes to the original environment, causing loss of surface karst features, destruction of the epikarst, and diversion of the surface hydrography (GUNN, 1993; PARISE & GUNN, 2007; PARISE, 2010). Even though in 1986 a specific law was promulgated to protect caves in Apulia, followed in 2009 by a further regulation, opening and progressive expansion of quarries has brought to repeated episodes of destruction of karst sites and caves. Lack of real enforcement of existing laws resulted so far in difficult safeguarding of the karst heritage, with particular regard to caves discovered during quarrying. Thus, many caves, even of remarkable importance, have been lost.

In the quarry object of this study (Cava Porcili), the local stratigraphy shows a well bedded Cretaceous carbonate succession, with presence of thin clay levels indicating emersions in the environment of sedimentation (FUNICIELLO *et alii*, 1991; PIERI *et alii*, 1997; FESTA, 2003). These clay levels seem to have played a significant role in the development of karst features, representing a very distinct impermeable strata throughout the succession, and at many heights within it.

In addition to stratigraphic bedding, and differences in lithology, several tectonic discontinuities may also be identified,

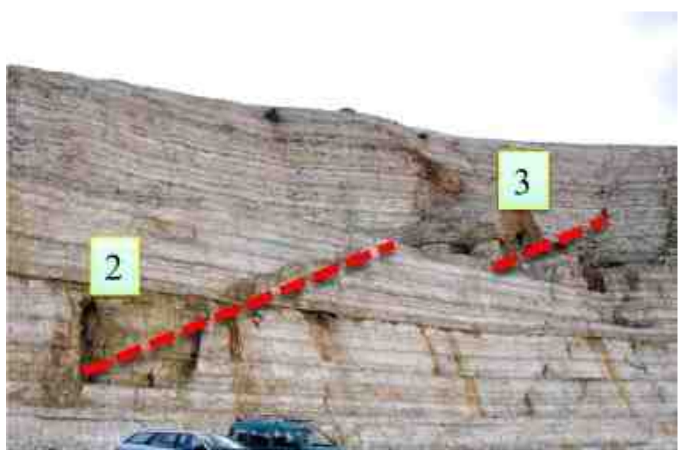

Fig. 1 – Tectonic discontinuities (marked by red dashed lines) controlling development of caves. Numbers 2 and 3 refer to numbering of the caves (see Table I).

locally marking the cave development (Fig. 1).

The quarry is located on the NW scarp of the Murge plateau corresponding to an eroded regional scale normal-to-

Grotta 3 Montenero Dellisanti (Abisso Igor)	88	517
Grotta 4 Montenero Dellisanti	27	470
Grotta 5 Montenero Dellisanti	64	467
Grotta 6 Montenero Dellisanti	135	457

Table I – List of explored caves.

Six caves have been found and explored within the quarry (Table I). In addition, at least another one, which entrance was located at the quarry floor (see yellow arrow in Fig. 2) had been filled with great amount of quarry wastes. The only data available on this cave is a previous exploration, carried out during the 90s, which proved it to be a 100-m deep shaft, with possible further development of the system in a parallel shaft (PARISE & TROCINO, 2004).

The caves explored in the quarry are all tectonically controlled, showing also inverse erosion processes. Some of them present a very simple morphology with a unique vertical shaft (Fig. 3) whereas other have a more complex morphology with vertical shaft, and horizontal galleries connecting chambers. In these cases orientation and geometry of the elements are controlled by fractures and fault patterns. Some of the horizontal conducts are partially filled by red clay deposits sealed by a thin layer of concretions. Chambers are characterized by inverse erosion morphology with pavement covered by fallen blocks.

CONCLUSIONS

The surveyed caves testify to important karst phase in the Minervino Murge area: wide rooms characterize most of the caves, which development is marked by vertical shafts, the deepest of which is 120 m. At several locations, explorations were stopped because of the presence of material dumped from the quarry; as a consequence, some caves have been completely filled, or the entrances destroyed.

Even though a significant part of the original karst system has been irremediably destroyed, the surveys of the remaining caves, and the information coming from the geological and structural research may be very useful to understand the speleogenetic

Fig. 3 – View of the main shaft in cave no. 5.

stages of development of the caves, and to reconstruct the karst phases that have interested this sector of the Murge territory.

Natural radioactivity in Križna jama (Slovenija): origin, distribution and health risk

ANTONIO MORETTI (*), GIANLUCA FERRINI (*), AMELIA MARIA MARI (**), CARMELINA DE ROSE (*) ,
ALOIS TROHA (***) & MATEJ KRŽIC (***)

Key words: *Križna jama cave, radioactivity.*

INTRODUCTION

The Križna jama (*Križna Cave* or *Cave of the Cross*) (Reg. No. 65 - Cave Register of Spel. Association of Slovenia), located in Loška dolina, is one of the best know karst caverns in the world for the impressive sequence of twenty two underground lakes separated by flowstone dams. The cave, which have a total length of about 10 km, is open all year for sightseeing of the initial portion of the main gallery while the visit of the inner sections is strictly regulated; Križna jama is famous also for its high biodiversity (45 defined troglobionts up to 2000 – 4th place in the world) and for the discovery of abundant remains of *Ursus spelaeus*.

In the cave, anomalous levels of radioactivity, characterized by strong seasonal variations (Fig. 1), were detected with higher values measured during the summer, when the cold air of the cave is trapped in the lowest portions of the karst system. On the contrary, during the winter, the indoor air, warmer than the outside, tends to escape toward the surface by the joint network, while the cave receives from the broad entrance an outside input of fresh and no radioactive air. The radioactivity level during the summer can reach very high values (up to 100 mR / h exposure to γ radiation, up to 10,000 Bq/m3 α activity in the air) with a resultant health risks for the staff permanently working in the cave and, lesser, for tourists. The detailed indoor measurement surveys carried out in different periods of the year from 2008 to 2011 outlined a complex temporal trend of the radioactivity values with significant seasonal linked daily variation: during spring and autumn the variations are connected to the outdoor temperature changes (Fig. 2); in winter the situation is more stable.

From a public health point of view the study of variations of the radioactive levels compared with the underground environment parameters pointed out a precise correlation between the values measured and the presence of a widespread aerosols in the cave (Fig. 4). This aerosol is present only in specific periods of the year and its movements are related to the internal air circulation pattern (fig. 5); it contains almost all of the radioactive nuclides recognized in the cave and is deposited on the walls and on the ground of the cavity.

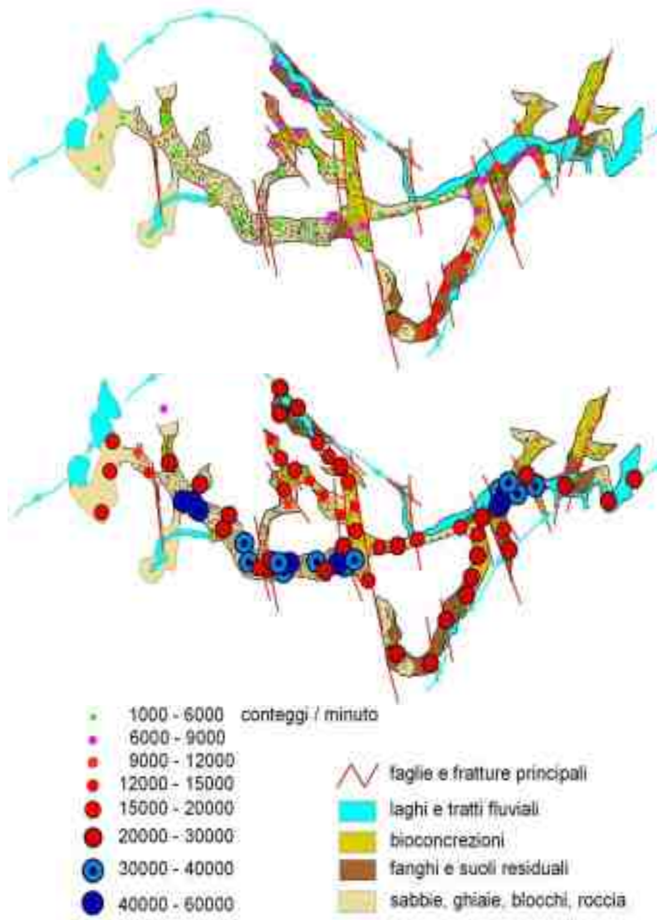

Fig. 1 – Seasonal variation of natural radioactivity surveyed in the cave in winter time (upper map) and in summer time (lower map). Radioactivity data are reported in counting/time (minute).

(*) Dipartimento Scienze Ambientali – Università dell'Aquila
(**) O.S.A. – Università dell'Aquila
(**) Križna Jama Cave, Slovenia

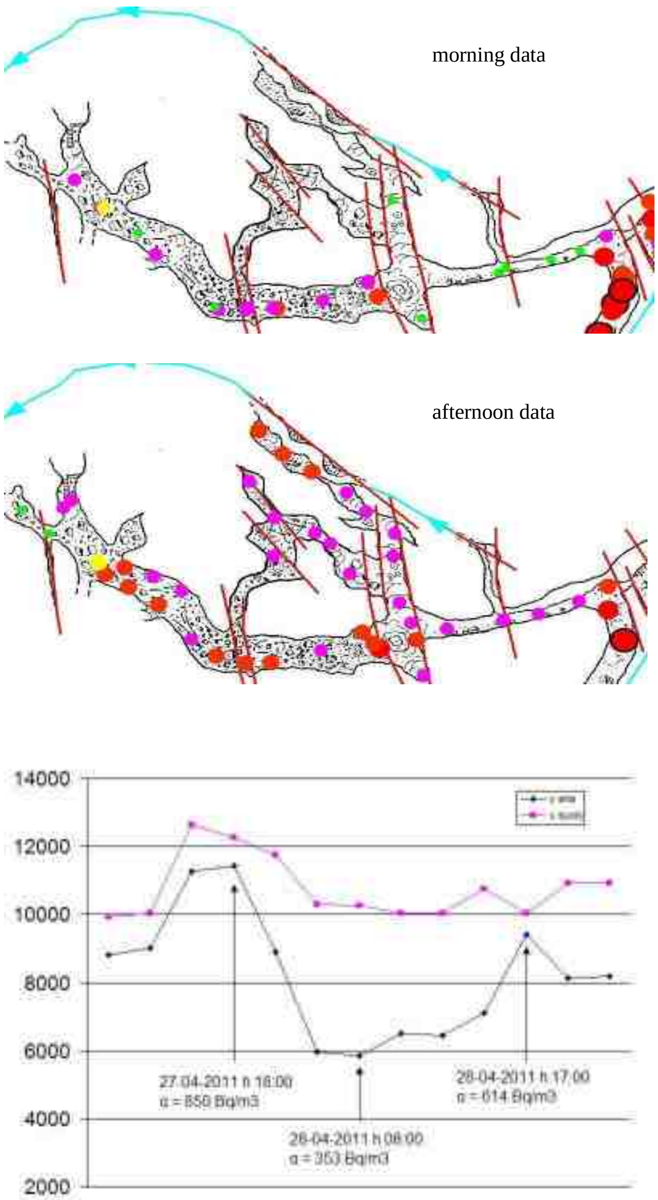

Fig. 2– daily variation of cave radioactivity value in spring time during the morning (upper map) and the afternoon.

Several α and γ spectrometry in situ measurements (Fig. 3) were carried out on the particulate deposited on the ground and collected, with proper filters, in the air: the measurements reveal the presence of ^{214}Pb and ^{214}Bi, from the decay chain ^{228}U-> ^{222}Rn, but also of ^{228}Ac, radionuclide belonging to the ^{232}Th family, for the first time reported in natural cavities (MORETTI *et al.*, 2008). The γ spectrometry measures attest the absence, in the studied part of the cave, of uranium isotopes confirming that the radioactivity vector is the air flow within the cave and the aerosol carried by it; this aspect is also confirmed by some α spectrometry measure which revealed a clear abundance, among the radon isotopes, of the elements with a longer half-life (^{222}Rn, about 3 days) respect to the shorter half-life ones (^{220}Rn, about 1 minute).

Fig. 3 – α and γ spectrometry in situ measurements.

Fig. 4 – Aerosol

Regarding the aerosol presents in certain periods of the year in the cave, no systematic investigations have been still carried out but, according our experiences, it was recognized only in few caves characterized by significant values of radioactivity measurable in the air. Some Authors (e.g. PASHENKO S.E. & DUBLYANSKY Y.V., 1997) suggest the possibility that the micro-droplets of the aerosol could be nucleated, starting from the moisture supersaturated air, by the α particles themselves,

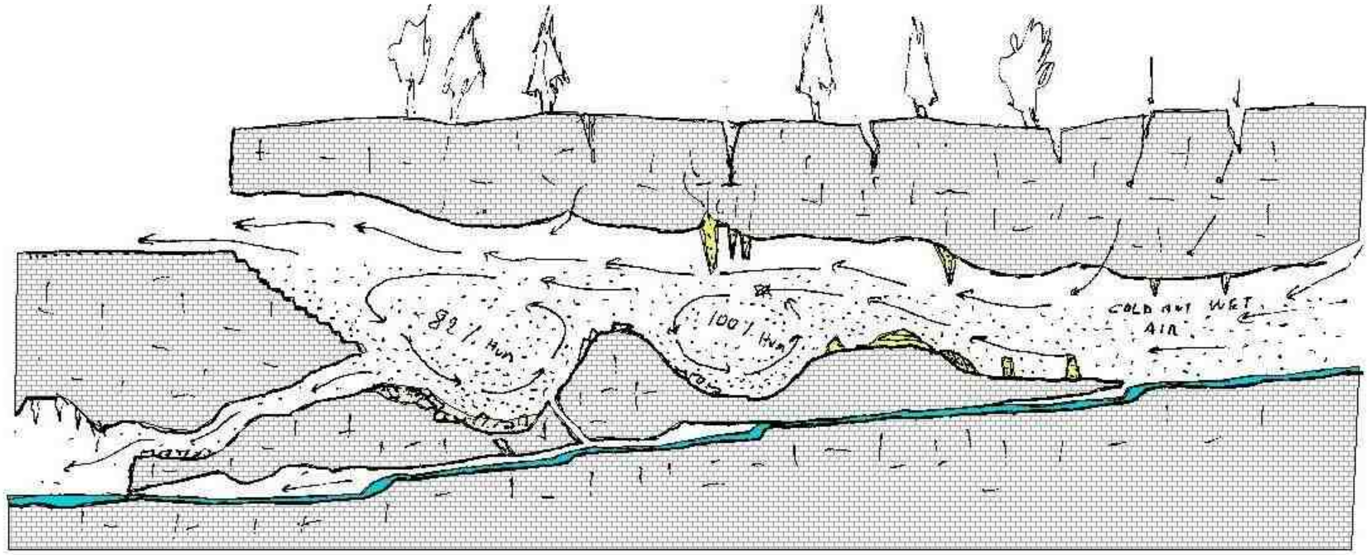

Fig. 5 – Pattern of air flow and aerosol in the terminal portion of the cave during summer time.

which form ionic nucleus He^{++}; later these particles attract the water vapor polar molecules. Regardless the origin of the aerosol, its presence increases greatly the health risk: in fact, once inhaled, it is almost completely held inside lungs, leading the radioactive particles to stick to the alveolus walls and favoring cancer processes in the affected cells. On the other hand, the presence of the aerosol is easily identifiable and preventable avoiding to attend the underground sites during certain periods or adopting personal protection measures; during the survey in Krizna Jama we have experimentally verified that a common dust mask affordable for few tens of Euro cents, holds about 80% of particulate radioactive. Despite the adverse psychological effect that these and other safety measures can have on paying visitors, we recommended the use of these equipment especially for cave staff; the use of dosimeters is strongly recommended. Recent studies pointed out that visits to any subterranean environment should possibly no longer be considered as a simple and riskless tourist activity particularly for the ill and elderly; it is therefore hoped to increase the awareness and education of the public on this topic, to wear protective masks and taking preventive control measures in caves.

Pozzo Cucù cave (Castellana-Grotte, Apulia): karst researches and considerations on the karst disturbance

MARIO PARISE (1) & VINCENZA MONTENEGRO (2)

Key words: *karst*, *speleology*, *cave deposits*, *disturbance*, *Apulia*.

INTRODUCTION

The karst system of Pozzo Cucù, located in the Low Murge sub-karst sector of Apulia, is one of the most valuable caves of the region. Identified with the number PU 1200 in the regional register of natural caves, managed by the Apulian Speleological Federation (FSP, website http://www.fspuglia.it/) it is only 1,5 km distant from the Castellana show cave (PU 8), the longest and most famous cave of Apulia (PARISE, 2011a). Pozzo Cucù cave was discovered in late 1980, during the foundation works for a building at the northern outskirts of town: the works brought to light a small shaft, 7-m deep, that initially seemed to show no further continuation. However, in the course of the first days of exploration, a passage was identified, thanks to air current, and it was thus possible to enter the real cave system, after another jump through a 8-m deep shaft. At depth of about 20 m from the ground surface, a cave with mostly sub-horizontal development was explored. It soon appeared as one of the longest caves in Apulia, with over 1 km of development.

In the area nearby Pozzo Cucù cave, several other subsurface karst features are present: the most important is Grotta della Jena (PU 7), where many palaeontological remains were found (DELL'ERBA, 1881), including a hyaena skull. Then, Grave Gentile (PU 11) is a 35-m deep vertical shaft, whilst the Inghiottitoio of Chiancofreddo (PU 806) is no more accessible since it was object of man-made infilling several years ago.

POZZO CUCU' KARST SYSTEM

The karst system of Pozzo Cucù consists of two main branches, respectively directed toward the SE and the NW. In addition, other rooms and passages (named Cavern of the Great Column), are present only a few meters from the main cave. No direct connection has been found so far between the two parts of the system. The SE branch, that is the longest, is characterized by large caverns, which size mostly derives from frequent instability phenomena, as shown by the widespread breakdown deposits marking the cave floors. These deposits mask for most of the development the real pavement of the cave, located some meters below. The terminal part of the SE branch is characterized, before the very final sectors consisting of low and narrow conduits, by one of the largest cavern in the system, the Bones Hall.

The NW branch, on the other hand, presents several low passages, corresponding to past phreatic conduits developed along the sub-horizontal bedding of the limestones (Fig. 1), with intervening wider rooms. At the terminal north-western part of the system, landslide deposits stop any further continuation, at some tens of meters from the site of Grotta della Jena.

Fig. 1 – View of one of the low passages that characterize the NW branch (photo courtesy of V. Martimucci).

Besides being accounted in the first-rank group of caves in Apulia due to its length, Pozzo Cucù system presents a great variety of underground karst features. Further, the cave has great importance also as concerns paleontological remains, mineralogy, biospeleology, and cave sediments.

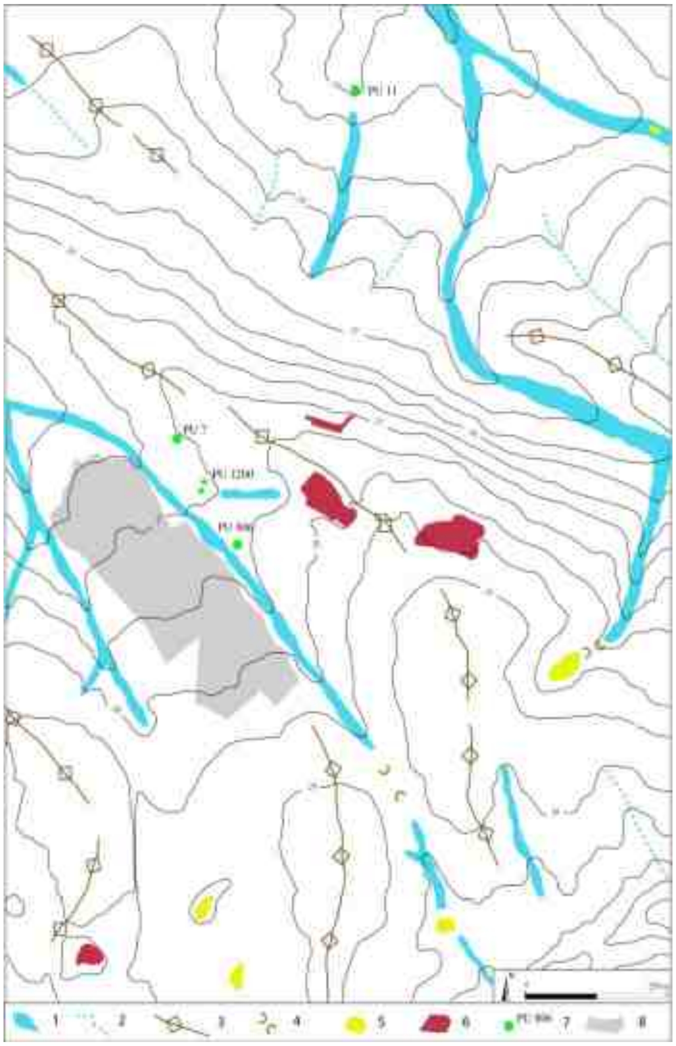

Fig. 2 – Geomorphological map of the Pozzo Cucù area, showing also the other caves mentioned in the text. Key: 1) karst valleys (*lame*); 2) temporary water lines; 3) ridge; 4) morphologic saddle; 5) doline; 6) quarry; 7) cave entrance; 8) urban area.

At Pozzo Cucù, several features have been identified as possibly relating some parts of the karst system to hypogene caves (PARISE, 2011b): ceiling pockets, locally developed along fractures, and cupola-form solution pockets at the ceiling.

The Pozzo Cucù karst system is located in a sector of Low Murge showing many surface karst features (Fig. 2), including dolines and slight karst valleys (locally called *lame*, see PARISE *et alii*, 2003). These latter become interested by surface runoff on the occasion of the main rainfall events, remaining otherwise dry for the rest of the time. As in the rest of Apulia, an almost entirely karst region characterized by outcrops of carbonate rocks, water infiltrates underground at the many swallow holes and dolines, as well as through the network of discontinuities in the carbonate rock mass.

This sector of Low Murge is very rich in paleontological remains, both found in caves and at surface excavations. At this regard, the Pozzo Cucù karst system shows several interesting sites, among which the most remarkable is the debris cone in the Bones Hall, at the terminal part of the SE branch. At this point, a natural access to the cave had to be located, that was later on closed by arrival of large amount of rock debris, including many bones and paleontological remains. Most of these are now covered by calcite deposits and flowstones, but still recognizable within the debris cone. Other paleontological remains are distributed in other sites of the karst system, and in particular close to the main entrance. In the first sector of the SE branch, as a matter of fact, a complete skeleton has been found, identified as a wild cat (MONTENEGRO *et alii*, 2005). The paleontological remains at Pozzo Cucù, together with those from Grotta della Jena, as well as from other sites in the Low Murge, represent a good piece of data for performing a reconstruction of the palaeo-climate of this sector of Apulia in the last epochs.

At this regard, further elements of interest derive from analysis of speleothems and deposits contained within the cave. In particular, at many points of the SE branch it is possible to observe black sediments (Fig. 3) covered by an alabaster crust. The first studies carried out by FORTI *et alii* (1985), and more recently confirmed by MONTENEGRO *et alii* (2002), have shown by means of chemical and mineralogical analyses on the two levels under the crust the presence of clay minerals (caolinite, illite, and muscovite), and oxides of iron, manganese and titanium.

Fig. 3 – Close-up view of the pockets within the carbonate strata, containing the black sediments in the SE branch of the Pozzo Cucù karst system.

The main phases of cave development have been inferred from these mineralogical analyses, integrated by observations on the underground morphologies of the cave (FORTI *et alii*, 1985): after formation of the cave, when circulation of aggressive water led to enlargement of the system, waters infiltrating from the surface were capable to mobilize Fe and Mn from the soil; once in the cave environment, they lost their aggressiveness allowing the deposition of Fe and Mn hydroxides. Then, formation of the crust above the clay deposits was related to alkaline waters, followed by infilling of the cave by clays and silts. Later on, a partial emptying of the cave system by flowing rivers occurred, that favored also the development of the second, deeper level of cave formation, consisting of narrow and decorated passages separated by breakdown deposits (Fig. 4).

Fig. 4 – SE branch of the system, showing in the foreground breakdown deposits (see also the shape left by the rock failures on the cave ceiling).

BIOSPELEOLOGY

Since discovery of the system, the first scientific researches performed at Pozzo Cucù concerned biospeleology. The presence of several species, including the Orthoptera *Troglophilus andreinii* and some Coleoptera as *Italodytes stammeri* and *Batrisodes oculatus* (DE MARZO & VIT, 1982; DE MARZO, 1989) was soon proved. Due to these discoveries, the cave was declared in 1995 a Site of Interest for the European Community (SIC, site code IT9120010). It has to be noted that, following the intense phase of biospeleological research in the years after discovery of the cave, very few further efforts in this field have been carried out later on.

ENVIRONMENTAL CONSIDERATIONS

As typical of the karst settings, where a direct link exists between the surface and the subsurface environments, any action performed at the surface may have serious environmental consequences for the underground karst ecosystem. At Pozzo Cucù, over the last decades many negative episodes were registered, even though the site is included in the list of protected sites of the European Community, as before recalled.

Implementation of the recently proposed Karst Disturbance Index (VAN BEYNEN & TOWNSEND, 2005) at the Castellana-Grotte area resulted in values of 0.57(CALÒ & PARISE, 2006), corresponding to the upper range of the "Disturbed" class. This is also in accordance with more general data about Apulia, which shows a level of "Significant disturbance" to the karst environment, according to revision of the first version of classification by NORTH *et alii*, (2009). These outcomes are mostly due to absence of real enforcement of the existing laws and regulations in the region, combined with lack of an environmental awareness, which have brought to an overall very low degree of protection of the karst settings, and the consequent high levels of disturbance exerted by man on the natural landscape.

New data on a cave along the coast of Polignano a Mare (Apulia) by means of geological, geophysical and speleological researches

MARIO PARISE (1, 2), VINCENZO MARTIMUCCI (2), NUNZIA PENTIMONE (2, 3) & PIETRO PEPE (2, 3)

Key words: *coastal karst, geophysics, speleology, Apulia*.

INTRODUCTION

The territory of Polignano a Mare, along the Adriatic coast S of Bari, is among the most important as regards coastal karst in Apulia. Over 70 caves, the great majority of which is located along the coast, represent the karst heritage of the area (FAVALE, 1994). Grotta della Rondinella (cadastral number PU 71) is located N of Polignano a Mare; a wide access allows to enter by the sea, leading to a nice pebble shore, whilst inland a collapse sinkhole represents the main access, produced by fall of the rock diaphragm above the cave. Even though the cave is in a coastal sector heavily frequented by tourists, it was never adequately safeguarded, and, as many other coastal caves in the area, commonly experiences negative effects due to anthropogenic disturbance. The present contribution describes the general aspects of some recent researches, carried out thanks to private funds, aimed at reaching a better knowledge of the karst features of the system.

GEOLOGY

In the Low Murge of Apulia, a territory that is characterized by many significant surface and subsurface karst landforms (PARISE, 2007, 2011), the coastline of Polignano a Mare is certainly the sector of greatest interest as regards coastal karst, as well as karst hydrogeology (GRASSI, 1973; ZEZZA, 1974). Many caves are located along the Polignano coast, mostly due to the action by the sea waves on the limestone cliffs.

Known since the first karst studies as one of the most important cave in the area (COLAMONICO, 1919; OROFINO, 1967), Grotta della Rondinella was later on studied for its breccia deposits (RUDNICKI, 1990), and for mineralogical analysis that brought to discover a new variety of francoanellite, that is the phosphate mineral phase $H_6K_3Al_5(PO_4)_8 \cdot 13H_2O$, which represents a lower hydrate of taranakite (BALENZANO *et alii*, 1979).

Located in a stretch of the coastline with cliffs lower than 10 m, Grotta della Rondinella is the larger karst cave in the sector north of Polignano a Mare. The geological setting of the Cretaceous bedrock, showing bedding in layers comprised between 10 and 70-80 cm, has an overall sub-horizontal attitude, with local variations due to folds and flessures, with increase in dip toward the cliff. An average dipping toward the north and the east is recognizable. The Plio-Pleistocene calcarenites are visible only north of the cave, nearby the Chiar di Luna Cave (PU 825), where the contact with the Cretaceous limestones is marked by a breccia with terra rossa matrix.

Near Grotta della Rondinella the attitude is strongly conditioned by the flessure related to the collapse sinkhole that is the inland entrance to the cave (Fig. 1), as shown by the clear syncline. Moving away from the cave entrance, on the other hand, the bedding goes back to sub-horizontal, with average dip of a few degrees toward ENE.

Fig. 1 – The sinkhole representing one of the accesses to Grotta della Rondinella.

Several discontinuity systems are recognizable in the area, affecting the Cretaceous bedrock: the main one is about perpendicular to the coast, whilst further discontinuities are related to the tensional release parallel to the coastline. These latter locally become of primary importance in controlling evolution of the present coastal morphology.

The well-cemented calcareous breccia, with terra rossa matrix, is visible in correspondence of the collapse sinkhole, as well as within the karst system, in erosional pockets located at variable heights of the cave roof. RUDNICKI (1990) interpreted these deposits as related to palaeo-karst phases started after the

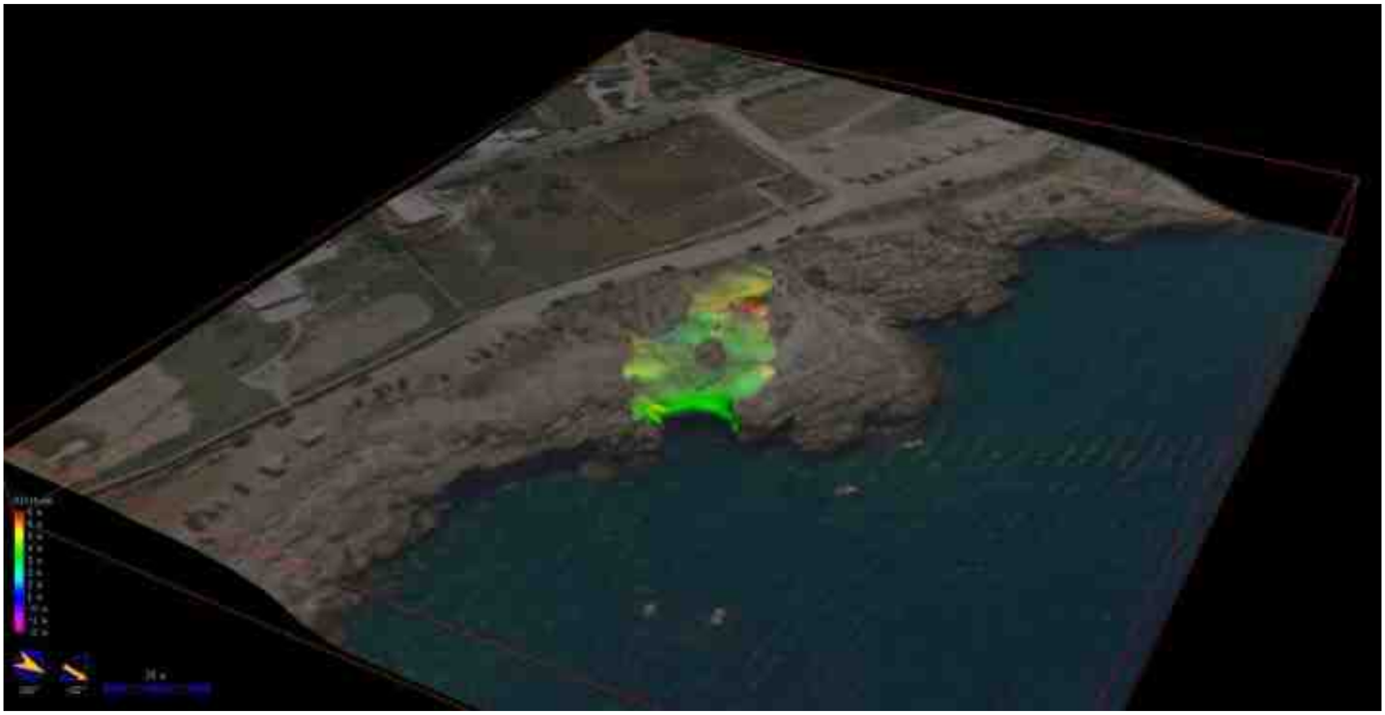

Fig. 2 – Perspective view of Grotta della Rondinella (Therion software elaboration), showing in the foreground the entrance from the sea. The black circular form in the center of the cave is the sinkhole shown in figure 1.

post-Cretaceous emersion, with later filling as a consequence of the sea level changes that interested this stretch of Adriatic coastline. Eventually, the Plio-Pleistocene deposits covered the older materials, and the subterranean hydric activity restarted after the last phase of land emersion.

The karst system was recently re-surveyed, using the modern technologies of cave surveying (Fig. 2): the survey highlights a prevailing development in E-W direction. Entering the system from the sinkhole, the passage to NW brings, moving above the fallen blocks (Fig. 3), to the sea (Fig. 4). On this side of the cave, along the northern wall, cave diving surveys allowed to find a previously unknown intrastratal gallery, controlled by tectonics along a N-S joint. The gallery develops for some 10 m, starting with height greater than the width (2,5 x 1,5 m), and then lowering to slightly more than 1 m, with a width of 5-6 m. Moving around the sinkhole deposits, one can reach a junction leading to the SE to the inner pebble beach. To the W, on the other hand, after a 1,5 m-high step, one may enter the main cavern of the system, with height between 2 and 4 m, and the base for large portions occupied by flowstones. At the cavern margins, narrow and highly dipping passages lead to the lower level, about 3 m below.

Fig. 3 – View, from inside the cave, of the sinkhole deposits, where is present the inland access to the karst system.

Within the cave, the main hypogean morphologies consist of highly karstified rock strata in the Mesozoic carbonate succession, showing development of multiple phreatic conduits, and the solution breccias described by RUDNICKI (1990). These latter typically originate in hydrothermal karst environment, but at Rondinella they derive from the action of meteoric waters, likely combined with ancient collapses that caused the sinkhole. Existence of a palaeo-karst system, and of a multi-stage evolution of Grotta della Rondinella, is also proved by the presence of at least two levels in the cave, as before described.

The structural survey performed in the karst system was aimed at identifying the likely controls exerted by discontinuity systems in the development of the underground voids. Statistics of surveyed data documented the presence of four discontinuity systems, the main ones being oriented NNE-SSW and N-S, with subordinate NW-SE and WNW-ESE systems. From the analysis of these data it appears that the cave strongly developed along intrastratal partings, at the same time with a structural control by tectonic discontinuities. Even within the cave the bedding is extremely variable, as already observed outside of it, as an effect of the flessure in the stratigraphy, related to occurrence of the collapse sinkhole.

GEOPHYSICAL SURVEYS

Two different geophysical methodologies were implemented in order to verify their validity to locate a known cave, and to look for evidence of further underground voids:

- a 3D electrical tomography (data elaboration by means of the ERTLAB programme by Geostudi Astier, Livorno);
- radar lines, covering an area of some 26000 m^2 by means of the contemporaneous use of two antennas: the 270 Mhz antenna was used to investigate different depths, with variable resolution, whilst the 70 Mhz antenna to get with good resolution the subsoil down to maximum depth of 15m. Data acquisition and elaboration were performed using the RADAN software, including the 3D QuickDraw module.

Choice of the two methodologies was dictated, given the local geological setting, by a preliminary analysis of both the known data and those resulting from the speleological surveys. Taking into account the depth and size of the karst system, the following methods were selected:

- the 3D geoelectrical method, with 96 electrodes distributed over a rectangular grid with 3 m-spacing, along lines consisting of 16 electrodes each;
- georadar surveys with medium (270Mhz) and low frequency (70Mhz) antennas.

Fig. 4 – The entrance from the sea, showing the flessure in the carbonate strata, and the marine notch (to the right of the picture).

The resistivity data, properly inverted, indicate presence of positive resistivity anomalies, visible both qualitatively through 3D volume representations, and horizontal planes at variable depths from the ground surface. This latter representation allows to have geometrical indications on the pattern of the anomalies in depth.

The radar surveys, on the other hand, appear to be more disturbed and less precise in this geological setting.

Overall, the anomalies found highlight the likely presence of further cavities W and NW of the terminal room of the known cave system of Grotta della Rondinella, at depths from 4,5 m to about 9 m.

CONCLUSIONS

The data here summarized represent an increase in the knowledge about Grotta della Rondinella and, more in general, karst of the area of Polignano. Beside better delimiting the development of the cave, the modern surveys added a previously unknown flooded gallery to the system. Further, they resulted extremely useful to plan the geophysical surveys which, in turn, highlighted the likely presence of other underground caverns, thus testifying the importance of the studied karst system.

Integration of geomorphological and speleological datasets in karst terrains

PEPE MARIANGELA (*) & PARISE MARIO (**)

Key words: *geomorphology, karst, morphometry, Murge, Salento*

INTRODUCTION

The development of karst processes requires some basic conditions, such as the presence of soluble rocks, water supply and hydraulic gradient (WHITE, 1988). A number of additional factors strongly affect solution, such as thickness of karst-prone rocks, presence of insoluble layers or of unconsolidated sedimentary covers, arrangement and distribution of mechanical discontinuities, hydro-chemistry of circulating waters, and vertical oscillations of the phreatic surface (JASSIM *et alii*, 1997; YAORU & COOPER, 1997; PAUKŠTYS & COOPER, 1999; COOPER, 2002; SALVATI & SASOWSKY, 2002; DELLE ROSE *et alii*, 2004; CLOSSON *et alii*, 2007; FORD & WILLIAMS, 2007; YILMAZ, 2007; MANCINI *et alii*, 2009). In addition to natural factors, anthropogenic activities also affect karst phenomena (CLOSSON & ABOU KARAKI, 2009; NORTH *et alii*, 2009; SORIANO *et alii*, 2012). The relative importance of all these factors changes from place to place. Therefore, an appropriate knowledge of local karst features is strongly required in carbonate terrains, in order to formulate suitable evaluations of the hydrological and geomorphological hazards.

The widespread presence of carbonate rocks in Apulia (SE Italy) makes this region a potential test area for this kind of analysis, showing a variety of conditions for development of karst processes. Furthermore, a regional database of natural and anthropogenic caves, built up by the Speleological Federation of Apulia (FSP), provides valuable, additional data about the underground karst features.

Neverthless, a regional, systematic database of karst landforms is missing, being the most specific maps restrained to well defined areas (e.g. RICCHETTI, 1987). Thematic maps provided by regional authorities (e.g. the Hydro-geomorphological Map by the Basin Authority of Apulia) miss some useful information, preventing specifical analyses on lower-rank classes of landforms.

This work performs some potential applications of a spatial database of integrated morpho-karst and speleo-karst features, in three sample areas, located in the High Murge highland and in the Salento peninsula. Each individual sample area shows peculiar karst features: Ruvo di Puglia countryside, at the eastern border of High Murge, is widely known for the abundance of natural caves, including the deepest pit of the region (Grave della Ferratella, PU 444); Barbarano del Capo (southern Salento) shows typical cover-collapse sinkholes (*Vore di Barbarano*); Santa Cesarea Terme (eastern Salento) performs hyperkarst features, connected to the presence of thermal underground waters.

METHODS

In the first stage of work, detailed hydro-geomorphological maps of the study areas have been realized, based upon field surveys and interpretation of multi-year aerial photographs, covering the time span from 1955 to 2001. Recognized elements have been drawn up in a digital format, using the Regional Technical Map (1:5.000 scale) as a topographic base. In particular, a hierarchical distinction among recognized morpho-karst elements has been outlined, basing on visibility, extension and depth. The term "doline" refers to topographically depressed areas of generally limited extent, showing a marked altitude drop. These latter are often enclosed in wider, flatter "depressions", which boundaries are more difficult to be outlined. Similarly, incised and not-incised fluvio-karst valleys have been distinguished, basing on morphological evidences, such as the incision depth. The hydro-geomorphological maps have further been integrated with speleological data provided by FSP, indicating location, plan view and section of the natural/artificial caves in the registers.

Cartographical data have been then employed for the morphometric analysis. This latter has been undertaken in only one of the analyzed areas (Barbarano del Capo). The following parameters, considered as the most representative for a morphometric description, have been adopted,: i) Total number of dolines; ii) Minimum and maximum extent of dolines; iii) Doline density (total number of dolines / total extent of the analyzed area); iv) Total extent of dolines; v) Percentage of area involved in dolines compared to analyzed area; vi) Average major axis (a) / minor axis (b) of dolines ratio.

Finally, structural analyses have been carried out in two sample areas (Barbarano del Capo and Ruvo di Puglia). On

(*) CNR, Istituto di Metodologie per l'Analisi Ambientale, Tito Scalo (PZ); mari.pepe81@gmail.com

(**) CNR, Istituto di Ricerca per la Protezione Idrogeologica, Bari; m.parise@ba.irpi.cnr.it

appropriate carbonate outcrops, dip-directions of faults and joints have been measured. A minimum number of 40 measurements for each station has been assumed as the threshold of statistical significance. Results have been then analyzed and plotted on rose diagrams and cumulative curves, in order to detect the likely connections between structural data and morphometric parameters.

RESULTS

Hydro-geomorphological maps highlight slight differences in karst settings among the analyzed areas. In the Salento peninsula, “dolines” and “depressions” represent the dominant landforms, often associated to sinkhole phenomena (e.g. the *Vore* di *Barbarano* in the Barbarano del Capo area, fig. 1). These features can be ascribed to lateral and vertical changes in the litho-technical properties of rocks, also deriving from the effects of

Fig. 1 – Comparison between hydrogeomorphological features and structural data in Barbarano del Capo area (southern Salento).

mechanical discontinuities of both stratigraphic and tectonic origin. In the High Murge (fig. 2), instead, higher topographical gradients and lithological uniformity of the bedrock favored the development of fluvio-karst valleys (SAURO, 1999; PARISE, 2011). These latter show a high variety of patterns: shallow valleys (*lame*-type, see PARISE *et alii*, 2003) locally deepen up to reach canyon-type morphologies (“incised valley”). As concerns the hydrographic pattern, this generally shows either straight or meandering flow paths, whilst local changes in large-scale permeability can produce dendritic hydrographic networks.

The morphometric analysis performs different values of all parameters, whether considering “dolines” or “depressions” (tab. 1). Apart from the specific values for the analysed case study, this feature indicates class-dependent results. A careful classification of morphological elements is therefore of primary importance whenever approaching a morphometric analysis.

The structural data collected, indicating local joints distributions, fit quite well with the regional trends in both the Barbarano del Capo (fig. 1) and Ruvo di Puglia (fig. 2) case studies. Furthermore, the comparison between the two hydro-geomorphological maps and the respective structural data indicate a strong tectonic control on the hydro-geomorphological features (hydrographic pattern in the Ruvo di Puglia area, and elongation of dolines/depressions at Barbarano del Capo). Finally, the structural data collected in Ruvo di Puglia area show a good fit with local speleo-karst network (fig. 2).

CONCLUSIONS

An appropriate knowledge of spatial distribution of karst features is of primary importance for mitigation of the hydrological and morphological hazards in carbonate terrains. The peculiar dynamics of karst settings requires integration of surface and underground datasets. Furthermore, a morphometric approach allows a quantitative description of both the morpho-karst and speleo-karst features, and hence a comparison between superficial and underground drainage systems.

Additional information about structural, litho-technical and hydrogeological settings provide useful information to outline genesis and evolution of karst landforms.

The Rumena flank margin cave and its implications in support of the paleogeographic evolution of the Monti di Capo San Vito (North-western Sicily)

RUGGIERI R. (*), MESSINA PANFALONE D. (*), ANTONIOLI F. (**), ROSSO A. (°), SANFILIPPO R. (°) & MANISCALCO R.(°)

Key words*: Biotic crusts, flank margin cave, speleothem with marine and continental layers.*

This paper concerns the discovery and the preliminary study of a unique karst cave located on a marine paleo-cliff in the territory of Custonaci (Province of Trapani) in north-western Sicily (RUGGIERI & MESSINA PANFALONE, 2011). The cave developed in the Upper Cretaceous limestone of the Monti di Capo Sn Vito structural-stratigraphic units (ABATE *et alii*, 1991; CATALANO *et alii*, 2011). Noteworthy, it preserves a series of morphological, paleontological and speleothematic features of paramount interest for the study and interpretation of geological, paleogeographic and paleoclimatic events that affected this outermost tip of the north-western sector of Sicily during the Plio-Pleistocene age.

The cave extends for about 80 m, with an ENE-SSW direction, parallel to the vertical slope of the marine paleo-cliff, along a bedding plane with a dip direction of N 260/27°. It consists in an elongated, wide but low cavity, about 2,5 m wide, made up of a series of hemispheric chambers merging one into the other. The walls and the roof of these chambers appear smooth and polished, except where calcite crusts cover them, and in some parts carved by small phreatic pockets and domes. (Fig. 1).

This general environment shows an almost mazy aspect with main chambers, separated by rock pendants and small low interconnected conduits. The chambers are partially to completely filled by red detrital clay-sandy soil.

From a morphogenetic point of view the Rumena cave is a *flank margin cave* (MYLROIE, 2008) which was subsequently invaded by the sea due to the retreat of the cliff, then colonized by marine organisms, and finally raised due to the tectonic activity during the Pleistocene. During the emersion phases the cave was remodeled reaching typical karst forms such as domes and channels caused by acid water condensation, and calcite deposition.

The sections of some stalactites clearly show the presence of three hiatuses in subaerial precipitations, corresponding to three transgressions (Fig. 2). Particularly the marine events are highlighted by the presence of lithophagous borings (Fig. 3) and organogenic (mostly coral) crusts (Fig. 2) on walls and the ceiling (ROSSO *et alii*, 2012).

The dating of corals using the ratio $^{87}Sr/^{86}Sr$ showed an age of 1.1-1.2 My., while the $\delta^{18}O$ measurement in the continental layers of a stalactite and the comparison between marine and continental data indicated that calcite precipitated during MIS 31-37 (ANTONIOLI *et alii*, 2012).

(**) ENEA, Casaccia, Roma, Italy.

(°) Department of Biological, Geological and Environmental Sciences, Section of Earth Science, Catania, Italy.

For all the above, in the Mediterranean context the Rumena cave is a singular example of *flank margin cave* developed in telogenetic limestones and a unique paleo-sea-level archive. The suite of morphological features, and biotic borings and encrustations record the history of the cave and its location above and below the sea level. Consequently, cave's detailed analysis will contribute significant data to reconstruct the paleogeographic evolution of the Monti di Capo San Vito coastal area.

The Rumena cave discovery and analysis reveals as the speleological exploration may represent a relevant tool for geological investigations.

Allogenic contact caves in Central East Sardinia (Italy): their speleogenesis and evolution

LAURA SANNA (*, **), JO DE WAELE (***), JOSÉ MARÍA CALAFORRA (**), ANTONIO ROSSI (º), SALVATORE CABRAS (ºº) & ALBERTO MUNTONI (ººº)

Key words: *Mesozoic dolostones, granites, dissolution, erosion, Supramonte cave.*

INTRODUCTION

The basement of Sardinia (Italy) is composed of Variscan rocks of which almost 40% is represented by granites (CARMIGNANI *et alii*, 2001). In the central-eastern part of Sardinia, granite batholiths are covered with Mesozoic carbonates, forming the large karst aquifers of Supramonte and the Gulf of Orosei. In these areas, allogenic recharge has enabled huge karst underground networks to develop at the lower contact between dolostones and granite rocks (DE WAELE *et alii*, 2002). Recently a new important system of passages excavated directly into granite rocks has been discovered in the Murgulavò Cave by cavers of the Centro Speleologico Cagliaritano (CSC) (CENTRO SPELEOLOGICO CAGLIARITANO, 2010). The aim of this work is to present the very special speleogenetic mechanisms that allow for the formation of such great cave systems at the contact with the underlying granites.

STUDY AREA

The Gulf of Orosei (Central-East Sardinia) is one of the most important karst areas of Sardinia. It occupies an area of more than 210 km^2 (DE WAELE, 2003), almost 80% of which is composed of Middle Jurassic-Lower Cretaceous dolostones and limestones that overly a crystalline Palaeozoic basement complex. These rocks are composed of metasediments and metavolcanic rocks, injected with granitic batholiths and late intrusive Carboniferous and Permian dykes. Where this basement complex borders the carbonate sequences, it often acts as allogenic recharge area to the karst aquifer. Marghine, a plateau around 1000 m asl, East of the Upper Codula Ilune Valley, is one of the most representative allogenic recharge areas of this kind (Fig. 1).

This Variscan basement has been eroded for millions of years before being submerged by the Jurassic sea around 170 Ma ago. The transition from granites and phyllites to the overlying Mesozoic carbonate platform is often characterised by the outcropping of siliciclastic sediments of variable thickness related to continental to transitional environments (DIENI *et alii*, 1983).

CAVES AND SPELEOGENESIS

In the Gulf of Orosei high mountain caves are mainly formed by erosion and dissolution processes close to the contact between carbonate rocks and the Variscan basement (DE WAELE, 2004). The transition between less permeable basement rocks and the carbonate platform greatly influences the asset of all caves discovered in this area. Allogenic recharge, characterised by low flow during most of the year and one to some flood pulses during which discharge can increase two orders of magnitude, creates contact caves that can reach quite large dimensions (e.g. Lovettecannas Cave, almost 6 km long). Further from the sinks, underground flow concentrates and, because of structural reasons, abandons the contact between the basement rocks and carbonates. Underground morphologies are characterised by enlarged canyon-like fissures in dolostones and larger more rounded dissolutional passages in pure limestones. In some cave, however, passages are almost completely excavated in non-carbonate host rocks of the basement complex. The best example of this type of caves is Murgulavò, at Baunei.

Murgulavò, one of the most beautiful caves in the Gulf of Orosei karst area discovered in June 2010 by cavers of CSC, is very rich in unique carbonate speleothems (Fig. 2). This 3 km long cave is constituted of narrow shafts in the Jurassic basal dolostones that rapidly descend down to a small river that flows at about 50 m depth from the entrance. From this point on a well rounded steep gallery, about 4 metres in diameters, is settled within the granites and only hundred metres downstream the cavity returns to develop within carbonate rocks, forming some large rooms. From time to time, especially toward the bottom of the great collapse halls (at about 280 metres deep), the cave crosses the basal (transgressive) part of the Mesozoic sediments characterized by sandstones, conglomerates and clays.

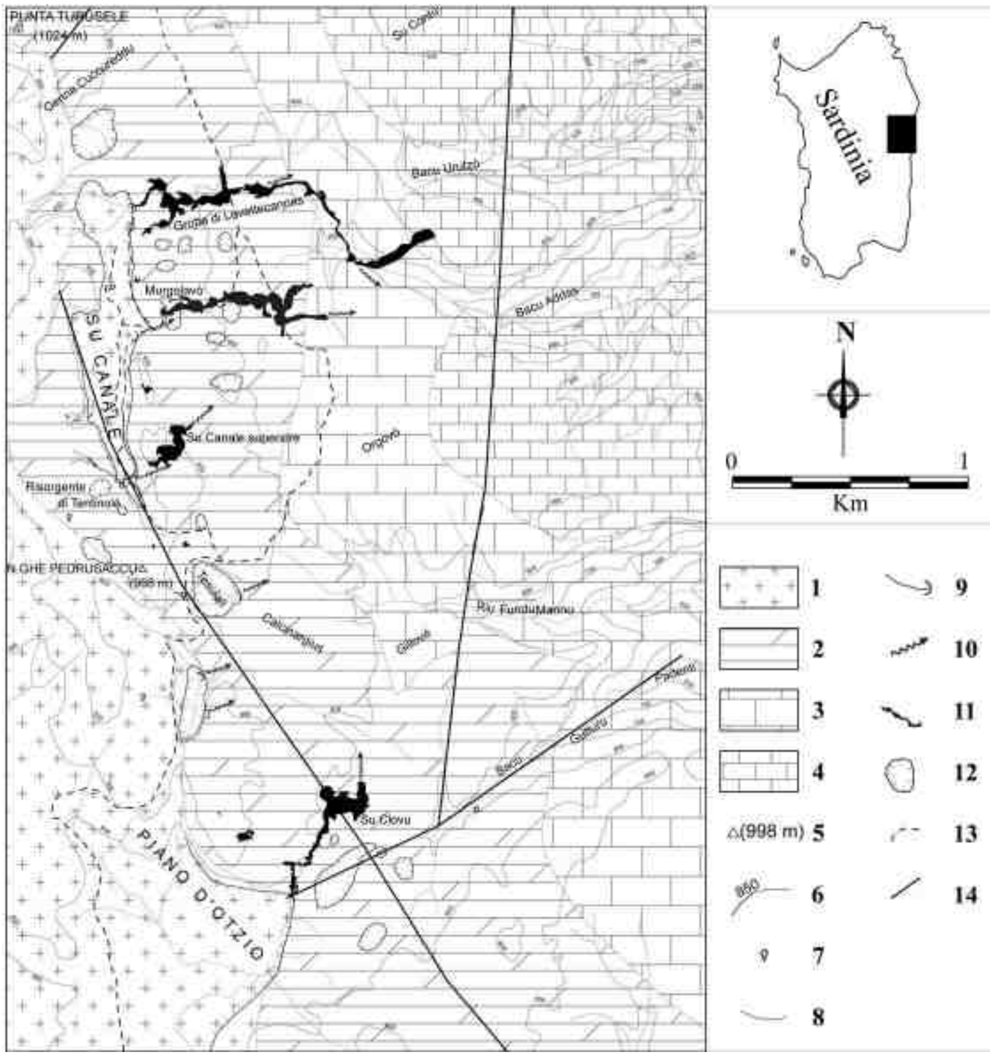

Fig. 1 – Geological sketch map of Marghine plateau. 1) Granites; 2) Dolostones; 3) and 4) Limestones; 5) Summits; 6) Contour lines; 7) Springs; 8) Surface drainage; 9) Sinkholes; 10) Underground water flow; 11) Cave conduits; 12) Dolines; 13) Roads; 14) Main faults.

The overall bedrock contours of the cave passages are smooth and white stalactites and draperies hang from the granite ceiling whereas a small underground river flows in between the boulder-choked floor.

Although most of the caves in granite rocks consist of enlarged fractures, the physical erosion features found in the Supramonte cave systems at the contact with non-carbonate rocks are rather complex, showing a very slow hydrolysis of silicates from groundwater circulation through the bedding planes and joints, producing a decomposition of igneous minerals in clays mixed with sand composed of resistant quartz and subordinate feldspar grains. X-ray diffraction analysis confirms the presence of kaolinite, montmorillonite, illite and chlorite, the typical secondary minerals association of feldspar and mica alteration, and some iron oxides. These minerals represent advanced weathering corresponding to intense hydrolysis. Water flow at the contact between lower granites and/or phyllites and overlying dolostones allows these loose materials to be eroded rather easily.

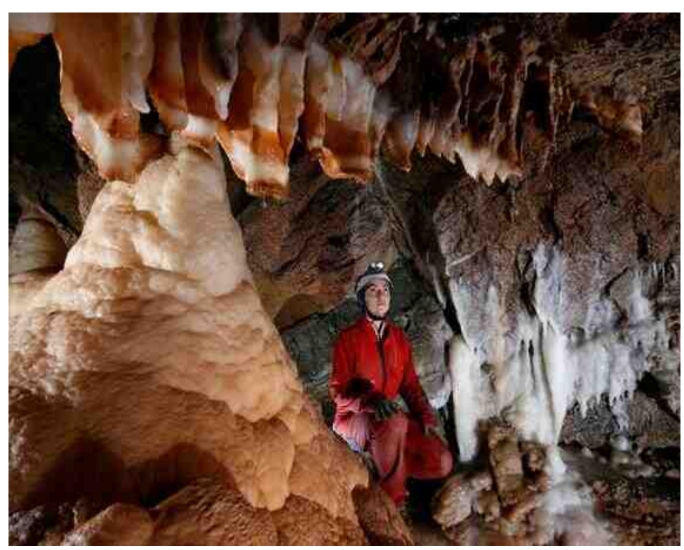

Fig. 2 – Murgulavò cave, with calcite speleothems partially filling the cave void excavated in granites (Photo by Alessio Laconi).

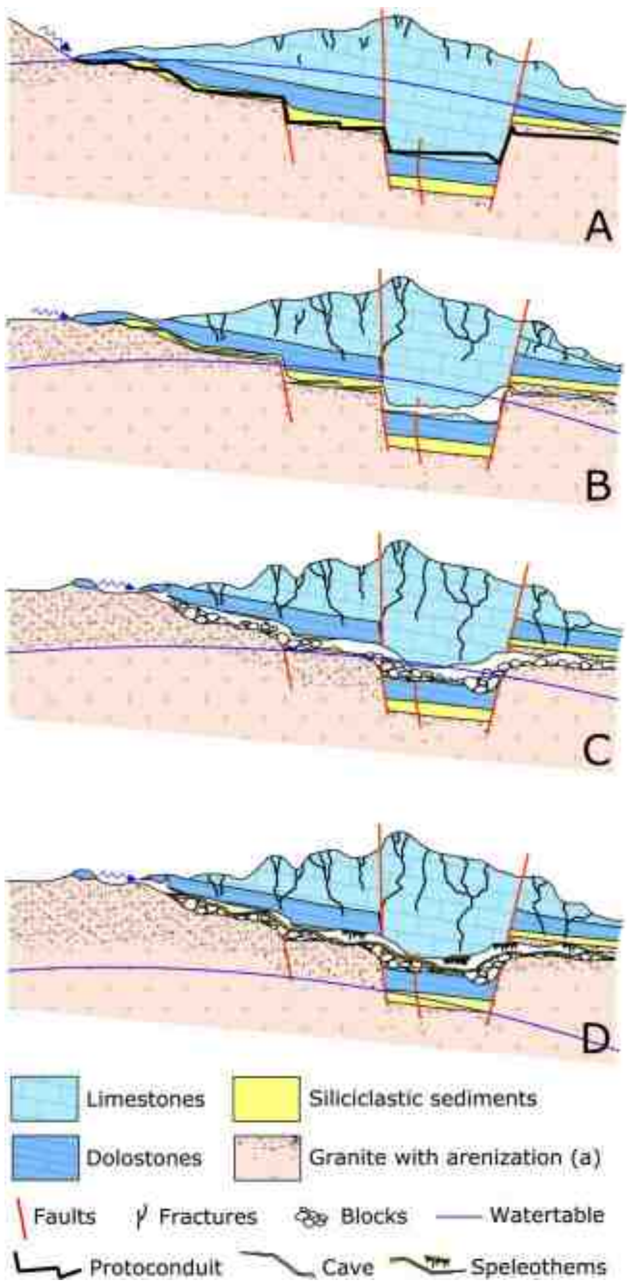

Fig. 3 – Speleogenetic evolution of Sardinian contact caves (not to scale). A. During wetter climatic periods, allogenic recharge from granites forces groundwater circulation into protoconduits formed by very slow hydrolysis along joints and fissures at the contact between partially saprolitized Variscan basement rocks and the overlying Jurassic platform in phreatic conditions. B. The watertable lowering increases arenization effects within conduits excavated in non-carbonate rocks and erosion of transgressive siliciclastic sediments; in the epiphreatic zones, dissolution enlarges passages in dolostones and limestones. C. The further widening of these karst conduits causes the collapse of the ceiling whereas water discharge thickens the arenization strip in the oxidation zone and allows loose material to be eroded. D. Under warmer conditions, allogenic water continues to feed the karst system by narrow sinkholes at the contact between impermeable and carbonate rocks, while water seepage leads to speleothem formation covering the boulder-choked floor.

DISCUSSION AND CONCLUSIONS

Groundwater erosion of the impermeable beds at the lower contact with the carbonate rocks is commonly recognized in central-eastern Sardinian cave systems. Speleogenesis of these cave systems is very much relied upon weathering of the basement rocks and their successive erosion by flood waters, rather than on dissolution of the carbonate rocks. In a first stage under humid tropical conditions, a rapid and abundant argillization (or clay formation) is involved. Then, in temperate environment, a form of skeleton arenization, consisting of the separation of the mineral grains and negligible clay formation, is yielded. Once a critical dimension of void is reached, cave formation occurs comparatively rapidly, leading to huge chambers in some thousands of years (Fig. 3). Mineralogical analyses of the weathering products at the contact between Palaeozoic rocks and Mesozoic sediments have revealed the predominance presence of kaolinite plus iron oxides formed by abundant leaching of granitic rocks. These non dissolutional processes are very important in the Murgulavò Cave and have formed large passages completely hosted in granites (Fig. 3). The study of these pseudokarst features indicates that granite arenization occurs at the contact between carbonates and granitic basement rocks, representing an important speleogenetic process in this karst area.

Acqua Fitusa Cave: an example of inactive water-table sulphuric acid cave in Central Sicily

MARCO VATTANO (*), PHILIPPE AUDRA (**), JEAN-YVES BIGOT (***), JO DE WAELE (°), GIULIANA MADONIA (*) & JEAN-CLAUDE NOBÉCOURT (°°)

Key words: *gypsum*, *hypogenic caves*, *sulphuric acid cave*, *thermal waters, Sicily.*

ABSTRACT

Hypogenic caves are generated by water recharging from below independently of seepage from the overlying or immediately adjacent surface. These waters are often thermal and enriched in dissolved gases, the most common of which are CO_2 and H_2S. Hypogenic caves can be thermal caves, sulphuric acid caves, basal injection caves. They differ from epigenic caves in many ways, such as: speleogenetic mechanisms, morphological features, chemical deposits, and lack of alluvial sediments (KLIMCHOUK, 2007; KLIMCHOUK & FORD, 2009; PALMER, 2011).

Several studies were conducted to evaluate the hypogenic origin of a large number of caves (AUDRA *et alii*, 2010; KLIMCHOUK & FORD, 2009; STAFFORD *et alii*, 2009). A significant contribution was given by the work of Klimchouk (2007) that systematically provided instruments and models to better understand and well define the hypogenic karst processes and landforms.

Detailed studies on hypogenic caves were carried out in Italy since the 90s in different karst systems, especially in the Central and Southern Appenines. These studies mainly concerned chemical deposits related to ascending water and micro-biological action (GALDENZI & MENICHETTI, 1995; GALDENZI, 1997; PICCINI, 2000; GALDENZI & MARUOKA, 2003, FORTI & MOCCHIUTTI, 2004; GALDENZI, 2012).

In this paper, we present the first results of researches conducted in Acqua Fitusa cave that was believed to be an epigenic cave until today.

Acqua Fitusa cave is located in Central Sicily, along the north-eastern scarp of a N-S anticline, westward vergent, forming the Mt. La Montagnola. The cave formed in the Upper Cretaceous Rudist breccias member of the Crisanti Fm., composed of conglomerates and reworked calcarenites with rudist fragments and benthic foraminifers (CATALANO *et alii*, 2011).

The cave consists at least of three stories of subhorizontal conduits, displaying a total length of 700 m, and a vertical range of 25 m. It represents a clear example of inactive water-table sulphuric acid cave, produced mainly by H_2S degassing in the cave atmosphere.

Despite the small size, Acqua Fitusa cave is very interesting for the abundance and variety of forms and deposits related to rising waters and air flow. A ~ 7 m deep inactive thermo-sulphuric discharge slot intersects the floor of some passages for several meters (Fig. 1). Different morphologies of small and large sizes, generated by condensation-corrosion processes, can be observed along the ceiling and walls: ceiling cupolas and large wall convection niches occur in the largest rooms of the cave; deep wall convection niches, in places forming notches, incise cave walls at different heights; condensation-corrosion channels similar to ceiling-half tubes carve the roof of some passages; replacements pockets due to corrosion-substitution processes are widespread; boxwork due to differential condensation-corrosion were observed in the upper parts of the conduits.

Sulphuric notches with flat roof, linked to lateral corrosion of the thermal water table, carve the cave walls at different heights recording past stages of base-level lowering.

Fig. 1 – Passage with discharge slot at the floor and different levels of wall convention niches.

(°°) Crespe, Le Hameau de l'Ara, 259 Bd Reine Jeanne, 06140 Vence, France (jcnobecourt@free.fr)

Gypsum deposits have been found in many parts of the cave. Replacement gypsum crusts are common in many passages; the gypsum is located in large vertical fissures along the walls, it can partially cover wall convection notches, or replacement pockets (Fig. 2). A gypsum body of about 50 cm of thickness was found on the floor of the biggest room in correspondence of which small ceiling cupolas are associated on the roof. Finally, centimetric euhedral gypsum crystals grew inside mud sediments.

Fig. 2 – Replacement pockets partially covered by gypsum crusts.

At present the cave is inactive with the thermal spring occurring 300 m north and at a lower altitude than the cave. These H_2S-rich waters are indicated as chlorine-sulphate alkaline, and have a temperature of about 25°C (CARAPEZZA *et alii*, 1977).

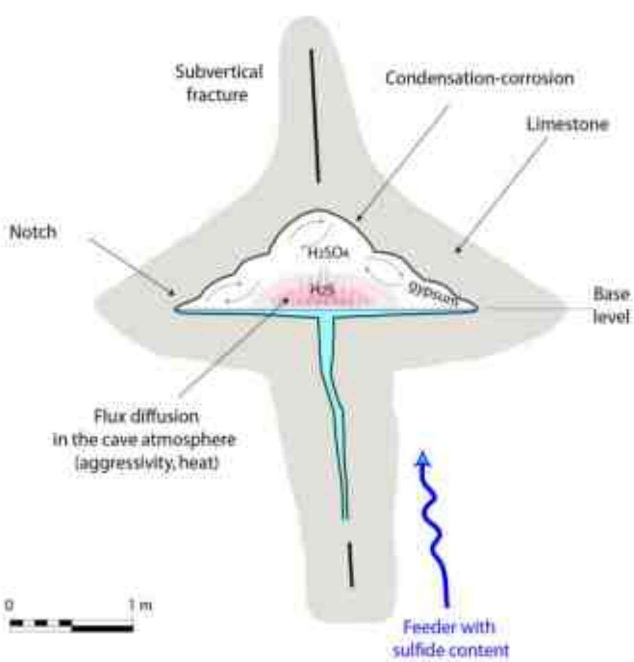

Fig. 3 – Sketch of the genetic mechanism of the Acqua Fitusa cave conduits due to H_2S degassing in the cave atmosphere.

The origin of the Acqua Fitusa cave is due to corrosion processes of carbonate rocks with replacement of gypsum by H_2S-rich thermal water (Fig. 3). In particular, the enlargement of voids and formation of the main morphologies are due to H_2S degassing in the cave atmosphere, oxidation of sulphides and thermal convection that produce strong condensation-corrosion processes above the watertable, according to the origin of sulphuric acid caves (FORD & WILLIAMS, 2007; AUDRA *et alii*, 2010).

Archaeological sites and relative sea level changes: recent results in the Mediterranean: a review

MARCO ANZIDEI (1,2), FABRIZIO ANTONIOLI (3), ALESSANDRA BENINI (2),

RITA AURIEMMA (4,5), EMANUELA SOLINAS (6)

Key words: *sea level change, archaeology, Mediterranean.*

Changes of sea level have modified coastlines and affected human civilizations since historical times. In order to understand present sea-level variability we must understand the past records, shown by geological, geomorphological and archaeological indicators that provide relative measurements of the observed changes. In this review, we will summarize what is known about past sea-levels, concentrating particularly on changes that have occurred over the past few thousand years since the termination of the Last Glacial Maximum.

We will focus on the Mediterranean that experienced a long story of sea level changes during the last 20 ka. The interpretation of sea level variations observed along the coasts of the Mediterranean must be also accompanied by the evaluation of vertical land movements, also generated at local scale by seismic and volcanic sources.

In this presentation, we will focus on the relative sea level changes, estimated by roman age coastal archaeological data. We will show data for the whole Mediterranean basin and particularly we will discuss some recent observations in the Phlaegrean Fields.Our results indicate for the Mediterranean significant variations of relative sea level in the last 2300 years, that vary with locations and suggesting that the observed signal can be accounted for eustatism and isostatic adjustment as well as by local vertical land movements induced by seismicity, volcanism and subsidence as well as anthropogenic signals, which have produced relative changes up to several meters.

New geochemical data relating to the interactions between thermal waters and the archaeological site of Hierapolis (Turkey)

CARMINE APOLLARO (*), DOMENICO MIRIELLO (*), ANDREA BLOISE (*), TERESA CRITELLI (*), ELISAVET DOTSIKA (**), STEFANO MARABINI (*) & GINO MIROCLE CRISCI (*)

Key words: *Hierapolis, thermal waters, travertine.*

INTRODUCTION

An investigation of the thermal waters which flow inside *Hierapolis*, archaeological site protected by UNESCO (Province of Denizli, Turkey), has been carried out in order to determine their origin and the depositional potentiality of travertine with time. One of the aim of this study is to delve into the interactions between the natural process which gave rise to the springs, that is the main reason of the human settlement for religious aim, and his urban evolution.

Hierapolis was built in the third century B.C. and despite the frequent devasting earthquakes, it has survived for over a millennium. It is located on the world-famous terrace of Pamukkale, peculiar for the white travertine waterfalls made of the calcareous deposits of thermal waters, which gave the name to the site ("Pamukkale" means "cotton of castle").

From a geological point of view, the site is located on the northern side of Denizli Basin, a graben whose trend is WNW/ESE and which is approximately 70 km long in the Western Anatolian Province. His master fault, which is close to the Hierapolis terrace, has been affected by hot springs (since Early Pleistocene) which give rise to the most important travertine deposits of the area (ALCICEK *et alii*, 2007, KELE *et alii*, 2011).

At present, the thermal waters spring from active fault zone which crosses lenghtwise all the city and which is marked by a system of morphological steps and crackings in the soil newly formed. From the fourteenth century, these waters have created different white travertine deposits with a thickness of 3-4 m, on both the western sector of the ancient city and the Pamukkale drop off.

(*) Department of Earth Sciences, University of Calabria.
Via Ponte Pietro Bucci, 87036 - Arcavacata di Rende (CS), Italy.
(**) Institute of Materials Science, NCSR Demokritos (Athens, Greece).
This study is part of the Italian archeological mission directed by Prof. D'Andria (Università del Salento).

As regard the provenance of these waters, the bibliography is in agreement with a meteoric origin at high altitude (over 600/750m). This condition is represented by the overlying plateau of Uzunpinar (Yenice horst) which is characterized by a metamorphic basement with murbles and a cover partially of Mesozoic limestones (KELE *et alii,* 2011).

Water samples were collected in the archaeological site (Fig. 1) in August 2011. Two of these samples (H6 and H11) coincide with the historical springs; samples H3, H4, H5, H9, H10, H12 and H14 are close to them while samples H2, H7 and H8 are far from them. Some groundwater parameters, such as pH, Eh, temperature, alkalinity and electrical conductivity, were measured in the field, while groundwater samples, suitably filtered and acidified, were used for laboratory analyses.

Fig. 1 – Archaelogical site and water samples location.

The concentrations of Cl^-, Br^-, SO_4^{2-}, F^-, NO_3^-, and PO_4^{3-} were determined by HPLC, whereas those of Ca^{2+}, Mg^{2+}, Na^+, K^+, SiO_2 and some trace elements were analysed by ICP-MS. Data quality for major components was evaluated by charge balance. Precision and accuracy for minor and trace elements was evaluated against two different standard reference samples.

The isotopic composition of hydrogen (^2H) and oxygen (^{18}O) was measured in Stable Isotope Unit, Institute of Materials Science, NCSR Demokritos (Athens, Greece).

The chemical composition of springs was characterized in

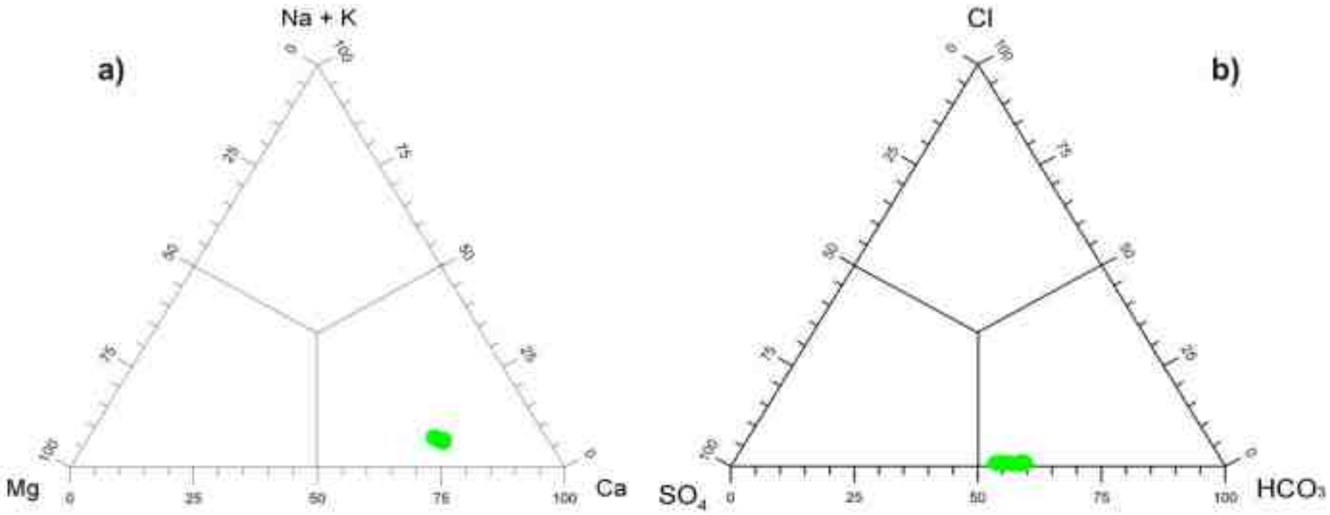

Fig. 2 – Triangular plot involving (a) Ca^{2+}, Mg^{2+}, and Na^{+}+K^{+}, and (b) HCO_3^{-}, SO_4^{2-}, and Cl^{-}, both prepared from concentrations in equivalent units.

terms of relative Cl, SO_4 and HCO_3 concentrations and Na+K, Ca, and Mg contents by using triangular plots (Fig. 2). Inspections of the data show that all waters have a Ca-HCO_3 composition.

Isotopic data of all waters are shown in Fig.3. In the same figure also the global meteoric water line (GMWL), the East Mediterranean meteoric water line (EMMWL) (CRAIG, 1961) for reference and the local meteoric line of Antalya, are reported. The correlation function for rainwater in the area is: $\delta^2H = 8\delta^{18}O + 18.6$ (DILSIZ C., 2006) similar to Hellenic Meteoric water line (DOTSIKA *et alii*, 2010).

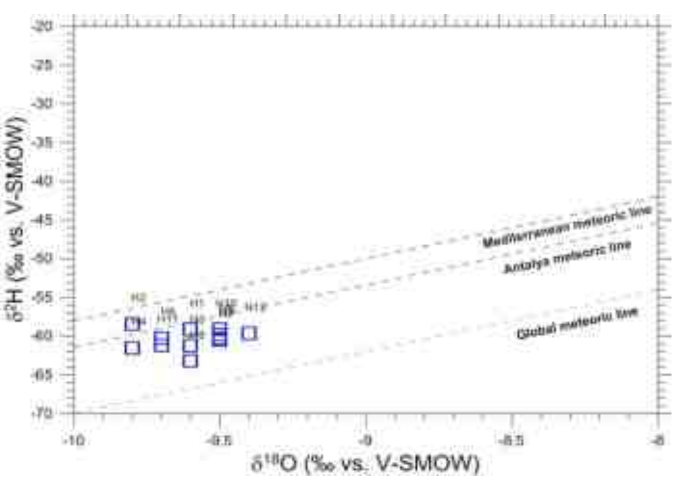

Fig. 3 – Isotopic data for the water samples.

Generally, an isotope relationship between δ^2H and $\delta^{18}O$ with a slope of about 8 is normal for meteoric precipitation of all types (CRAIG, 1961), as well as for surface waters not subjected to excessive evaporation relative to input.

The position of the samples of thermal waters is very close to global meteoric water line but it is not adjacent to Antalya meteoric line indicating that these thermal spring waters have a purely meteoric origin but its isotopic composition is different from the isotopic composition of waters from Antalya region.

Probably, the *Hierapolis* thermal waters, of meteoric origin, are recharged from different altitude area. In fact, negative values of $\delta^{18}O$ are considered to indicate a relatively high elevation recharge area and probably the ^{18}O observed variation is due to different alimentation zones.

The preliminary geochemical data seem to be in agreement with the hypothesis that, *Hierapolis* hot springs (whose average flow in the year is about 365/385 l/s, at present), underlie a wide underground basin which probably increased his extent with time because of the coseismic effect of many earthquakes which has been proved, from the archaeological side.

Genesis of black crusts on building stones from three Italian cities: relations with environmental pollution

D. BARCA (*), C.M. BELFIORE (°), G.M. CRISCI (*), M.F. LA RUSSA (*), A. PEZZINO (°) & S.A. RUFFOLO (*)

Key words: *Black crust, trace elements, LA-ICP-MS analysis, atmospheric pollution.*

INTRODUCTION

The deposition of atmospheric pollutants on stones is one of the most important causes of the deterioration which affects the facades of buildings and monuments (AMOROSO & FASSINA 1983; DEL MONTE et alii 1981; TURKINGTON et alii 1997; ZAPPIA et alii 1998).

In polluted environments, black crusts usually develop on calcareous rocks.

In this contribution, we characterise some black crust samples collected from monuments and buildings of three Italian cities: Milan, Rome and Catania. Specifically, the examined specimens include:

1) three samples from the cloister of San Cosimato convent in Rome, now the Regina Margherita Hospital;

2) two samples from the sculpture of an angel located in Pessano con Bornago, a small industrial centre near Milan;

3) seven samples from monuments and buildings variously distributed in the Catania city centre.

Both substrate and black crust were studied for each sample through the synergic utilization of traditional analytical methods (polarizing optical microscopy, SEM-EDS and FT-IR), in combination with an innovative technique, i.e. laser ablation inductively coupled mass spectrometry (LA-ICP-MS).

The aim of this study was to evaluate the degree of chemical contamination of examined stones through the determination of trace elements variability from unaltered substrate to black crust. In addition, relations between concentrations of polluting elements in black crusts and environmental conditions were also investigated, thus allowing to understand the role of the different sources of pollution.

A complete discussion of the data presented here is reported in two papers recently published by the authors (BARCA et alii 2010, 2011).

RESULTS

Petrographic observations revealed that all analyzed black crusts have similar compositional features, given the constant presence of gypsum and calcium oxalate. The thickness of black crust varies from 10-100 µm in the thinner layers to 100-600 µm in the ticker layers.

In some black crusts (Catania and Milan samples) a high amount of carbonaceous particles has been observed (Fig. 1).

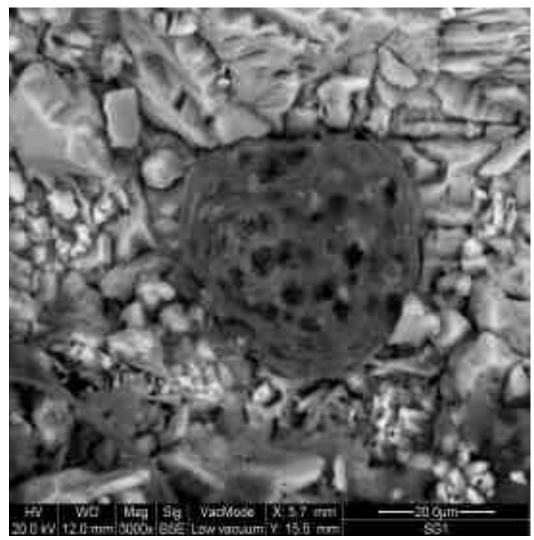

Fig.1 BSE-SEM image showing lenticular gypsum crystals and a carbonaceous particle embedded within the black crust of a sample from the cloister of San Cosimato (Rome).

Some differences characterize the examined samples in relation to the type of substrate and the state of conservation. Frequent micro-fractures can be observed in marble substrates (Rome and Milan samples), where the damage layer often causes cleavage in calcite crystals (Fig. 2). On limestone and calcarenite substrates (Catania samples) sporadic penetrations of the black crust into the stones can be frequently observed.

FT-IR analyses of all black crust samples exhibited the characteristic absorption peaks of gypsum ($CaSO_4 \cdot 2H_2O$) and revealed the presence of calcium oxalate monohydrate $CaC_2O_4 \cdot H_2O$ (whewellite).

The results obtained from LA-ICP-MS investigations highlighted a different chemical behaviour between substrates and black crusts.

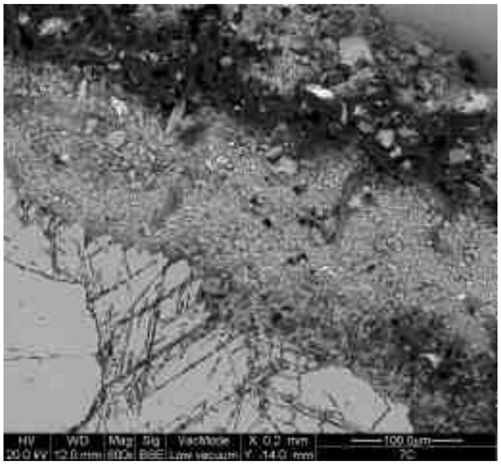

Fig. 2 BSE-SEM microphotograph of a black crust developed on a marble sculpture in Milan**.**

A general enrichment of all heavy metals was observed on the black crusts of the studied samples with respect to substrates.

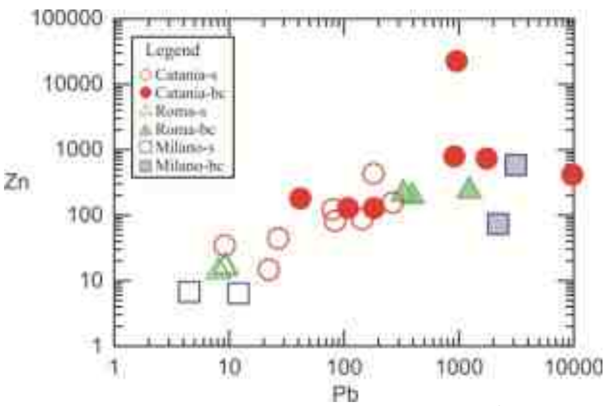

Fig. 3 Binary diagram Pb vs. Zn plotting the mean values of concentrations determined by LA-ICP-MS on black crusts (bc = full symbols) and substrates (s = empty symbols) of all samples.

As an example, the binary diagram Pb vs. Zn (Fig. 3) has been reported here. The higher concentrations of Pb and Zn refer to all samples collected in Milan, four samples from Catania and one from Rome. Moreover, the concentrations of heavy metals in the black crusts from different buildings in Catania show substantial differences. Such variations can be ascribed to variable outdoor conditions, e.g. the presence of road traffic. In this respect, samples showing the lower heavy metals concentrations were collected from buildings facing on a pedestrian street (via Crociferi). Conversely, samples with the higher concentrations of heavy metals come from buildings facing on streets where the vehicular traffic is intense.

Most of black crusts from Catania show heavy metals concentrations comparable with those of samples from Rome and Milan, cities where the air quality is known to be quite poor, being subjected to sources of considerable pollution, such as the presence of industries, vehicular traffic and domestic heating (MARCAZZAN et alii, 2003; PERRINO et alii 2008). The higher concentrations observed in some specimens from Catania with respect to those from the two other cities can be explained with an additional contribution from airborne volcanic ash emitted by Mt. Etna volcano, which is very close to the city of Catania.

In conclusion, results obtained demonstrated that this innovative approach in the study of black crusts represents a reliable indicator of the environmental pollution.

New insights on the possible location of the Roman Harbour of *Pompeii*

PAOLO BENEDUCE (*), PAOLO M. GUARINO (°) , SERGIO LONGHITANO (*) & MARCELLO SCHIATTARELLA (*)

Key words: *Geoarchaeology, Pompeii (Italy), sedimentological analysis, well log stratigraphy* .

INTRODUCTION

The effort for a reliable palaeoenvironmental reconstruction of the territory surrounding the Roman city of *Pompeii* at the time of the 79 AD major eruption involved, in the last two decades, many research groups belonging to the international archaeological and geological communities. Recent contributes among others (CINQUE & RUSSO, 1986; PESCATORE *et alii*, 2001; STEFANI & DI MAIO, 2003; CINQUE & IROLLO, 2004) lead to the determination of some geographic elements accepted by most researchers such as, for example, the position of the 79 AD coastline (more internal than the present-day one) and the presence at its back of two dune ridges (Bottaro and Messigno dune belts). There is no agreement, on the contrary, about the definition of other palaeogeographic elements, such as the location of the harbor of *Pompeii*, which, as well-know from ancient sources, had to play an important role in the management of commercial relationships among the Mediterranean coastal settlements. STEFANI & DI MAIO (2003) assume its location in the mouth of Sarno River, in a position north of the present-day one, in contrast to CINQUE & RUSSO (1986), which hypothesized the existence of a sort of bay farther south (i.e. in correspondence of the present-day Sarno River mouth). CURTI (2004) suggested the possibility of a fluvial/lagoon port near the south-west side of the town, in a palaeo-Sarno river bend, based on several documented evidences, such as the presence of a temple dedicated to Venus, a goddess originally linked to the protection of sea ports, the presence of a stores (*horrea*) area near the temple, and the absence of archaeological finds in this area. Further, just in this area, borehole core sampling and geophysical investigations have been recently carried out (BENEDUCE *et alii*, 2008), allowing a larger collection of data that strengthen this thesis.

(*) Dipartimento di Scienze Geologiche, Università della Basilicata, Potenza, Italia.

(°) Istituto Superiore per la Protezione e la Ricerca Ambientale (ISPRA), Roma, Italia.

The present study describes unpublished results deriving from sedimentological analyses performed on several samples from the cores drilled by BENEDUCE *et alii* (2008), and discusses their implications in the framework of the paleoenvironmental reconstruction and location of the ancient harbor of *Pompeii*.

GEOLOGICAL SETTING AND STRATIGRAPHIC LOGS

The Roman city of *Pompeii* is located between the foothills of the south-western slope of the Somma-Vesuvius volcanic complex and the coastal-alluvial plain of the Sarno River (Fig. 1a). It stands on a hill with a maximum height of 54 m a.s.l., due to the relict structure of an ancient volcano (CINQUE & IROLLO, 2004), partially buried by alluvial and volcaniclastic deposits supplied from the southern slopes of the Somma-Vesuvius edifice. It is a semicircular morpho-structure mainly set in massive and scoriaceous lava flows by Strombolian activity. Its physical continuity near the archaeological area of *Pompeii* is interrupted by the Versilian palaeocliff along the Vesuvian coast (CINQUE & RUSSO, 1986).

The activity of the Somma-Vesuvius complex in the last 17,000 years has been divided into eruptive cycles started with a major explosive Plinian eruptions, that have repeatedly shaped and changed the morphology of the volcanic edifice and ended with a minor intense, often effusive, eruption. Tephra levels covered large areas of the Campanian Plain and surrounding mountains, with a thickness of several meters. The 79 AD eruption, as described by Pliny the Younger, is one of the most important of the Vesuvius, having buried the Roman cities of *Herculaneum*, *Pompeii*, *Oplontis* and *Stabiae*, causing destruction and casualties.

Based on four continuous core drilling carried out as part of a research aimed to reconstruct the area close to the Porta Marina zone in the archaeological site of *Pompeii*, a 25 m-thick stratigraphic succession has been investigated (Fig. 1b). In the sector closest to the archaeological area (S1, S2, and S3 boreholes), the 79 AD products, here consisting of gray pumice fallout and ash surge found in the first 2.00-8.00 m, lay on fine-grained pyroclastics with little brick fragments, without sedimentary structures and likely related to a continental environment. In the S4 borehole (i.e. the most distant from the present-day boundary of the excavated town), the 79 AD products overlie a high-energy fluvial formation.

In all cores, the oldest unit consists of beach (supratidal) coarse sands and lava pebbles, laying on a pyroclastic cinerite related to the Vesuvius proto-historic activity. The stratigraphic intervals drilled by the S4 borehole form the following sequence (from the top to the bottom): 0.00–4.50 m: anthropic backfill; 4.50–5.90 m: reworked pyroclastics; 5.90–6.20 m: clayey silt with pebble clasts and pumice; 6.20-7.00 m: lithic clasts and pumice in sandy matrix with lava pebbles; 7.00–7.70 m: reworked deposits of 79 AD eruption; 7.70-8.60 m: ash flow deposits of 79 AD eruption; 8.60–11.20 m: white to gray pomiceous lapilli of 79 AD eruption; 11.20–12.20 m: clayey and sandy silt; 12.20–13.60 m: medium to coarse sand with lateritic fragments; 13.60–16.50 m: very poorly sorted lithic clasts and pumice in sandy matrix with lava pebbles; 16.50–20.00 m: blackish sand with gravel; 20.00–23.50 m: ash layers with interbedded palaeosols.

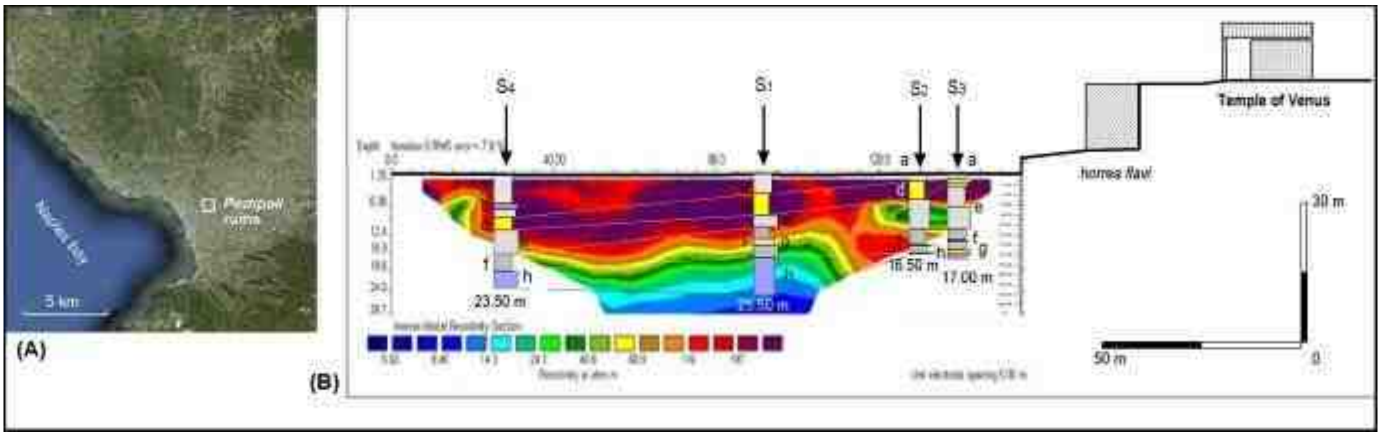

Fig. 1 – (A) Location of the study-area and (B) log-correlation in the frame of the resistivity section (after BENEDUCE *et alii*, 2008). Legend: **a**. anthropic backfill and reworked pyroclastics; **b**. clayey silt with pebble clasts and pumice (low- to mid-energy fluvial environment); **c**. pumice elements in ash matrix (reworked products of 79 AD eruption); **d**. whitish dense-texture pumice with scoriae and lithics and thin ash layers (79 AD eruption); **e**. sand and pebbles with lateritic fragments (high-energy fluvial facies); **f**. black sand with gravels, flat lava pebbles (supralittoral facies); **g**. ash pyroclastics; **h**. proto-historic pyroclastics.

NEW SEDIMENTOLOGICAL DATA

Grain size analyses and morphometric quantitative evaluations have been assessed on 4 gravel-sand, subordinately mud, samples (*S4a-d*) deriving from various stratigraphic core intervals of S4 borehole Sedimentological analyses have been performed on samples from stratigraphic horizons drilled at about 6.00 m, 12.00 m, and deeper than 16.00 m.

Sediments have been properly washed and treated in order to use sieve and densimeter grain size techniques. Roundness has been quantitatively obtained by using the method proposed by WADELL (1932, 1933, 1935).

The results of the Wadell's method applied on 11 pebble-sized samples deriving from the coarsest fraction (Fig. 2) demonstrate as the roundness values oscillates between 0.23 and 0.63 (<1), indicating a very good degree of roundness.

With regard to granulometric analysis, sample *S4b* and *S4d* show the highest mud content, whereas they have a low amount of fine pebbles. On the contrary, sample *S4a* and *S4c* have more pebble-sized elements (Fig. 3), whose diameter ranges between 1 up to 3 cm and whose morphometry lie in the field of the spheroids. All four samples are therefore very poorly sorted.

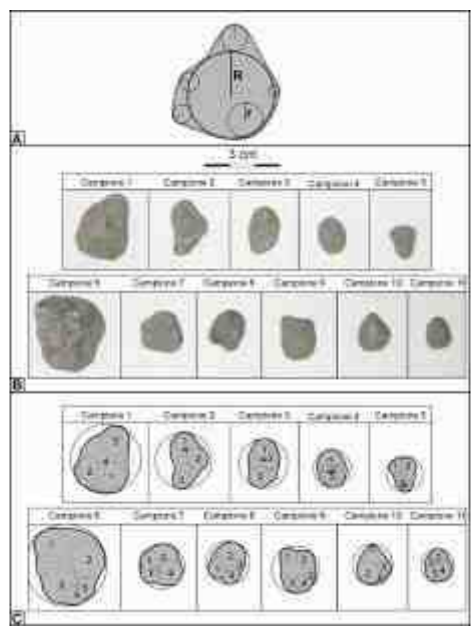

Fig. 2 – Results of the Wadell's method applied on 11 pebble-sized clasts. Legend: (A) Basic method. (B) Samples. (C) Results

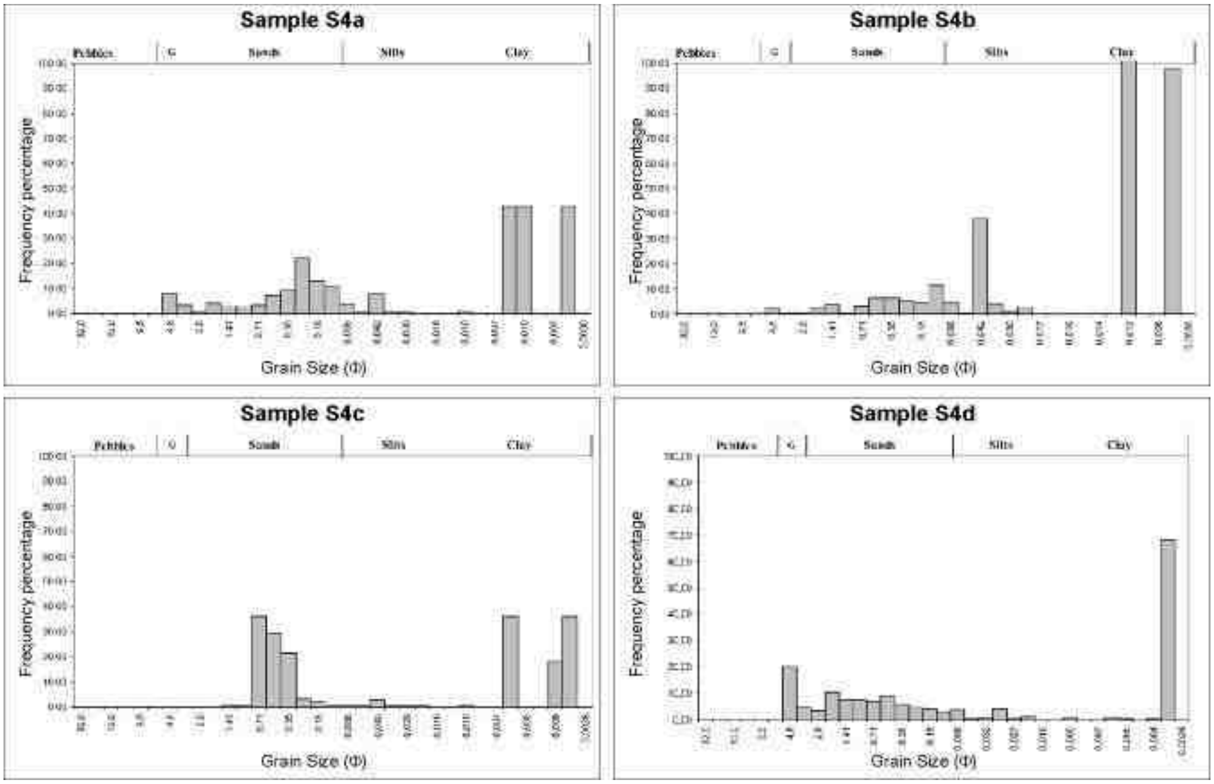

Fig. 3 – Grain size histograms obtained from analyzed samples.

FINAL REMARKS

The sedimentological features of the collected samples analyzed revealed sediments forming very badly sorted assemblages of mud-rich, sand-dominated deposits, containing scattered, very well rounded pebbles up to 3 cm in size. The absence of sorting and the occurrence of scattered pebbles indicate a transport agent represented by currents with changing energy, capable to transport the fine and the coarser fraction during different power stages. Moreover, the roundness and the spherical morphometry of pebble clasts suggest a high amount of sediment transport, which is typical on channel-fill sediments.

Therefore, the key-candidate environment to locate the analyzed deposits is most likely a river channel, where the continuous changes in current competence generated the sedimentary deposits documented in the present study.

A constrained geophysical model of the landslide that affects the Agrigento Cathedral

PATRIZIA CAPIZZI(*), RAFFAELE MARTORANA (*), PAOLO MESSINA (*), & SALVATORE SCHIAVONE (*)

Key words: *Hydrogeological risk. HVSR, electrical resistivity tomography, seismic tomography.*

INTRODUCTION

Geophysical methods can be an useful tool for the characterization of landslides in order to define boundaries and lithological features (BOGOSLOVSKY & OGILVY, 1977; COSENTINO *et alii*, 2003). Among these methods, seismic and electrical ones are the most widely used (GÖKTÜRKLER *et alii*, 2008), as they allow to measure compression and shear wave velocity and electrical resistivity. These physical parameters are essential to estimate the mechanical and hydrogeological properties of landsliding materials (Donohue *et alii*, 2012).

The uncertainty of interpretative models obtained by geophysical methods is mainly due to the amount of available experimental data against the number of parameters used to describe the system, to the simplified geometry of the reference models and to the mathematical approximations to solve the forward and inverse problem. Integrating independent geophysical methods, however, allows to apply constraints to the inverse problem and to limit the uncertainty of the interpretative model, to obtain a detailed reconstruction of geometrical pattern of the properties investigated. However, a proper calibration of the inversion still requires direct data, such as borehole lithologies.

A geophysical survey carried out with several prospecting methods has allowed the evaluation of the limits of interpretation of each methodology and the optimization of the synthesis models.

As part of studies of the landslide in the hill of Agrigento, which involves the St. Gerland Cathedral, the Regional Department of Civil Protection of the Sicilian Region has promoted a series of non-invasive geophysical surveys to increase the knowledge of the lithostratigraphic succession in the subsoil. The overall project involves the execution of geotechnical, geophysical and geostructural measurements to investigate the causes that triggered the landslide that affects the slope on which it is founded the Cathedral of Agrigento (Fig. 1).

Fig. 1 – Immagine del versante settentrionale della cattedrale di Agrigento, dove sono state eseguite le indagini geofisiche.

The aim of the investigations was to provide a highly detailed tridimensional reconstruction of the subsoil, highlighting the stratigraphic succession, the lateral lithological variations, evaluating the mechanical properties of rocks and detecting the presence of cavities.

HISTORICAL OUTLINE

The Cathedral of Agrigento is located on the top of the western part of the hill of Agrigento. It was originally built in 1094 by the Bishop, Gerland of Besançon, cousin of Count Roger the Norman, a few years after the Norman conquest of the city, occurred in 1087. The Latin cross church has a length of about 100 meters and a width of 40 meters. The building was originally dedicated to the Virgin Mary of the Assumption and later consecrated to St. Gerland.

The church was built in six years (1096-1102), but in 1244 it was partially destroyed due to a landslide in the western slope of the hill. Later the Cathedral suffered further damages caused by the earthquake of the Val di Noto in 1693 and by another landslide in 1745. For all the consequent reconstructions and restorations, the Cathedral is now a valuable testimony of different artistic expressions. The original Arab-Norman style is

(*)Dipartimento di Scienza della Terra e del Mare (DiSTeM) – Università degli Studi di Palermo

Lavoro eseguito nell'ambito di una convenzione tra il Dipartimento Regionale della Protezione Civile della Regione Siciliana ed il dipartimento DiSTeM dell'Università degli studi di Palermo con il contributo finanziario del DRPC.

recognized in the transept and in the clock tower, which rises above the chapel of St. Bartholomew. The Gothic-Chiaramonte style can be admired in the first part of the church with its octagonal columns supporting the pointed arches. The architectural theme of the facade and the bell tower is of Renaissance style. Finally the decoration of the chancel and the central section of the church are baroque.

GEOPHYSICAL SURVEYS

Geophysical surveys were focused on the slope in the north side of the Cathedral, in the churchyard and in the nave. In the area of the hill slope four geophysical lines were considered, in which four 2D electrical resistivity tomographies (ERT) and, in correspondence, four seismic refraction tomographies (SRT) were carried out. In the same area a 3D electrical tomography and profiles of HVSR microtremors measures and of MASW surveys have been performed to reconstruct 2D sections of shear wave velocity. The acquired data were used for construction of a 3D geophysical model of the subsoil in the slope area. In the churchyard a 3D electrical tomography was carried out using a U-shaped electrode array, and finally the indoor was investigated by down-hole vertical seismic soundings.

In a preliminary phase SRT, ERT, HVSR and MASW measures data set was processed and inverted independently. The results obtained were compared among themselves and with the available stratigraphic borehole data to define a set of localized lithological boundaries and to use it for subsequent constrained inversions that has allowed to significantly increase the robustness of the geophysical models.

The resulting seismic and electrical tomographies superimposed (Fig. 2) show a good agreement and their integration allows better knowing the complexity of the subsoil.

In fact, the alternations of the biocalcarenite, sands, silt and clay layers are complicated by the presence of dislocated biocalcarenitic blocks, by fractures partially filled with clay or water ,by the evidence of landslides and by the presence of several cavities.

From the interpretation of the geophysical measurements and the integration of borehole data, a 3D model of the subsoil has been sketched for the side of the hill interested by the landslide. This allowed to detect and to map alternations of clay, silt and sand deposits such as biocalcarenite levels and blocks. Surveys performed indoor and in the churchyard allowed to investigate the electrical and mechanical properties of materials involved and the foundations of the church.

Nano-structural analysis of bio-mediated Ca-carbonate in *B. subtilis* cultures

CEFALÀ MASSIMO (*), PERITO BRUNELLA (**) & PERRI EDOARDO (*)

Bio-mediated Calcium carbonate precipitation, a widespread phenomenon among bacteria, has been investigated, using mineralizing *Bacillus subtilis* biofilm cultures, due to its wide range of scientific and technological implications in the biomimetic, materials science, and in the field of bioremediation. In particular, bacterial Calcium carbonate mineralization has also been proposed as a tool in the conservation of monumental calcareous stones.

The mineral precipitates obtained in the cultures, were observed with both the Environmental Scanning Electron Microscope -in atmospheric pressure- on untreated samples, and the Scanning Electron Microscope -in high vacuum- on dehydrated metal-coated samples.

Precipitates, which nucleate apparently randomly along the biofilm, appear in spots less than < 1mm in diameter showing a sub-circular, rarely broadly hexagonal section, with well-defined boundaries. They show radial-oriented more or less elongated crests and are crossed by planar and parallel growth surfaces, less than 1 micron spaced, that can crosscut the whole mineral body.

The precipitation of mineral is very active along the lateral surfaces of the mineral units in contact with the biofilm; on the contrary, biofilm-free surfaces do not show active precipitation. The mineral nucleates firstly around the bacterial bodies, forming a sort of envelope or sheath that reproduces the bacterial shape. The wall of the sheaths shows a thickness of 150-300 nm and their length is consistent with the bacterial bodies, 1-2 microns. Closer observations reveal that nucleation takes place on the outer part of the cell wall. The nano-structure of these mineral sheaths is constituted of coalescing mineral units 100-200 (mesocrystals) nm in size, that show an irregular shape giving to the precipitates a characteristic granular surface. Sheaths form firstly separately, if there is enough spaces among bacterial bodies, but, are later laterally connected through the precipitation of mineral in the interspace of the sheaths. This space is generally of few microns and occupied by extra cellular polymeric substance. Mineral precipitates that form in these interspaces are constituted of the same mesocrystals that compose the sheath, showing the same granular aspect of the surfaces. However, their coalescence originate sub-micron in size polyhedrons.

Not all the external surfaces of the precipitates show the previous described granular texture, as both bacterial sheaths and polyhedrons occasionally present planar and regular smoothed surfaces. These surfaces reminding a crystal face, but with an irregular profile, often dendritic, due to the intersection with the granular surfaces themselves, and with few defects represented by occasional holes. Moreover, planar surfaces of separated precipitates seem sub-parallel. In few cases two surfaces intersect forming a linear edge in a single polyhedron.

Polyhedrons grow reaching larger dimensions (microcrystals), up to 4-5 microns, before their complete junction with the adjacent ones. Polyhedrons develop incorporate the bacterial mineral sheaths, as the latter after formed do not show any increasing of dimension.

Finally, the preliminary results of this this study suggest that:

- Mineral precipitates result from the enveloping of the microcrystals, implying their polycrystalline nature. However, the microcrystal enveloping seems to takes places in optical continuity as the iso-orientation of the polyhedrons and the crosscutting of the whole body by the growth-surfaces;
- the mineral precipitates in *B. subtilis* cultures show a nanostructure comparable with many others microbial-mediated carbonates that form in natural microbial biofilms;
- the nano-particles assemblage is a common pathway of bio-mediated minerals in contrast with the more 'usual' ions assemblage of abiotic minerals;
- the formation of the mineral sheaths around the bacterial bodies and the successive mineralization of the inter-paces among bacteria, previously occupied by the extracellular substances, implies that both the cellular wall with its biochemical functions and the extracellular substances can be involved in the process of mineralization.

Potentialities of spectrometric analysis for the evaluation of pollution impact in deteriorating stone heritage materials

V. COMITE (*), D. BARCA (**), C.M. BELFIORE (*), A. BONAZZA (°),G.M. CRISCI (**), M.F. LA RUSSA (**), A. PEZZINO (*) & C. SABBIONI (°)

Key words: *Black crust, environmental pollution, heavy metals, LA-ICP-MS analysis.*

INTRODUCTION

Black crusts are known to be one of the major damage forms affecting the built heritage in urban areas worldwide.

In particular, when the substrate of monuments and buildings is constituted by carbonatic rocks, its interaction with the atmosphere gives rise to the formation of calcium sulphate, which forms the black crusts (AMOROSO & FASSINA 1983; CAMUFFO *et alii* 1983; BRIMBLECOMBE *et alii* 1989; AUSSET *et alii* 1999). The dark color of these layers is generally related to the presence of carbonaceous particles mostly resulting from the combustion of hydrocarbons.

In this work, an integrated analytical approach has been used, including conventional techniques (optical and scanning electron microscopy and infrared spectroscopic techniques) associated with a recently tested methodological approach for the chemical characterization of black crusts, i.e. laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS).

The study has been carried out on black crust samples taken from the Corner Palace (Venice, Italy), located on the Canal Grande, opposite the Guggenheim Museum. The Palace, dating back to the sixteenth century, was designed for the rich and influential Cornaro family by Jacopo Sansovino, the architect responsible of the renovation of the entire city in that period.

The predominant building material of the Palace is the Istrian stone, a compact ivory limestone coming from an important quarrying area lying in the north-eastern part of Italy, between Trieste and Monfalcone.

Three samples of black crusts were collected at different height on the Palace façade: 1) CV5 at about 25 m from the ground level; 2) CV8 at 15 m; 3) CV12 at 5 m.

Through the utilization of LA-ICPMS (BARCA *et alii* 2010, 2011), the study aims at a dual purpose: (a) to evaluate the degree of contamination of the examined stone (by determining the variability of trace element concentrations from unaltered substrate to black crust), according to climatic conditions, atmospheric pollution and exposure to wash-out; b) to define the outdoor conditions of the examined monument through a geochemical characterization.

RESULTS

Thin-section observations allowed to classify the substrate as a micritic limestone, according to Folk (1959), composed of microcrystalline calcite (crystals size < 4 mm). All analyzed black crusts contain crystals of gypsum along with a calcium oxalate film, as confirmed by FTIR analyses. In fact, infrared spectra of all black crust samples exhibit the characteristic absorption peaks of gypsum and calcium oxalate, together with the stretching vibrations of calcium carbonate, these latter related to the calcareous substrate.

Micromorphological analyses by SEM revealed some differences among the three examined black crusts samples, being CV5 and CV8 constituted by an almost homogeneous single layer, conversely CV12 is characterized by a greater thickness and a multiple stratigraphy composed of four layers (Fig. 1).

Results obtained by LA-ICP-MS analyses highlight a different chemical behavior between the substrate and the black crusts, and also between the different layers observed in the sample CV12. The higher concentrations in the black crusts and, to a lesser extent, on the altered portions of the substrate, of those trace elements which are scarce in the primary stone (As, Co, Cr, Cu, Fe, Mn, Ni, Pb, Sb, Sn, Ti, V and Zn) suggest that the crusts formed on the Corner Palace were greatly influenced by atmospheric inputs and, in particular, by anthropogenic pollution.

The relatively high variability in the composition of the black crusts from different sites of the same monument are due to variable indoor conditions, such as the height of sampling and exposure to atmospheric agents (MARCAZZAN *et alii* 2003; PERRINO *et alii* 2008). It's worth noting that some

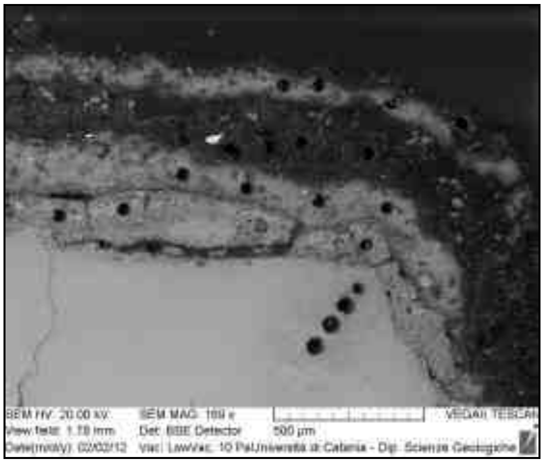

Fig. 1 – BSE–image of CV12 sample. The black crust displays a multiple stratigraphy composed of four layers of degradation. The marks of LA-ICP-MS analyses are visible in the image.

differences are also observed in the heavy metals concentrations of the four layers analysed in the sample CV12. In particular, the innermost layer of black crust, which is at direct contact with the substrate, shows higher concentrations for most of the heavy metals, particularly Pb. This result could be related to the change of fuel used by boats in recent years.

CONCLUSIONS

This work highlights how the application of LA-ICP-MS to the study of black crusts on monuments allows not only to determine the concentration of a high number of trace elements, but also to evaluate the degree of contamination of carbonatic substrates according to the variable climatic conditions and the environmental pollution.

New evidence for sub-geometric ceramics from Baragiano and Torre di Satriano archaeological sites

DE FRANCESCO A.M. (*), SCARPELLI R. (*) & PERRI F. (*)

Key words: *clayey materials, Lucanian area, provenance, sub-geometric ceramics*

INTRODUCTION

"Torre di Satriano" and "Baragiano" indigenous sites are located in the north-western lucanian area. This area evidenced a growing local ceramic production and a homogeneous phenomenon of diffusion of greek pottery, starting from the end of the seventh century B.C., when Metaponto town was instituted.

On the basis of greek sources, the northern lucanian area was occupied by the *Peuketiantes* people, a near ethnos of Enotri people and was characterized by the production of the sub-geometric ceramic (Fig.1), that were widespread among neighboring production centers (OSANNA, 2004).

Technological and provenance information were obtained in the previous work (SCARPELLI *et alii*, 2010). Two groups were identified on the basis of petrographic (OM; optical microscope) and chemical analyses (XRF; X-ray fluorescence): the group 1 is characterized by "more fine" ceramic samples and the group 2 constituted by "less fine" ceramic samples. This difference is mainly observed for Torre di Satriano ceramics samples, that are the wider group.

Mineralogical analyses (Powder X-ray diffraction; PXRD) and SEM (Scanning Electron Microscope) morphological studies suggested firing temperature higher than 850°C, as confirmed by the presence of neoformed mineral phases (gehlenite, hematite and diopside) and the high degree of groundmass vitrification (e.g. MANIATIS & TITE, 1981; CULTRONE *et alii*, 2002).

The comparison with Plio-Plesistocene clayey materials of the northern lucanian basin, suggested the use of local clay with a small depuration treatment and/or aplastic fraction addition for the group 1 ceramics. Conversely, the more fine ceramics of group 2, showing different chemical variations for major and trace elements probably related to both clay levigation processes and use of other fine-grained sediments (e.g. Lower Cretaceous-Miocene terrains), cropping out around the archaeological sites.

REGIONAL GEOLOGY

The southern Apennines is an east-verging accretionary wedge developed in Neogene times above west-dipping subduction of the Apulian-Ionian lithosphere (DOGLIONI *et alii*, 1996). The southern Apennines and northern Calabria are associated with the Tyrrhenian backarc basin and bear today a frontal active accretionary wedge, below sea-level, whereas the main elevated ridge to the west is undergoing uplift and extension. The tectonic style of the area is dominated by a large-scale duplex system, consisting of a complex architecture of tectonic units derived from the internal Apulia carbonate platform, overlain by a rootless thrust sheet derived from the

Fig. 1–Representative photographs of the studied ceramic fragments.

(*) University of Calabria, Department of Earth Science , via Pietro Bucci-87036 Arcavacata (CS), Italy; defrancesco@unical.it

western Adria palaeomargin and distally related oceanic basins (e.g. PATACCA & SCANDONE, 2007 and references therein). According to different palaeogeographic restorations (e.g., PATACCA & SCANDONE, 2007 and many others), the southern Apenninic tectonic units derive from deformation of different palaeogeographic domains, represented, from west to east, by the Liguride-Sicilide Basin (Flysch Domain), the Apennine carbonate platform, the Lagonegro basin and the Apulian carbonate platform (External Domain) (Fig. 2).

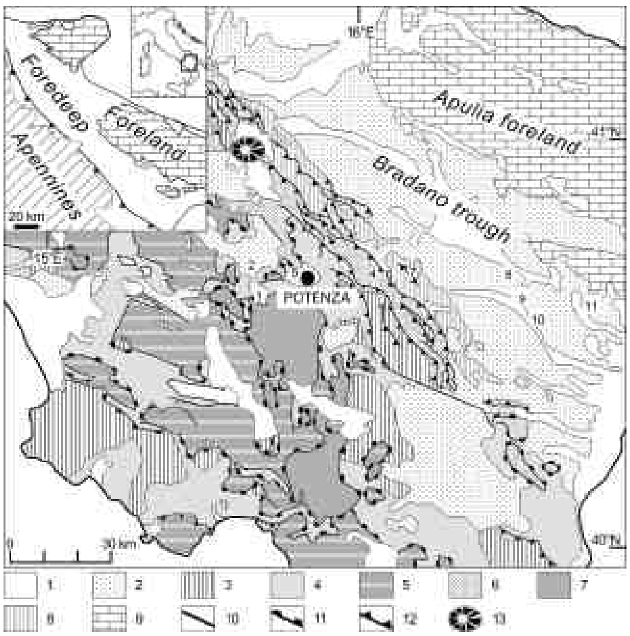

Fig. 2 – Geological sketch map of southern Apennines (modified from PATACCA & SCANDONE, 2007). Tectonic Units - 1: Continental and coastal deposits; volcanic rocks and volcaniclastic deposits (Holocene - middle Pleistocene). 2: middle Pleistocene - Pliocene thrust-top deposits. Terrigenous marine and paralic deposits filling the Bradano trough and unconformable overlying the Apennines Units. 3: Miocene deposits (Gessosso-Solfifera Formation, San Bartolomeo Formation, Gorgoglione Formation, Albidona Formation). 4: North-Calabrian and Sicilide Units (lower Miocene - Cretaceous). 5: Aburno-Cervati, Monti della Maddalena and minor units derived from the Campania-Lucania carbonate platform (lower Miocene - Upper Triassic). 6: Sannio Unit (middle Miocene - Lower Cretaceous). 7: Lagonegro Unit (Lower Cretaceous - Middle Triassic). 8: Tufillo - Serra Palazzo and Daunia Units (upper Miocene - Paleogene). 9: Cretaceous carbonates of the Murge foreland. 10: Faults, including normal faults, lateral ramp and strike-slip faults. 11: Low-angle thrust. 12: High-angle thrust. 13: Vulture Volcano. Source materials (numbers on the map) – 1, Tito clays; 2, Baragiano clays; 3, Varicolored Clays (MONGELLI, 2002) of the Sicilide Unit; 4, Flysch Rosso shales (MONGELLI, 2002) of the Sannio Unit; 5, Potenza clays; 6, Tricarico clays (MAZZOLENI & SUMMA, 1996); 7, Grassano clays (SUMMA et alii, 2010); 8, Timmari clays (DELL'ANNA & LAVIANO, 1991); 9, Miglionico clays(DELL'ANNA & LAVIANO, 1991); 10, Pomarico clays (DELL'ANNA & LAVIANO, 1991); 11, Montescaglioso clays (DELL'ANNA & LAVIANO, 1991).

The Sicilide Unit consists of three major intervals: Lower Varicolored Clay (Cretaceous), Corleto-Perticara Fm (Cretaceous-Miocene) and Upper Varicolored Clay and Tusa Tuffite (Oligocene/Miocene-Burdigalian) (PATACCA & SCANDONE, 2007). The Sicilide Unit tectonically overlies the Alburno-Cervati Unit, the Lagonegro and the Sannio Unit (Fig. 2). The Lagonegro, Sannio and Molise nappes, are here considered derived from a single, wide basin located between the Apenninic Platform and the Apulia Platform. Northwards this deep-marine basin had to be replaced by a system of platforms and basinal tongues (PATACCA & SCANDONE, 2007).

DISCUSSION AND CONCLUDING REMARKS

In this phase, the number of analyzed ceramics have been increased, in particular for the Baragiano area. Successively, the ceramic vessels have been compared with literature data of Plio-Pleistocene (DELL'ANNA & LAVIANO, 1991; MAZZOLENI & SUMMA, 1996; SUMMA *et alii*, 2010) and Meso-Cenozoic (MONGELLI, 2002) clayey materials from different sources in the lucanian area.

The comparison was performed by statistical treatment (PCA; Principal Component Analysis).Figure 3 shows the first two PCs calculated using selected major elements.

The elements with high variability can be grouped on the basis of their directions (SiO_2; $Fe_2O_3+TiO_2+Al_2O_3$; $CaO+MgO+K_2O$). The Torre di Satriano ceramics are well separated in two groups. The first group shows more affinities with clayey materials

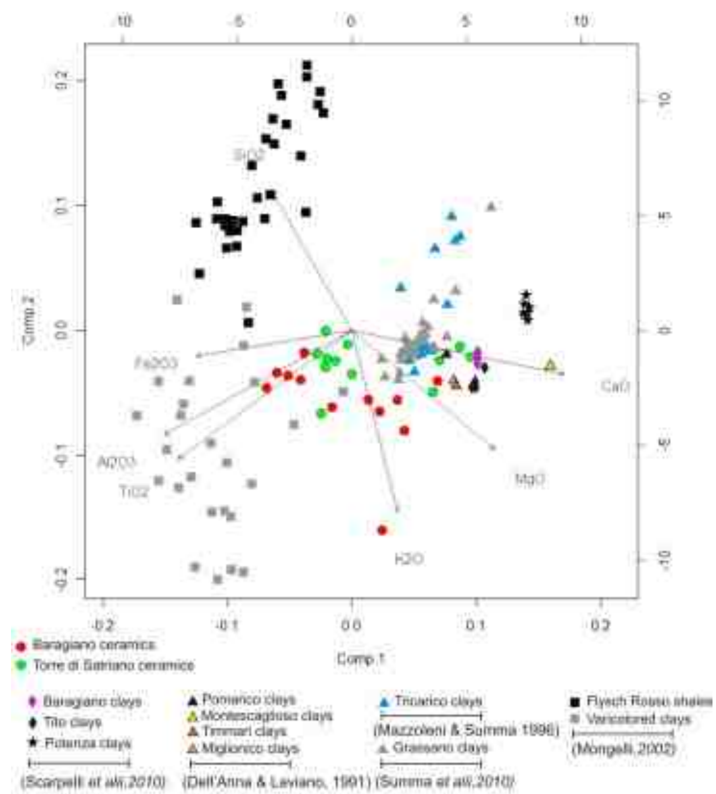

Fig. 3 – Principal Component Analysis (PCA) of the studied ceramic samples and the source materials.

sampled near Tito and Baragiano, confirming the previous observations (SCARPELLI *et alii*, 2010). Moreover this ceramic group are also comparable with Plio-Pleistocene clays collected around Tricarico (MAZZOLENI & SUMMA, 1996) and Grassano (SUMMA et alii, 2010) village and with Plio-Pleistocene clays collected along the Bradano trough (Timmari clay, Miglionico clay and Pomarico clay; DELL'ANNA & LAVIANO, 1991) (see Fig. 2). The clay samples collected around Potenza and Montescaglioso (along the eastern Bradano trough; Fig. 2) are outliers since they are enriched in CaO (Fig. 3).

The second group seems to show affinities with Meso-Cenozoic sediments (Fig. 3). Among these, the Varicolored Clays (MONGELLI, 2002) of the Sicilide Unit (see Fig. 2) are the source materials characterized by Fe_2O_3+TiO_2+Al_2O_3 contents close to those of the second group ceramic samples (Fig. 3). Furthermore the new analysed Baragiano ceramics highlight a greater chemical variability and highest similarity to the ceramic samples of the group 2.

This work shows the first evidence of chemical compatibility between the studied ceramic samples and source materials of various age (Meso-cenozoic sediments and Plio-Pleistocene clays), and provides new hints for further investigation.

The Roman mortars of the *archeological site of Hierapolis* (Turkey): petrographic- mineralogical and chemical characterization

R. DE LUCA (*), D. MIRIELLO (*), G.M. CRISCI (*), A. BLOISE (*), C. APOLLARO (*) & F. D'ANDRIA (**)

Key words: *Hierapolis, mortars, plasters, Roman technology, petrographic-mineralogical and chemical characterization, image analysis.*

ABSTRACT

This work presents the preliminary results concerning the characterization of Roman mortars and plasters from the archaeological site of Hierapolis, an ancient Greco-Roman city in south-west of Turkey.

This site, protected by UNESCO, nowadays is located in the village of Pamukkale (province of Denizli) famous for its hot springs that give rise to massive travertine terraces.

The 21 samples studied, taken from the excavation campaign of 2010 in the Italian Archaeological Mission at Hierapolis in Phrygia directed by F. D'Andria, come from different areas of the site: the door of Frontinus, the Temple of Apollo, the Stoa of the Basilica, the Aghyasma, the Nymphaeum of the Tritons and the Sanctuary of the Nymphs.

Their characterization took place through different analytical techniques such as: optical microscopy in polarized light, X-ray diffractometry (XRPD), X-ray fluorescence (XRF) and thermal analysis DSC-TG. These techniques, in first analysis, have determined the mineralogical, petrographical and chemical properties of samples, allowing a compositional comparison among them.

On the samples was carried out, also, a detailed image analysis in thin section through the use of the software *JMicro Vision*, this analysis allowed us to determine the exact percentage of aggregate and binder used in the mortars and to study some textural characteristics such as macroporosity.

The compositional comparison shows significant differences between groups of mortars and plasters of the same period. In particular it is possible to divide the samples into two different groups according to the percentages of aggregate and binder. Among these samples, it is also possible, to make a further subdivision considering the samples containing *cocciopesto*, a material used by the Romans as a pozzolanic additive to create hydraulic mortars. In the aggregate, there is also the abundant presence of metamorphic rocks (marble, phyllite and quartzite) and bioclasts.

The purpose of this paper is to provide more information about the production technology of the Romans. It represents the first phase of study necessary to guide subsequent spectroscopic analysis and to obtain more detailed information on the origin of the raw materials used in the mixtures.

Fig. 1 – Hiérapolis – Ruins of the archaeological site of Hierapolis in the concretions of travertine (Pamukkale).

FIGURES

The site overlooks the valley of the river Lykos (the Cürüksu), a tributary of the Meander . To the archaeological site is added the particularity of white travertine waterfalls formed by the calcareous deposits of thermal waters, which gave the name to the turkish site "Pamukkale" which means "cotton of castle".

Technological and geochemical study of historical mortars from the Roman "Villa dei Quintili" (Rome, Italy)

GIUSJ V. FICHERA (*), DONATELLA BARCA (**), CRISTINA M. BELFIORE (*), MAURO F. LA RUSSA (**) & ANTONINO PEZZINO (*)

Key words: *Historical mortars, pozzolana, SEM-EDS, LA-ICP-MS.*

ABSTRACT

This contribution is concerned with the study of historical mortars from the Roman archaeological site "Villa dei Quintili" (Rome, Italy). The monumental complex, dating back to the 2nd century A.D., owes its construction to the brothers Sextus Quintilius Condianus and Sextus Quintilius Valerius Maximus, in 151 A.D. The villa was used as imperial residence until the 6th century (PARIS 2002), after that, it gradually decayed and in 1986 became property of the State.

The monumental villa consists of several edifices showing building techniques that can be referred to different construction phases. It is worth noting that near the *Tepidarium*, one of the thermal areas, a limekiln was discovered, which was probably in use until the Renaissance.

The study regarded forty-six mortar samples, collected from different edifices within the monumental complex, i.e. the thermal area (*Calidarium* and *Frigidarium*), the *Viridarium*, the Nymphaeum and some residential areas.

A multianalytical approach has been used in order to completely characterize the samples. Specifically, polarizing optical microscopy observations, along with morphological and microchemical analyses by SEM-EDS were carried out to investigate some specific technological aspects of the examined mortars, such as the composition and texture of binder and aggregate and the ratio between the two components. Punctual analyses of both binder (lumps) and aggregate were also performed through LA-ICP-MS to determine the concentration of trace elements and gain information about the provenance area of raw materials.

The petrographic analysis of mortars permitted to distinguish two types of mortars on the basis of texture and compactness of binder and the ratio binder/aggregate (Fig. 1). Such different features seem to correspond to two diverse historical periods and two different construction phases, as supposed by archaeologists.

SEM-EDS analyses of lumps revealed that aerial lime was used for the preparation of all examined mortars, except for five samples that resulted to be feebly-hydraulic. Therefore, the high idraulic index (0.30 to 2.90), which characterizes the binder of all samples, indicates that the hydraulicity of mortars was obtained through the addition of *pozzolana*. In fact, compositional profiles performed at the rims binder/aggregate revealed a deep

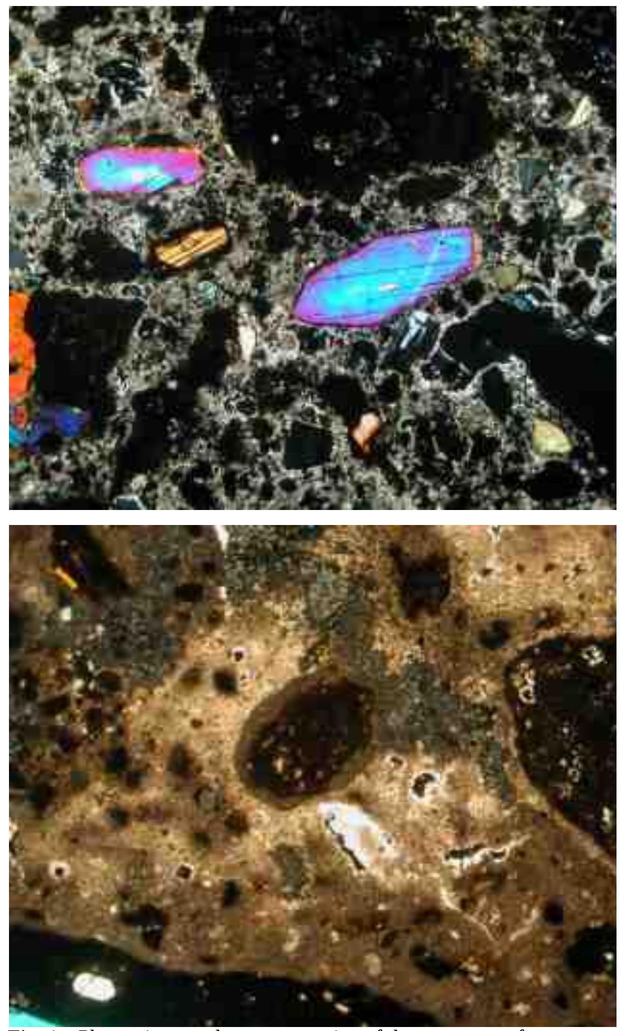

Fig. 1 – Photomicrographs representative of the two types of mortars.

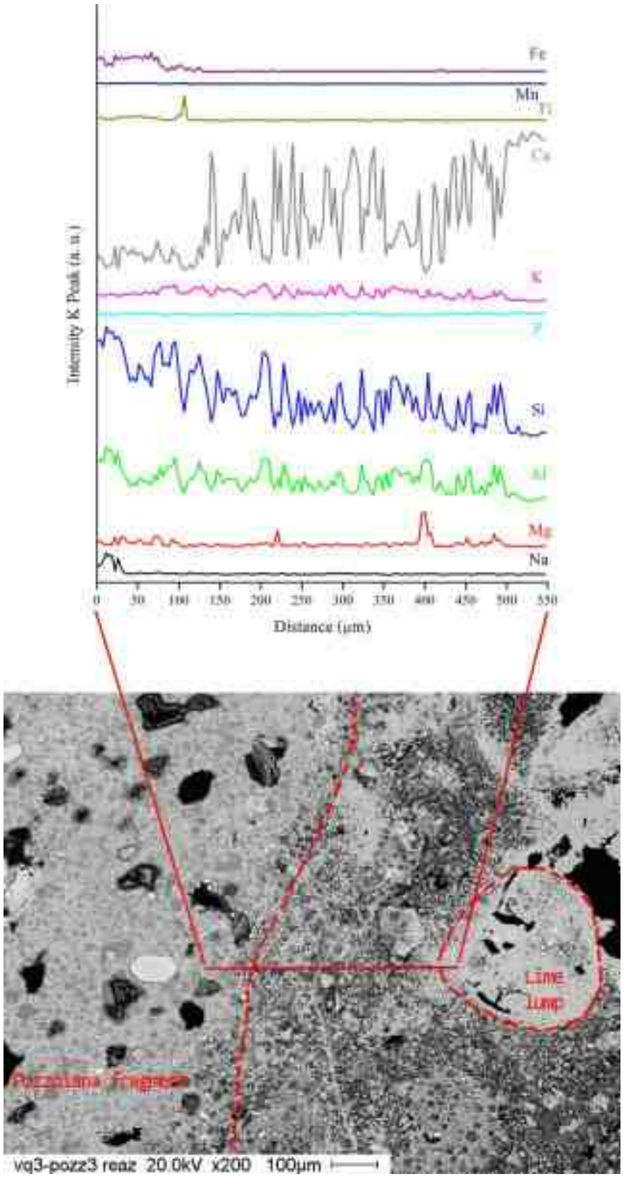

Fig. 2 – A SEM-EDS compositional profile of a reaction rim around a pozzolana fragment.

transformation of the binder (Fig. 2).

With the aim of identifying the source area of the raw materials used, results obtained from microchemical analyses of the volcanic aggregate have been compared with literature data, thus allowing to better constrain the provenance area (BARONE et alii 2010). These studies refer to major and trace elements of pozzolana samples from the Alban Hills area and clinopyroxenes occurring within volcanic rocks of the Roman magmatic province (e.g. Conticelli et al. 2010; Dallai et al. 2004; Gaeta et al. 2006; Boari et al. 2009).

Finally, the composition (in terms of both major and trace elements) of a fragment of lime found inside the limekiln was compared with that of lumps in the mortar samples.

Key words: *Arkose, calcarenites, dimension stones, Capo d'Orlando Flysch, black crusts, hybrid arenites, petrography, Barcellona Pozzo di Gotto.*

INTRODUCTION

We live immerse in a built environment made of buildings and infrastructures. Improving the built environment, also from an aesthetic point of view, has a positive feedback on the quality of life. In a stagnant economic scenario, the old cities of Italy face the challenge to revitalise their run-down areas with sensible and cost-effective conservation and restoration policies. This study focuses on the natural stones employed as building blocks for portal and window frames that characterise the urban landscape of *Barcellona Pozzo di Gotto* (NE Sicily). The use of basic petrographic observations allows to characterise the rock types employed between the XVI and XIX centuries for the construction of private buildings, to evaluate their decay degree and to propose a cost-effective restoration strategy based on the use of local stones, easy to found and, hopefully, with reasonable purchase and transportation costs.

SAMPLING STRATEGY

This study implied three levels of investigation: (1) field observations (2) petrographic work by optical and electronic microscopy and (3) comparison of the data with the newly available geological maps and with the oral tradition acquired from local sculptors such as Salvatore De Pasquale and Mario Affannato.

A short list of 18 sites has been prepared from the data set of architectonic elements considered as historical and architectonical heritage in the *Barcellona Pozzo di Gotto* City Plan approved in 2002. The criteria used in the short list have been the following: stone typology (preliminarily differentiated on the basis of colour and presence/absence of macrofossils), age of construction, urban/rural environment, building orientation and lack of any restoration work. The latter condition was set in order to study the stone deterioration resulted from the interaction between stone surfaces and the environment. We have thus identified 3 groups of stones: (a) white-grey to yellow fossiliferous sandstones; (b) non fossiliferous grey, yellow and beige sandstones and (c) grey to yellow microconglomerates. In addition, erosion and black crusts with variable appearance have been identified as the main forms of stone decay.

RESULTS

Petrography

The fossiliferous sandstones were sampled from one pilaster and some portals. The compositional and textural characteristics of at least one thin section from each sample were determined using a polarizing microscope and by point-counting. The modal composition varies from hybrid arenites to biocalcarenites. In detail, the hydrid arenites show alternating carbonatic (mostly bioclasts) and siliciclastic domains, the latter containing also abundant opaque minerals (up to 13 vol%). Hybrid arenites have primary porosity that ranges between 5 and 14%, and cementation degree varies from 54 to 89%. Two types of cements occur, (i) fine-grained pore-lining calcite coating the framework grains and (ii) coarser pore-filling calcite.

Three non-fossiliferous lithotypes, a gray sandstone and two yellow to gray microconglomerates, were sampled from some pilasters and one window frame. They are arkoses and show a clast-supported fabric with framework grains comprising subangular to subrounded quartz and feldspars, micas (muscovite, biotite), and metamorphic rock fragments. The latter clearly shows a gneissose texture defined by mica-rich films alternating with quartz-rich microlithons. The matrix is scarce (modal abundance < 6 %). Porosity, is both primary and secondary, it is very low for the microconglomerate (1%) compared to the sandstones (5 %). The cementation degree varies as a function of lithotype, with the gray sandstone being less well cemented than the microconglomerate (67% vs. > 90%, respectively).

Diagnosis of stone decay

The decay has been described according to the Italian standard procedure UNI 11182 (2006). The detailed description of the decay features observed on the 18 sites from Barcellona Pozzo

(*) Dipartimento di Scienze della Terra e Geologico – Ambientali, University of Bologna (Italy)

maura.fugazzotto@gmail.com; r.braga@unibo.it

di Gotto is available in Fugazzotto (2012). On summary, the alteration features can be divided into four groups: (1) stone decay induced by material loss (e.g., erosion), (2) discoloration, (3) biocolonization and (4) gypsum-rich black crusts. Gypsum-rich crusts are visible on all the studied typologies of rock and they show different morphologies according to the composition of the stone. On the arkoses, the gypsum-rich crust is thin, superficial and partially detached from the stone substrate. It falls spontaneously and can be easily sampled with a scalpel. On hybrid arenites/calcarenites the crust is coherent, compact and perfectly adherent to the stone substrate. As a matter of fact, to sample this type of crust it is also necessary to sample a part of the stone substrate.
The laboratory analysis through the scanning electron microscope (SEM) with energy-dispersive X-ray spectroscope (EDS) shows that both types of crusts have similar chemical composition. Both are composed of aggregates of gypsum that incorporate particles ranging in size between 10 and 30 µm. Al and Si, with minor Fe, Mg and K, dominate the composition of these particles. Euhedral crystals of halite, likely derived from sea spray, are locally observed. SEM images reveal different morphology between the two crust types. The black crust occurring on the arkoses consists of particulate dispersed over a gypsum matrix; the crust on the fossiliferous stones is characterized by a fine-grained aggregate of well-developed gypsum lamellae.
Optical microscopy using ultraviolet light (fluorescence microscope) shows only one case of surface fluorescence on a hybrid arenite. The blue-green fluorescence is not very intense and suggests the presence of biological-derived products. SEM images indicate that the surface is characterized by the occurrence of Ca-rich filaments, possibly calcium oxalates.

DISCUSSION AND FINAL REMARKS

The petrographic study indicates that most of the dimension stones used for portals and window frames of private buildings belong to two distinct rock types: arkose and hybrid arenites (± biocalcarenites). The comparison between the arkose and literature data show that the composition of the former agrees with the composition of the *Flysch di Capo d'Orlando* formation.
The provenance of the hybrid arenites is more difficult to asses. The available modal data on the widespread *Calcarenite di Floresta*, white-greyish biocalcarenites of lower to mid-Miocene age, differ from the composition of the fossiliferous dimension stones sampled from Barcellona Pozzo di Gotto and surrounding areas.
The careful examination of the new Italian geological map, sheets 587-600 Milazzo-Barcellona Pozzo di Gotto - scale 1:50000 (ISPRA – www.isprambiente.it) shows that the (bio)calcarenites belonging to Plio-Pleistocene *Formazione di Rometta* may represent the rock type quarried to provide part of the dimension stones of the Barcellona Pozzo di Gotto built environment. Our speculation about the provenance of the biocalcarenites used in portals and window frames is also supported by (a) the closeness to the city of the Rometta (bio)calcarenites and (b) the oral tradition by local stonemasons and artists.
The study of the stone decay shows that the most common decay is the erosion, especially on the arkoses. The fossiliferous lithotypes, instead, do not suffer from loss of material but are more susceptible to biological degradation. Gypsum crusts on both stone types embed various types of particulate matter (clay-rich soil dust, carbon). The main difference is the firm attachment of the gypsum-rich crust to the hybrid arenite substrate whereas the thin crusts on the arkoses are easily susceptible to flaking. This different behavior is likely due to the different composition of the substrate. On a whole, the fossiliferous stones used in the masonry of *Barcellona Pozzo di Gotto* show better conservation conditions that the arkoses. The latter need significant restoration work aimed to replace, in many cases, the damaged dimension stones. Our study indicate (1) all the stone types required to implement restoration policies are available nearby *Barcellona Pozzo di Gotto* and (2) fossiliferous stones are to be preferred over the arkoses.

Il ruolo della geologia e la gestione della complessità

CATERINA GATTUSO, BENIAMINO RECCHIA

Le indagini diagnostiche assumono un ruolo di rilievo all'interno di un piano diagnostico poiché permettono di identificare i materiali costitutivi di un manufatto nonché di delinearne lo stato di conservazione. L'acquisizione di conoscenze sui materiali permette inoltre di svolgere studi sulla loro "tracciabilità" in termini dei trattamenti subiti a fini costruttivi. Gli di studi finalizzati alla ricerca della provenienza, permettono inoltre di sviluppare dei protocolli sperimentali utili per fare delle comparazioni finalizzate alla definizione di interventi adeguati e compatibili.

Le indagini diagnostiche per essere ben orientate devono inserirsi in un contesto conoscitivo più ampio che considera i diversi aspetti che caratterizzano il manufatto, quello storico-architettonico, quello geologico e ambientale e quello costruttivo.

Il presente lavoro vuole evidenziare come le sinergie interdisciplinari permettono di comporre e gestire la complessità della conoscenza con particolare riferimento al ruolo che le competenze geologiche svolgono.

Per meglio illustrare la metodologia il lavoro comprende una applicazione con riferimento ad un caso studio rappresentato dal Monastero del Colloreto (CS). Tale applicazione è impostata su un'indagine conoscitiva orientata ad un possibile e successivo intervento di restauro.

Sviluppata la fase di prediagnosi che permette di evidenziare i passaggi storici che hanno determinato le forti trasformazioni del monastero, e quindi di ricostruire il quadro dell'anamnesi viene poi descritto lo stato attuale dell'edificio monastico e del suo contesto, con particolare riferimento agli aspetti geologici.

Sono Stati quindi studiati i materiali lapidei componenti il Monastero: dopo un campionamento effettuato in situ, i campioni sono stati sottoposti a vari tipi di analisi. Dopo il riconoscimento macroscopico e l'analisi della sezione sottile i campioni sono stati sottoposti ad analisi chimiche eseguite attraverso la tecnica della spettrometria per fluorescenza (XRF) e analisi di perdita per calcinazione.

Tutto ciò allo scopo di ricavare una sorta di "atlante" dei materiali componenti il Monastero, realizzato attraverso la redazione di Schede Analitiche che descrivono sinteticamente ogni singolo tipo di campione.

Un ulteriore procedimento analitico ha riguardato l'identificazione di provenienza dei campioni. Con questo procedimento si è provveduto a tracciare un possibile metodo di indagine e a verificarlo effettuando un principio di analisi.

La conoscenza completa e approfondita del manufatto, redatta utilizzando la logica della cartella clinica digitale ha fatto da base per le fasi successive di questo lavoro. In particolare la schedatura dei materiali è molto utile per strutturare la fase di posdiagnosi in previsione di un intervento di restauro, in quanto fornisce le informazioni necessarie sui materiali in modo schematico ed immediato ed in maniera non avulsa dal contesto conoscitivo più completo.

Multi-scale study of the role of the biofilm in the formation of minerals and fabrics in calcareous ambient-water travertine

EDOARDO PERRI (*)

ABSTRACT

Active sites of formation of ambient-water travertine (also known as 'tufa') represent a good opportunity for study the ability of microbial biofilms to mediate the formation of carbonate minerals in continental environments. If the study of this process is fundamental to understand the origin of the travertine deposit itself, a very common building stone, it can also useful in sites where others stone materials are encrusted by this type of deposits. Moreover, some processes of microbial biomineralization can be reproduced in lab and developed under control, for bioremediation purposes.

Three sites of actively-forming tufa, two barrage systems and one terraced slope system, located in northern Calabria (Italy) and in north-east England, have been investigated with the purpose of studying the neo-formed carbonate minerals at the interface with the organic components that compose the associated biofilms. Several depositional facies are distinguished, notably peloidal to aphanitic, laminar and dendrolitic fabrics composed of micrite and microsparite, and isolated botryoids and continuous crusts composed of sparite. All fabrics occurring in all depositional facies are organized into layers with a more or less well-developed seasonal cyclicity.

Low-Mg calcite precipitates more or less constantly during all seasons within the active depositional zone. This extends for a few hundred microns upon the external surface of the deposits, where the biofilm occurs. The latter is composed of a heterogeneous community of green algae, filamentous cyanobacteria and other types of prokaryotes, Actinobacteria and fungi, with a variable amount of extracellular polymeric substances (EPS). Porous micro-columns (50 to 150 μm in size), separated by interstitial spaces, characterize the active depositional zone. Here precipitation always begins with organomineral nanospheres (10 to 20 nm diameter), both along the external surfaces and within internal cavities of the micro-columns, by replacing degraded organic matter, and at point-sites suspended within living cyanobacterial tufts along the external surface of their EPS sheaths, indicating that the biological activities of the biofilm are crucial, with its living organisms and non-living organic matter.

Organomineral nanospheres successively agglutinate to form irregular to rod-shaped crystal aggregates, 100-200 nm in size, that with their further agglutination create two basic types of larger, more ordered, crystal structure: polyhedrons in the range of 1-2 μm, and minute triads of calcite fibres varying in length from ~0.4 (short triads) to ~1 μm (long triads). Basic crystal structures coalesce to form larger crystals (mainly tetrahedrons tens of microns in size) that constitute the micro-columns.

Innovative experimental approaches applied to the study of ceramics from underwater archaeological excavations

PEZZINO A. (*), DE FRANCESCO A. (**), MONTANA G. (°), AZZARO E.M. (°), BELFIORE C.M. (*), FAZIO E. (*), LA RUSSA M.F. (**), POLITO A.M. (°), PUNTURO R. (*), RANDAZZO L. (°)

Keywords: *Underwater archaeological ceramics, degradation of archaeological ceramics, ceramic restoration.*

INTRODUCTION

This contribution is intended to present a biennial research project, funded by the MIUR-PRIN 2009, dealing with innovative experimental approaches applied to the analytical study and the restoration of ceramic finds recovered from underwater archaeological excavations. The project involves three Research Units belonging to the University of Catania, the University of Cosenza and the University of Palermo.

The central assignment of this project comes from the concern that during the last decades only a limited interest was dedicated to the study of degradation processes affecting archaeological ceramic in seawater environment (LEMOINE *et alii* 1981; BÉARAT *et alii* 1992; PRADELL *et alii* 1996). This was likely due to the complicatedness in simulating the processes leading to the compositional and/or physical modification of ceramic artifacts during their marine burial. Alteration and/or degradation of ceramic involve numerous variables which are related to the intrinsic characteristics of the ceramic paste (i.e. packing, size, distribution and composition of the temper grains, composition and texture of clayey groundmass, size distribution of pore spaces, etc.,) as well as to the conditions provided by the aquatic medium (i.e. temperature, pH, Eh, biological activity, salinity, etc.,). It has to be underlined that the current analytical approaches taking significantly into consideration the chemical modifications of the ceramic objects can be mainly addressed to the so called "provenance studies". In fact, the alteration and contamination processes involving archaeological ceramic in burial environment (BUXEDA I GARRIGÓS J. 1999) can seriously interfere with the assignment of the object to a specific production center, issue of decisive importance in the reconstruction of ancient economic history.

In the above descrive framework is positioned the present research project, which is mainly focused on the investigation of chemical, mineralogical, physical and mechanical transformations occurring during the permanence of ceramic in seawater.

The experimental part of the research, currently in progress, is accomplished on a series of ceramic test-pieces (briquettes and cylinders) purposely manufactured in order to reproduce consistent compositional and textural characteristics. Ceramic briquettes were placed in specifically designed and man-made Ertacetal® (acetal copolymer) stamped cover shields, and kept in two open underwater environments correspondingly characterized by monitored oxidizing or reducing conditions (Fig. 1). In contrast, ceramic cylinders were placed in custom-made glass containers partially filled with two different types of bottom sediment, under a continuous seawater flow of around 5 liters per minute (Fig. 2). The main physical-chemical parameters being monitored and controlled as well.

Fig. 1– Ertacetal® cover shields with ceramic briquettes kept in open underwater environment characterized by oxidizing conditions.

(**) Università della Calabria, Dipartimento di Scienze della Terra, Cubo 12 B, Via Pietro Bucci, 87036 Arcavacata di Rende (Cosenza), Italy.

(°) Università di Palermo, Dipartimento di Scienze della Terra e del Mare, Via Archirafi 22, 90123 Palermo, Italy.

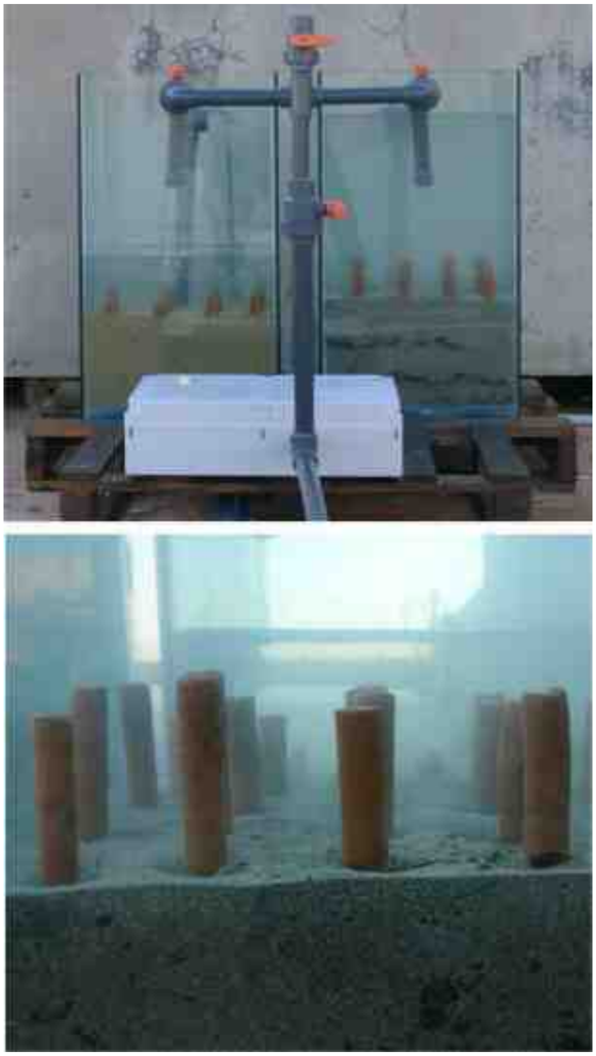

Fig. 2 – Ceramic cylinders placed in custom-made glass containers with two different types of bottom sediment.

Both the above described experimental equipments are hosted at the protected harbor of the Italian CNR-IAMC (National Research Council - Institute for Marine and Coastal Environment) next to Mazara del Vallo, Sicily. A fructuous partnership with researchers and technicians belonging to the above mentioned institution was truly realized. Cylinders and briquettes will be periodically collected within four different steps (3 months, 6 months, 12 months, 18 months) in order to investigate the different forms of alteration and deterioration developed and to quantify the modifications occurred into the designed ceramic pastes under different conditions.

The research project can be schematically shared into different steps. An initial effort has been already dedicated to the upgrading of the scientific literature on the subject. This was considered important for preparing a proper starting point for the experimental part. During the same step a large number of archaeological ceramic samples were collected from the late Roman relict at Cala Tramontana in the island of Pantelleria, under the supervision of the Sicilian Soprintendenza del Mare in order to be fully characterized. During the subsequent phase the already cited ceramic test-pieces (briquettes and cylinders) were produced using well studied Sicilian raw materials (clays and sands with individual mixing and tempering procedures). In particular, two different types of materials, a calcareous clay and a non-calcareous one were mixed with two categories of sand temper, respectively of volcanic and sedimentary nature. The obtained experimental pastes were accordingly fired at different temperatures under oxidizing kiln atmosphere. In the meantime, all the customized experimental facilities have been calculated and realized (Ertacetal® cover shields, glass containers and the whole plumbing system).

The next strictly analytical steps of the research are going to be focused over the revision of the different forms of inorganic alteration/deterioration that likely will develop in the exposed briquettes and cylinders. Biological aspects will be also considered and accurately investigated paying special attention to the subject of biomineralization. The correlation between physical and chemical transformations and compositional or textural features will be carefully examined. The discrepancy of the bulk chemical composition of the ceramic test-pieces before and after the experimental exposure to seawater will be measured. In the cylinder shaped test-pieces the before/after changes in composition will be also appraised between the parts exposed to flowing seawater and the parts placed at various depth in the sediment. Moreover, a quantitative model for calculating the correction factors concerning the most relevant major and/or trace elements will be considered. This latter outcome could be used for comparable authentic case studies (i.e. coastal areas in the Mediterranean Basin), thus arising a satisfactorily level of transferability of knowledge.

Another important issue to be developed within the present research consists in the identification and increase of optimal conservation procedures. In fact, different techniques for the extraction of marine salt from the ceramic body will be comparatively tested and proposed as innovative and more efficient procedures. They are expected to be purposely suitable for laboratory fieldwork during submarine archaeological research and for the preliminary treatments preceding the museum exhibition of the most precious findings. In addition, innovative methods for encrustations removal as well as consolidation and protection treatments for this category of archaeological ceramic finds will be tested.

Characterization of Cappadocian tuff cave churches: preliminary results.

ROVELLA NATALIA (*), LA RUSSA MAURO (*), RUFFOLO SILVESTRO ANTONIO (*), CRISCI GINO MIROCLE (*)

Key words: *Cappadocian tuff, cave churches, stone decay*

INTRODUCTION

The Cappadocia Region, situated in Central Anatolia, Turkey, is an important part of Turkey's heritage, due to its historical past, natural beauty, rock-hewn churches, and unique fairy chimneys. Goreme National Park and the rock sites situated within this region were included in the World Heritage List in 1985 (ERGULER, 2009). The area is encompassed within the Nevsehir plateaux, the central part of the Central Anatolian Volcanic Province (CAVP) (fig.1).

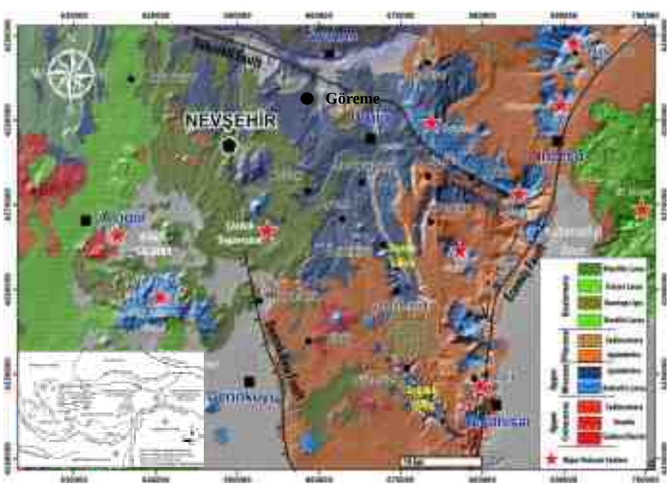

Fig. 1 – Cappadocian geological map (AYDAR *et alii*, 2012)

It is composed by a succession of Neogene dacitic to rhyolitic ignimbrites and fallout deposits interstratified with continental sediments (LE PENNEC *et alii*, 2005) of average age between 14 and 2.7 Ma. The sites of study are Tokali rupestrian church in Göreme Open Air Museum (fig. 2-3) and the Forty Martyrs rupestrian Church in Şahinefendi (fig. 4-5), located at 30 kilometers away from the first one. The present work belongs to a greater research project about cave churchs' conservation coordinated by Prof.ssa Andaloro from Tuscia University (Italy).

Fig. 2 – Kavak's ignimbrite in Goreme site.

Fig. 3 – Tokali's Church in Goreme's Open Air Museum.

Şahinefendi and Göreme locations belong respectively to Cemilkoy and Kavak ignimbrites members of the Ürgüp volcanic formation (Temel *et alii*, 1998). The Cemilkoy ignimbrites has an estimated volume of 300 km^3, an outcrop area of 8600 km^2 with a maximum thickness of 110 m at Cemilkoy village. Besides the age of this volcanic rocks is calculated to 7.6-8.4 Ma, whereas, its source has been located at the south of Derinkuyu. Besides the age of this volcanic rocks is calculated to 7.6-8.4 Ma, whereas, its source has been located at the south of Derinkuyu.

The ignimbrites is made up of nonwelded pyroclastic flow deposits interbedded with lacustrine and fluvial sediments. The Kavak ignimbrites are made up of ash-fall and flow deposits interbedded with volcanic–clastic sediments.

(*) Earth Science Department, University of Calabria, Via Pietro Bucci, cubo 12B, 87036 Arcavacata di Rende (CS), Italy.

This unit covers an area of 2600 km^2, having a volume of 80 km^3; its thickness is between 10 and 150 m. K/Ar dating gives ages of 8.6–11.2 Ma, making it the oldest ignimbrites.

Fig. 4 – Cemilkoy ignimbrite in Sahinefendi site.

The source of this ignimbrite is situated in an area between Nevsehir and Derinkuyu; at Goreme, the Kavak sequence reaches a thickness of 95 m and is composed of four pyroclastic flow deposits (LE PENNEC *et alii*, 1994). From a phisical point of view the Cappadocian tuff may be classified as having poor to very poor durability (TOPAL & DOYURAN, 1998).

Fig. 5 – The Forty Martyrs' Church in Sahinefendi site.

In fact tuff chimneys of rocky churches show clearly erosional and weathering phenomena favoured by rock mineralogy and porosity, lichenic growth, alternating very hot and very cold weather, rain and wind actions causing collapses, deep fractures and exfoliation phenomena. For this reason characterizaction through petrographic, porosimetric analyses, capillarity water absorption test were carried out on geological and mortar samples so that conservatores will be able to understand degradation processes and take up a campaign of effective and lasting conservative intervention.

RESULTS

The petrographic analysis performed at the POM show a porphyritic structure with vitrophiric groundmass. Juvenile fragments identified are: plagioclase, quartz, pumice, shards. On the other side Lithic fragments are composed by lavas, gabbros, metamorphic fragments, quartz, plagioclase, biotite, amphibole, oxides, altered volcanic glass with microliths (fig. 6-7). According to Schmid (1981) classification these ignimbrites are 'vitric tuff'.

Fig. 6 – Geological sample thin section (Plane Polarided Light)

Fig. 6 – Geological sample thin section (Plane Polarided Light)

From petrographic point of view in mortars taken from the church of the Forty Martyrs the binder shows a brownish color and about 20% primary porosity whereas secondary one is less than 10%. In the aggregate plagioclase, glass fragments, pumice, quartz, biotite, iron oxides and lithic fragments are identified. Besides their distribution in binder is quite homogeneous and there isn't any orientation. The binder/aggregate ratio is 70/30 (fig. 8-9).

Fig. 8 – Mortar thin section (Plane Polarized Light).

Fig. 9 – Mortar thin section (Crossed Nicols).

Capillarity water absorption test evaluates the amount of water absorbed by a stone specimen per surface unit (Qi) over time. Qi is defined as: $Qi = (m_t - m_0)/S$, where S is the area of the base of sample, m_t and m_0 are the sample weights measured during the test, respectively, at the time t and the time 0. Inthis on geological samples this test revealed high absorption with Qi growing from 81 to 479 mg/cm2 reaching samples saturation just after 240 hours (fig. 10).

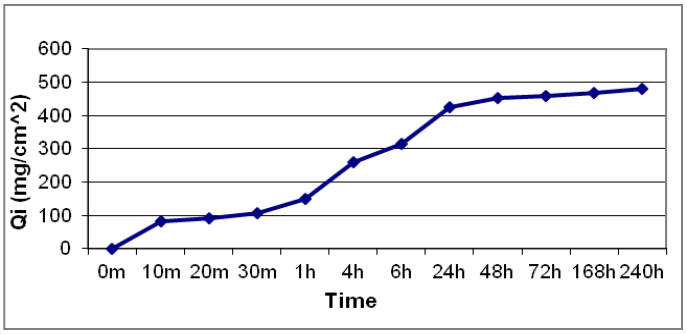

Fig. 10 – Capillary water absorption test.

The porosimetric analyses detected pore size range between 0,006 µm and 20 µm with mean value of 0,06 µm (mesoporosity) and mercury intrusion of 0,55 mL/g/µm defining a porosity of 42%. This high porosity is a very important datum for future restoration interventions.

CONCLUSIONS

The results obtained by this first characterization highlight that alteration and decay processes identified in Cappadocian tuff are tightly linked to phisical properties of the material. In particular there is a correlation between microstructural features of the analyzed samples and decay phenomena observed.

Archaeometric characterisation of votive materials from the sanctuary of Apollo at Pompeii

SCARPELLI R. (*), DE FRANCESCO A.M. (*) & COTTICA D. (**)

Key words: *Archaeometric analysis, Pompeii, votive materials.*

INTRODUCTION

The contribution presents the results of archaeometric analyses performed on votive ceramic samples found near the sanctuary of Apollo at Pompeii (Naples, Italy) during the excavations carried out in 1980-81 at the eastern side of the Forum of the city.

The characterisation of these votive materials is part of a wider project that aims to investigate different ceramic classes from Pompeii, focusing the attention on regional, micro-regional and extra-regional mechanisms of pottery distribution between the IV_{th} century-79 AD.

The preliminary analysis, performed on common ware samples, verified the archaeological hypothesis about the presence of extra-regional productions in the considered period providing information on the complex trade mechanisms in the Bay of Naples (SCARPELLI *et alii*, 2011a; SCARPELLI *et alii*, 2011b).

In this second phase we considered the votive objects, ceramic materials dating to the II_{nd} century B.C. and considered as local production of workshops (not yet identified) for devotees.

The samples belong to different typologies such as *Thymiatheria* (incense burner), terracotta figurines and miniature vessels (Fig.1) that have the function of votive offerings for the divinity.

Most of these are characterised by a similar composition to the common ware production (COTTICA *et alii*., 2010), which is also presented for comparison.

(*)University of Calabria, Department of Earth Science , via Pietro Bucci- 87036 Arcavacata (CS), Italy

(**)Ca 'Foscari University, Department of Classical Studies and Near Eastern Studies, Dorsoduro 3484/D - 30123 Venice, Italy

The petrographic (OM), mineralogical (XRD) and chemical (XRF) analyses aim to verify the homogeneity, for the votive pottery group, concerning the raw materials and the production technology.

Fig. 1 – Miniature vessels samples.

The presence of volcanic inclusions and mineralogical phases of Vesuvian provenance (Fig.2), confirms the local production for all samples.

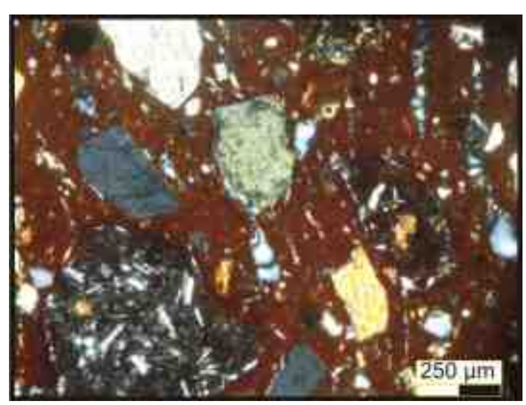

Fig. 2- Microphotograph of a representative terracotta figurine

In addition the observed variations regarding the petrographic features and the chemical compositions (major and trace elements), could ascertain the presence of more ceramic ateliers specialised in the production of different potteries or, simply, verify the supplying of clayey materials from different sources in the Vesuvian area.

The new finding of a Mycenaean tholos in the alluvial deposits of the Messina coastal plain (north-eastern Sicily): stratigraphic and palaeoenvironmental consequences

ROBERTA SOMMA (*), LAURA BONFIGLIO (**), STEFANIA LANZA (**), GABRIELLA MANGANO (**), ROBERTO MICCICHÈ (°), GABRIELLA PAVIA (°°), GIOVANNI RANDAZZO (**), LUCA SINEO (°), GABRIELLA TIGANO (°°) & GIUSEPPE ZAFFINO (**)

Key words: *archaeology, coastal plain, Holocene, Mycenaean tholos, Strait of Messina.*

During recent decades, the intense research in the field, realized by the Messina Cultural and Environmental Heritage Survey with the collaboration of some researchers of the Messina University, has provided the occasion to integrate archaeological, stratigraphic, and palaeoenvironmental data useful for reconstructing the geological framework of the coastal plain underlying the urban area of Messina and of its natural seaport.

A close correlation between the evolution of the Messina coastal plain and the distribution of the archaeological sites is evident on examining the stratigraphic sections from numerous artificial cuts made for excavations. In fact, several archaeological soils appear intercalated with Holocene siliciclastic sediments (gravels, sands, silts, and clays) in alluvial, deltaic, and/or marsh environments developed along the Messina coastal plain. These deposits resulted mainly from the erosion of the metamorphic basement and the overlying Cenozoic sedimentary cover cropping out on the hills west of the city. The intercalated anthropic layers hold structures and manufactured products of different ages and typology (Neolithic, Bronze, Greek Archaic, Hellenistic, Roman, and Byzantine sites).

A recent excavation undertaken for construction in the southern part of the Messina coastal plain (near the mouth of the Gazzi stream) has highlighted a Mycenaean tholos which can be correlated with the Sicilian Middle Bronze age.

A multidisciplinary research on this monument has begun by the above-mentioned staff mainly to estimate the age and to define the sedimentary environment of the clastic beds hosting this new and important archaeological finding.

The ongoing multidisciplinary research on the Messina tholos is planned in order to study: the archaeological features and the different distribution of the building stones inside the tomb; the petrographic features of the building stones and their provenance areas; the sedimentary features of the clastic deposits hosting the tholos and related environmental conditions; and the palaeobiological characteristics of the human bones found inside the tomb.

These new multidisciplinary data will be fit into the framework of present knowledge of the Messina archaeological levels to establish a better definition of the times and conditions of formation of the Holocene coastal plain on top of which the city of Messina rises. The new and the already known archaeological evidence also demonstrates the existence of non-episodic relationships between the eastern Mediterranean and the north-eastern Sicily from the late Neolithic age onwards.

Ground Penetrating Radar and Geoelectrical Surveys to investigate the Santa Filitica Archaeological Complex (Northern Sardinia)

TESTONE V. (*), LONGO V. (*), ALGERI G. (°), BOTTACCHI M.C. (°) & CAMPO D. (°)

Key words: *Archaeological site, Electrical resistivity tomography, Ground-Penetrating-Radar, Santa Filitica.*

INTRODUCTION

Over the past few decades, the application of non-invasive geophysical techniques for archaeological investigation became an almost usual tool in helping the archaeologists to limit the areas to be excavated, in such a way to reduce the time and cost of archaeological campaigns (DIAMANTI *et alii* 2005; CHIANESE *et alii.*, 2010).

The electrical and electromagnetic methods are widely used to locate and characterize the remains of buried archaeological structures (DE LA VEGA *et alii.*,2005; NEGRI *et alii.*, 2008; PIRO & GABRIELLI, 2009; JOL, 2009).

The performance of these techniques depends on the physical property contrast generated by the buried targets (walls, cavities, buildings etc.), with respect to the surrounding medium.

The case presented here is an example of a multimethod (electrical and electromagnetical) survey on an archaeological site in Northern Sardinia: the monumental complex of Santa Filitica (Fig.1).

The archaeological area of Santa Filitica is located a few meters from the shore, on the coast between Porto Torres and Castelsardo along the SS 200.

S. Filitica is a multistratified settlement, formed by archaeological structures of different historical epochs: the remains of a Roman villa, a settlement to V-VI century A.D. and a Byzantine village (ROVINA, 2003; ROVINA 2008).

The archaeological campaigns have brought to light 14 different spaces of the Roman villa, including a thermal area where block- and mortar-bearing walls and mosaic floors occur.

Regarding the byzantine village, only few quadrangular homes and dry walls still remain.

Based on these archaeological evidences, we decided to investigate, with ground penetrating radar and electrical resistivity surveys, an unexplored area adjacent to the excavations.

The aim of this work was to demonstrate the advantages of combining geophysical methods and their effectiveness to detect, map and characterize different type of buried archaeological structures.

With both techniques have been obtained 2D and 3D high resolution models.

Fig. 1: Aerial photo of Santa Filitica archaeological site.

GROUND PENETRATING RADAR SURVEYS

The electromagnetic surveys were conducted in reflection mode using a monostatic G.P.R. (Ground Penetrating Radar) IDS model "RIS_MF_HiMod", composed of a control unit (DAD Control Unit Fast Wave) working simultaneously with two transmitters (Tx) 200 and 600 MHz and two receivers (Rx).

The acquired data were processed and filtered with: move start time, vertical band pass filter, horizontal band pass filter smoothed gain.

Both parallel and perpendicular 2D-scans were performed, with 0,5 m spacing, in order to build 4 different grids (Fig.2A) from which 2D radar sections and C-scan were extrapolated.

The grids, located in function of the obstacles on the ground, cover a total area of about 900 m^2.

The extremes of the investigated area were spatially located using a GPS "Leica™ Viva".

(°) Centre for GeoTechnologies - Siena University

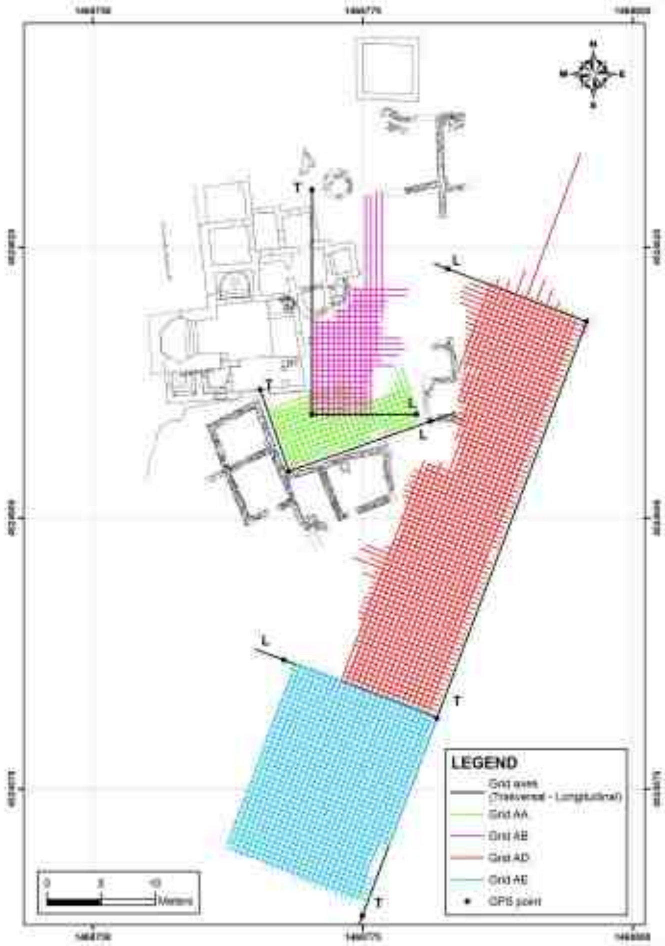

Fig. 2A: Site plan including GPR surveys location. The grids were located in function of the obstacles on the ground such as walls and archaeological structures.

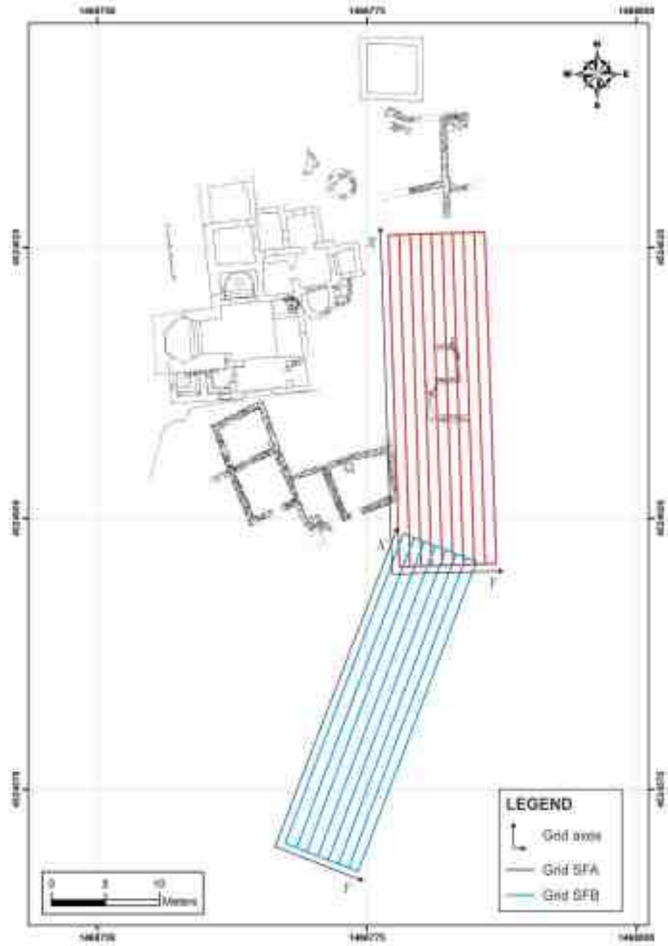

Fig 2B: Site plan including electrical resistivity surveys position. The red lines indicate 2D ERT of SFA grid, while blue lines show 2D ERT of SFB grid.

ELECTRICAL RESISTIVITY SURVEYS

The geo-electric surveying was conducted with a Terrameter SAS 1000 device, a single-channel georesistivimeter developed by ABEM Instruments (Sweden), combined with ES 10-64 electrode selector.

Electrical surveys have covered two rectangular areas to the east (SFA) and south (SFB) of the current limits of excavation (Fig 2B).

The SFA area (measuring 31,5 x 9 m) was investigated by a set of 10 parallel 2D electrical lines, while SFB area (measuring 31,5 x 7 m) was investigated by a set of 8 parallel 2D electrical lines. For both surveys was adopted inter-line spacing of 1 m.

For each 2D electrical lines, 64 metal electrodes were deployed in a straight line with constant spacing of 50 cm and a unit length of 31,5 m.

The measurements were carried out using Dipole-Dipole array, sensitive to horizontal changes in resistivity and thus suitable for detecting vertical structures like walls and cavities.

The data from each 2D survey line was initially inverted independently by the RES2DINV software (Geotomo software) to give 2D cross-sections (LOKE & BARKER, 1996a).

After, the whole data set was combined into a 3D data set and was inverted with RES3DINV software (Geotomo software) to give a horizontal depth slices (LOKE & BARKER, 1996b).

Whereas the 2D calculations were derived from real field data, the 3D data resulted from their interpolation.

Finally, 3D models were obtained through the resistivity values exported and interpolated by the software “RockWorks 2009 (Rockware software)” (Fig. 4).

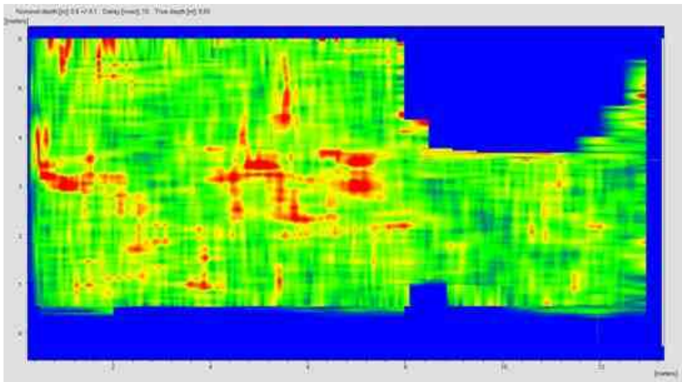

Fig. 3: Radar time-slice showing red reflections correlated to anthropic structures.

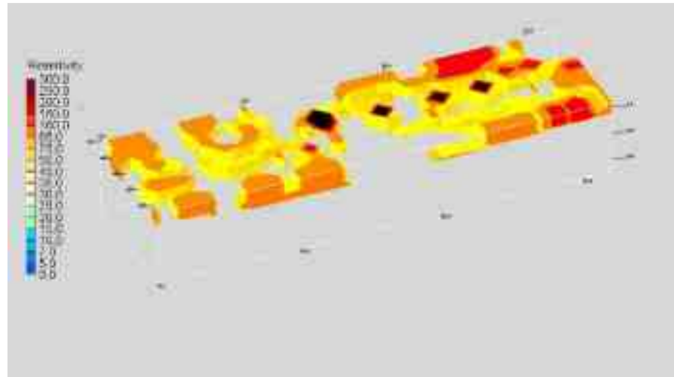

Fig. 4: Resistivity model 3D at 99 Ω·m.

CONCLUSION

The geophysical models show electromagnetic and electrical anomalies related to buried man-made structures in the shallow level of the investigated area (Fig. 3-4).

The layer containing the archaeological targets has a maximum thickness of 3 meters and in the 2D sections of both methods can be distinguished clearly.

Below this level, the saturated soil caused a strong attenuation of the radar signals.

In electromagnetical and electrical horizontal depth slice, rare alignments of walls were found, probably due to multiple collapsed structures and the heterogeneity of the site.

Even if both methodologies can be considered suitable to detect buried archaeological remains, the electrical resistivity tomography (ERT) gives more detail on the size and depth of some targets, such as walls and vertical structures.

In synthesis the combination of information, obtained from the different methods, has proved an useful tool to design future archaeological excavations.

Geo-petrographic and litho-applicative characterization of the Sarnico Stone, Lombard Southern Alps, Italy

GABRIELE VOLA (*), GIOVANNI CAVALLO (°) & GUIDO CORREDIG (°)

Key words: *building materials, Bergamascan Stones trademark, Cretaceous Lombard Flysch, Lombard architecture, Sarnico Sandstone*

GEOLOGICAL PROVENANCE AND TECHNICAL CHARACTERIZATION

The Sarnico Stone is a significant historical-contemporaneous building material and ornamental stone from the Southalpine foothills, between Brianza and Lake Iseo (BERSEZIO et alii, 1990). The main quarrying district is in Sebino area (Sarnico, Gandosso, Villongo, Foresto Sparso, and Paratico), but subordinately was exploited in several localities of the Province of Bergamo (Mapello and Brusaporto), and in Brianza (Oggiono). The use in the traditional architecture is attested since the XII-XIII century, even if the first use comes back almost to the Lombard period (BALZARINI et alii, 2001; BIGIOGGERO et alii, 1998; BUGINI et alii, 2004; SOCIETÀ GEOLOGICA ITALIANA, 2002).

The same lithotype, locally denominated *Pietra Cote* in the Seriana Valley (Pradalunga), and *Pietra Molera* in Brianza (Oggiono), was exploited for the production of millstones, and commercialized for many centuries all over the world, as well (COLLECTIVE, 2003a; VALOTI, 2010).

The "Sarnico Sandstone", Coniacian Age (ca. 88-85 Ma), was formalized in the geological literature by VENZO (1954), and reported in the geological map of Bergamo at the scale 1:100,000. Recently, the same lithological unit was reported in different geological maps at the scale 1:50,000 (BERSEZIO et alii, 1990; JADOUL et alii, 2002; BERSEZIO et alii, 2010; BINI et alii 2011; CASSINIS et alii, 2011; GAETANI et alii, 2010).

As far as the Sebino quarrying district, two ancient quarries are still active in Paratico, Brescia, and a new one, recently opened in Gandosso, Bergamo (REGIONE LOMBARDIA, 2008).

(*) Dimension Stone Consultant, Bergamo, Italy, gabriele.vola@gmail.com
(°) SUPSI-DACD-IMC, Canobbio, Canton Ticino, Switzerland

Authors acknowledgment to Mr. Bresciani, Pietra di Sarnico Orobica S.r.l.

Nowadays, the production is mainly represented (ca. 80-90%) by the traditional Sarnico Stone, a fine-grained bluish-grey coloured lithoarenite. The remaining part corresponds to the so-called "old-looking style" commercial type, which is pale yellowish brown in colour due to the presence of chromatic alterations *in situ* (CAVALLO et alii, in progress). Both types periodically present medium-grained siliciclastic textures, as well (Figure 1a,b,c).

As far as mineralogical-petrographic analyses on samples from the active quarry in Gandosso, Bergamo (VOLA, 2011), and the dismissed quarries in Oggiono, Lecco (CAVALLO & CORREDIG, 2011), show the prevalence of medium to fine and very fine-grained feldspatic lithoarenites, passing to lithic arenites. The composition of clasts includes sedimentary rocks fragments (dense flint, siltstones, sparite, and dolomite), metamorphic ones (slates, weathered phyllades, and micaschists), and, finally, isolated minerals, such as feldspars (plagioclase prevailing on microcline), detritic muscovite, altered chlorite of chamosite type, pyrite, and zircon, as already reported by previous Authors (FERNANDEZ, 1963; FORNACIARI, 1989) (Figure 1d,e).

Physico-mechanical analyses and technological tests on samples from the new quarry in Gandosso, Bergamo, were carried out in conformity with harmonized standards (see Table 1). As far as the compressive strength (Rm = 166 MPa, under ambient conditions) curiously increases after freezing-thawing cycles (Rm = 204 MPa). Flexural strength under concentrated load after freezing-thawing cycles (R_{tfm} = 16 MPa) attests suitability for slabs production and use in external environments. Water absorption coefficient, thermal expansion, and abrasion resistance are comparable with those of other sandstones on the market. Frost resistance and high durability have been demonstrated in external applications, mainly floorings for pedestrian walks, and claddings. Nowadays it can be satisfactory used for different applications, including replacement in historical buildings if strictly required, and new constructions in ancient or rustic backgrounds. The mineralogical composition, and technical properties guarantee a good workability, so that the creation of different superficial and decorative finishing is facilitated. Recently, experimental large polished tiles have been produced for internal flooring, as well.

ARCHITECTONICAL USES

The use of Sarnico Sandstone is widespread in many monuments and historical buildings. The oldest evidences are not limited to Bergamo area, such as the 12th century cinerary urn in the church annexed to the Cluniacensian monastery of Sarnico, but also in Brianza as the facades of the 12th century San Giovanni Baptistery in Oggiono, Lecco (FIGUS, 2011) and in Tessin canton, southern Switzerland, even if for the Swiss monuments, and in particular the Romanseque bell tower annexed to the Santa Maria del Borgo church in Mendrisio (ZALA, 2010), sandstones belong to the Pontida Flysch Formation. The exploitation of the big quarry in Sarnico started in the 15th century and between the 17th and 19th centuries the production reached the peak (SOCIETÀ GEOLOGICA ITALIANA, 2002). The Sarnico Sandstone was used as building material and for decorative purposes associated with other stones: the columns in the Santo Sepolcro church (1521), those in the courtyard of De Beni Palace (1515) in Bergamo (RODOLICO, 1965). The stone-cutters, locally termed *pica preda*, referred that the *turchina* (turquoise in color) had the best technical properties compared with the analogous Lombard and Tuscan sandstones.

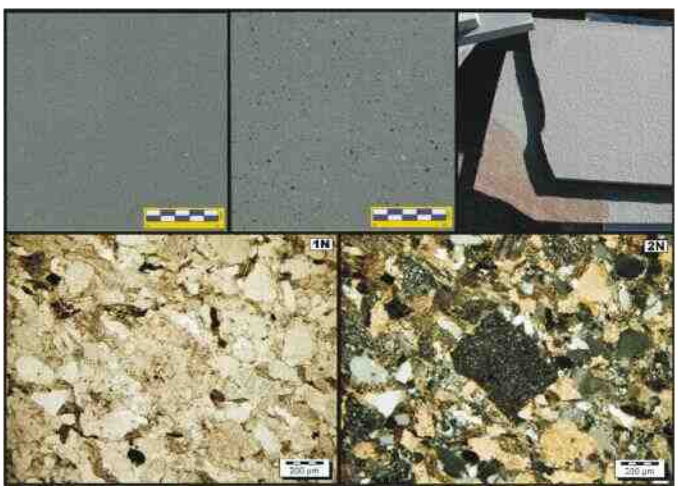

Fig. 1 – Sarnico Stone from the new quarry opened in Gandosso, Bergamo. A: fine-grained type; B: medium-grained type; C: bluish-grey and stained yellowish-brown slabs; D-E: micrographs on thin section (Vola, 2011).

BERGAMASCAN STONES TRADEMARK

The procedure to adhere to the Bergamascan Stones' trademark of origin has been recently undertaken. This specific trademark, created by the Chamber of Commerce of Bergamo, was previously released to other stones of the Province of Bergamo: Arabescato Orobico from Camerata Cornello, Branzi and Valleve porphyroids, Ceppo conglomerates, Credaro and Berbenno stones and, finally, Zandobbio marble (COLLECTIVE, 2012).

This instrument, with a voluntary character, is aimed for the valorisation and promotion of the Bergamo stone products, and includes a study of peculiar geological features, such as the stone's petrographic name and formation it belongs to, the spatial distribution of the deposit, and, finally, the technical characterization of the stone. Considering these facts, the Quality Seal for Bergamo stones represents a premise for material uniqueness evaluation from environmental and geographical point of view, accomplishing also the goal of evidencing properties and applicability in different building contexts. The Bergamascan stones trademark represents an added value compared to a simple, but compulsory, CE marking, which is limited to guaranteeing stone product eligibility for scheduled applications, in accordance with the European guideline CPD-89/106/CEE (MERISIO, 2002; COLLECTIVE, 2003b).

Gypsum outcrops in the Benestare village: a geological, architectural and anthropological treasure of the Locride area (South Calabria).

ANGELA ALFIERI (*), DOMENICO CARRÀ (*), DOMENICO MONTELEONE (*), SALAVATORE NAPOLI (*), TERESA PELLE (*), BARBARA SAMMARTINO(*), ATTILIO VARACALLI (*), EMANUELA ZAPPIA (*)

Key words: *Carcamusa, Locride, Gypsum, Geosite, Messinian, Muratura Formacea, South Calabria.*

INTRODUTION

Gypsum is a sulfate mineral composed of calcium sulfate dihydrate ($CaSO_4·2H_2O$). It is also known as evaporite mineral that forms as an anhydrite hydration product. Gypsum is a common mineral in the Messinian sedimentary sequences in association with Messinian sedimentary rocks.

In the Mediterranean area, the origin of gypsum deposit, is referred principally to the Messinian salinity crisis epoch (RUGGERI *et alii*, 1967) when evaporation, concentrated hypersaline seawater solution in the basin, forming huge thickness of evaporite deposits, that covered the seafloor (GAUTIER *et alii*, 1994).

In Italy the Messinian evaporite deposits, outcrops mainly in the north-central region of the Appennines belt, in Sicily, and in South Calabria, along the ionian coast.

According to CAVAZZA (1997) the Messinian depositional sequence, in south Calabria, is composed of basal marine-transitional pre-evaporitic unit overlay by a coarse-grained alluvial-fan conglomerates unit. The third and most recent unit is composed of thin, shallow-marine-to-continental progradational units that indicates the reestablishment of normal marine conditions at the end of the salinity crisis.

The main target of this study is the understanding of the cultural and environmental relevance of gypsum for the community of Benestare (small village sited in the Locride area in South Calabria) approaching our research by a multidisciplinary method that integrated geological, anthropological, mineralogical and architectonical analyses (ALFIERI *et alii*, 2010).

THE BENESTARE GYPSUM

Location and use of Benestare gypsum

At north west of Benestare Messinian evaporite outcrops extensively on a strip of territory sites and border the eastern side of Monte Verraro. In Timpa and Pignataro localities the gypsum deposit present huge lenth and thickness and is interested by two open-pits (Fig. 1).

For decades, mining of gypsum fueled the development of the community and of the urban nucleus of Benestare. Modern and ancient buildings, small and large houses, are made of gypsum in this village. The villagers named "*vena*" the gypsum outcrops, due to the use of this evaporitic deposits.

In Benestare, mining of gypsum started in the second half of 1800 AD, initially using hand tools and later by modern mechanical equipments supplied by mining companies.

The use of modern technologies and the industrial approach quickly changed the landscape morphology of Benestare, in particular due to the rapid progress of outcrops excavation.

Mineralogical characteristic

Selenite is the most abundant mineral of gypsum that we found in Benestare outcrops. This type of mineral is generally found in various macrocrystalline species. It may be primary, generated by the crystallization of mother liquors, or secondary, generated by the deposition of supersatured solutions into the cavities of rocks. During the growth phase, crystals share the same growth-plane and this lead the crystals to a particular gemination. Gypsum crystals that we sampled in Benestare present two species of germination called *"ferro di lancia"* the first (Fig. 2A) and *"coda di rondine"* the second (Fig. 2B).

Fig 1- Benestare open-pits location in *Timpa* (a) site and *Pignataro* site (b)

Gypsum deposits and depositional environment in Benestare

Messinian Benestare gypsum were deposited in a continental environment when the seawater overflowed into a marginal basin and underwent to an intense evaporation becoming a supersatured solutions in salt minerals. Due to the limited supply of fresh water from inland, the solutions rich in salts, crystallized in a lagoon bed giving rise to evaporate deposits. The cyclic repetition of this process lead to the formation of huge thickness gypsum deposits.

Building constructive character of the Benestare village

Traditional employ of gypsum in the building of Benestare most of all concerns a stonework technique called "*muratura formacea*", created combining fired gypsum dust whit inert material and water. These combined elements were placed into a wood formwork creating a compact core. Already during Roman period this technique was known and used to made stonework in uncooked clay called "*opus caementicium*".

Initially, in Benestare, gypsum was quarry manually in blocks from the mountains by the villagers.

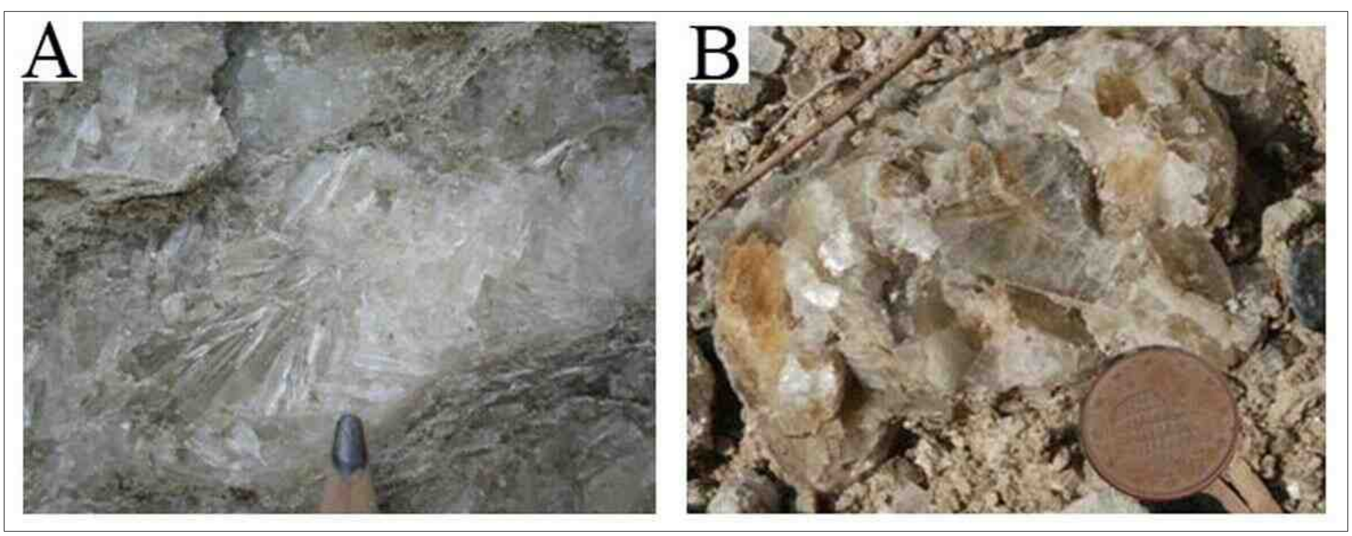

Fig 2 – "*ferro di lancia"* gemination (A); "*coda di rondine"* gemination (B)

After the extraction the blocks were carried into characteristics circular brickwork ovens called "*carcamuse*" (Fig. 3A). Here inside, the master builders of the village, named "*mastri jibbissari*", disposed the blocks in perfect circular order, one upon the others, and cooked gypsum for many hours until it assumed a particularly white color shade. Only at this time gypsum was carried out from *carcamuse* and was ready for the building use.

The most part of the urban set of Benestare is characterized by simple buildings consisting of one or two floors plus a basement called "*basso*" used for storeroom, galley or stable (Fig. 3B).

Usually, the contiguous floors, were connected on the top using wood stairs or stairs built using a stone shell called "gooseneck". The wheelbase between two floors was usually characterized by a wood floor plus canes lathing and gypsum mortar, that acted as fireproof material, between the different architectonic elements.

ABSTRACT

Il presente lavoro nasce con l'obiettivo di valorizzazione alcune peculiarità geologiche del territorio calabrese come patrimonio e risorsa di sviluppo, soprattutto a testimonianza della nostra Geostoria e per un turismo culturale qualificato.

L'area di interesse si sviluppa lungo la rupe su cui sorge il Castello Ruffo di Calabria (Fig.1); la stessa corrisponde allo stretto promontorio allungato in direzione SE - NW e delimitato da due ripide scarpate, disposte ortogonalmente, che emergono dal mare con un dislivello massimo di circa 70 metri. La rupe è collegata alla terraferma ed al centro storico di Scilla solo dal suo lembo meridionale ed il castello dei Ruffo domina le due baie di Marina Grande e Chianalea.

La realizzazione delle infrastrutture viarie e portuali alla base del versante ha artificiosamente separato la falesia dal mare, adducendovi indirettamente un'azione protettiva in quanto la falesia non risulta più soggetta a processi di sottoescavazione, ancora visibili ad esempio in Via Grotte. Tuttavia, l'elevata acclività e la fessurazione dell'ammasso roccioso ha fatto si che quest'area fosse ripetutamente soggetta a fenomeni di crollo, come testimoniano i numerosi dati storici e interventi di sistemazione del versante e del castello.

Il castello di Scilla è ritenuto da molti il più bel castello della Calabria (Fig. 2), non tanto per la struttura in sé quanto per l'importanza storica e soprattutto mitologica, oltre che per la bellezza e la suggestione del luogo. Descritto già nell'Odissea di Omero, fu spesso teatro di numerose dominazioni a causa della sua favorevole posizione, proprio all'ingresso dello Stretto di Messina.Le sue origini sono incerte, secondo alcuni di età sveva per altri di impianto normanno, ma per la sua posizione strategica è verosimile che sia stato fortificato fin dal V secolo a.C.. Sullo sperone roccioso vennero edificati, probabilmente tra il IX e l'XI secolo d.C., il monastero e la chiesa dei padri basiliani, consacrati a S. Pancrazio che, come mostra un'antica pianta topografica, sorgevano all'interno del castello nell'ala occidentale.

Nel 1255, per ordine di Manfredi, Pietro Ruffo fortificò ulteriormente le rocca a cui assegnò un presidio. Nel 1421 un De Nava, cavaliere di Alfonso D'Aragona, prese possesso della Rocca di Scilla trasformando il preesistente convento in castello che con le sue fortificazioni divenne un valido centro di resistenza.

Nel 1533 Paolo Ruffo acquistò dal cognato De Nava il castello, fortificandolo ulteriormente e restaurando anche il palazzo feudale.

Il castello fu danneggiato dal sisma del 1738 e, dopo l'occupazione da parte degli Inglesi e dei Francesi, nel 1860 fu trasformato da Giuseppe Garibaldi in presidio militare. Recentemente è stato restaurato. Un ponte consente l'accesso alla fabbrica, il cui ingresso principale è caratterizzato da un portale in conci di pietra sormontato dallo stemma dei Ruffo e dalla lapide che ricorda il restauro cinquecentesco.

Dotato di prigioni ubicate nella cantina e di sotterranei non più praticabili, il Castello essendo stato dimora di una delle più potenti famiglie del regno possiede ampi saloni che ospitavano collezioni di quadri, argenterie e ori.

Data la posizione dominante del castello sullo Stretto di Messina, nel 1913 venne costruito un faro per fornire un riferimento alle navi che attraversavano lo stretto. Il faro di Scilla, una piccola torre bianca con la base nera, è tuttora attivo ed è gestito dalla Marina Militare.

Le peculiarità geologiche e morfologiche dell'area hanno di fatto favorito lo sviluppo storico e artistico di questo estremo lembo di territorio. Ivi affiora, infatti, un tenace substrato cristallino-metamorfico interessato da un'evoluzione tettonica recente e dal relativo sollevamento polifasico (Catalano et alii, 2003), a cui si devono le elevate energie del rilievo dell'intero settore prospiciente l'attuale linea di costa. Lungo il transetto Gambarie – Scilla (Miyauchi et alii, 1994), sono stati individuati almeno dodici ordini di terrazzi marini, il primo dei quali si

Lavoro eseguito bell'ambito del progetto di "mitigazione del rischio idrogeologico della Rupe di Scilla ".Provincia di Reggio Calabria.

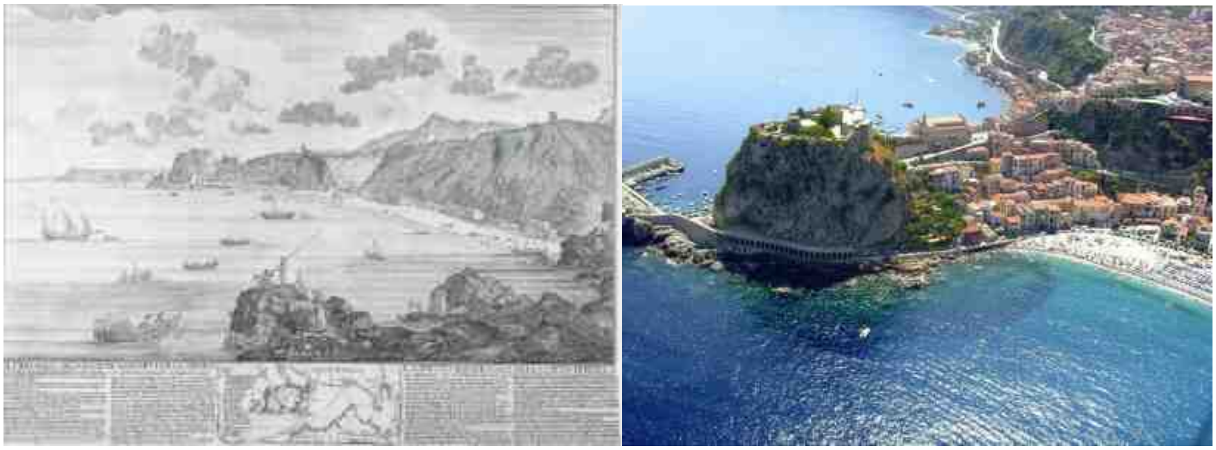

Fig.1-Immagine storica della Rupe di Scilla e del Castello (a) e vista odierna da sud (b).

ritrova attualmente a 1350 m s.l.m., in corrispondenza dei Piani di Aspromonte. Nel tratto costiero in cui ricade l'abitato di Scilla, gli ordini di terrazzi presenti sono: quello di Scilla, a quota 180 m s.l.m. (X° ordine, circa 121±7 con depositi a Strombus bubonius), quello dei Piani di Melia e dei Piani di Tagli-Runci-Solano a quota 600 m s.l.m. (IV° ordine, circa 950 ka con depositi sommitali a Globorotalia truncatulinoides e Hyalinea balthica) e quello dei Piani di S. Anastasio-S. Domenica a quota 750 m s.l.m. (III° ordine). I sistemi di terrazzi più estesi e continui sono ubicati intorno ai 100-200m, a 350 ed oltre i 590m s.l.m..

In particolare, la rupe in studio è caratterizzata dall'affioramento di un complesso di rocce metamorfiche ribassate da una faglia sulla cui sommità si colloca il Castello Ruffo di Calabria. Il complesso è costituito da Scisti e paragneiss biotitici bruno – nerastri (Fig.3), localmente gneissici con vene e filoni di quarzo, pegmatite e granito a grana fine che localmente danno luogo a migmatiti e gneiss granitoidi. I filoni tagliano pervasivamente la roccia con un'orientazione casuale, senza mostrare un andamento prevalente anche se, all'interno di

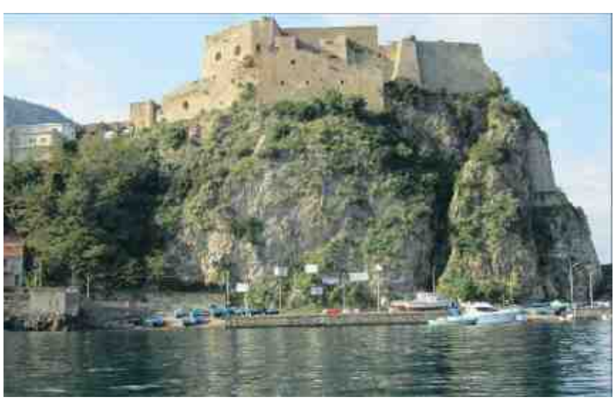

Fig.2-Vista da nord della rupe, del Castello, del barbacane e del quadro geologico.

pegmatiti quarzose, la formazione di macrocristalli di biotite appare iso-orientata a testimonianza di notevoli stress tettottonici coevi all'intrusione filoniana.

I filoni di quarzo a volte presentano degli spessori centimetrici e risultano intrusi nella roccia incassante in maniera conforme all'andamento dei piani di scistosità (Fig.3a). In altri casi, invece, le intrusioni filoniane pur conformi alla scistosità sono state deformate con delle pieghe ad alto angolo, a testimonianza degli intensi stress tettonici cui sono stati soggetti questi litotipi (Fig.3b). In altri casi, invece, gli stress indotti dalle vicissitudini tettoniche dell'area hanno portato alla rottura la roccia lapidea ed alla fagliazione della stessa in più punti con un' immersione verso SE (Fig.2, 3c). Nel corso dei rilievi si è potuto verificare come i piani di faglia identificati siano sempre riempiti da brecce cataclastiche , costituendo di fatto un punto di debolezza strutturale per l'ammasso, in corrispondenza del quale sono stati osservati dei processi di "svuotamento". Altre volte tali brecce sono state permeate da fluidi pegmatitici che si sono mossi attraverso faglie intraformazionale o punti di debolezza strutturale della roccia.

Geodiversity in the Geopark of Cilento and Vallo di Diano as heritage and resource development

ANIELLO ALOIA (*), DOMENICO GUIDA (**) & ALESSIO VALENTE (***)

Key words: *Geodiversity, Geopark, Cilento, Italy.*

INTRODUCTION

In the south of Campania is located one of the largest parks of Italy founded in the 1991. It occupies a territory of over *1800 km²*, which includes the Cilento with its impressive mountain and the striking coastline, and the "Vallo di Diano", a NW-SE directed depression in the Apenninic chain. In detail, its boundaries are represented to the north by the Sele Valley and the relative coastal plain, to the east by the fore-mentioned "Vallo di Diano", in which the Tanagro River flows, to the south by the Lucanian mountains and the Policastro Gulf and to the west by the Tyrrhenian Sea. In the area included within these boundaries can show a great number of geological features with different degree of importance and interest in order to provoke the interest of everybody, not only of geologists. For this reasons, in 2010 the National Park of Cilento and Vallo di Diano became a member of the European Geoparks Network (EGN). The application was also favoured by the presence of other aspects in the park, unique and exceptional, already considered by UNESCO as part of their programs, such as archaeological (Paestum, Velia and Padula), ecological (biodiversity with extreme value species), historical and cultural (e.g. abandoned suburbs of Roscigno Vecchio and S. Severino; Sanctuary of the Madonna of Novi on Gelbison M.). The integration of these issues could lead to strong economic development initiatives, especially in the tourism sector. Through these initiatives the citizens of the park could benefit, some 270.000 inhabitants, that can find ways to revitalize their territory.

WHAT GEODIVERSITY?

The area of the Geopark of Cilento and Vallo di Diano has a geological heritage characterized by a high degree of diversity (SANTANGELO *et alii*, 2005; ALOIA *et alii*, 2011).

(*) National Park of Cilento and Vallo of Diano, Vallo della Lucania (SA) Italy.
(**) University of Salerno, Fisciano (SA), Italy.
(***)University of Sannio, Benevento, Italy.

Such heritage is well preserved both in coastal and in mountain areas. Its geological framework is made up by sedimentary rocks both carbonate and siliciclastic, which have been affected and deformed during several tectonic phases. In consequence of the different response of these rocks to the tectonic and then to the morphogenesis, the landscape shows great variability. More specifically, it consists of steep mountains, often eroded by deep gorge, which can reach rapidly the sea or lower gradually towards relatively wide river valleys, and then the sea. Thus, the coastline is mostly high and rocky, like a cliff, and subordinately close to the mouth of the rivers low and sandy or gravelly, like a beach.

Various categories of geosites were distinguished including the most common ones (stratigraphical, geomorphological, structural, hydrogeological, palaeontological) together with those with particular panoramic (scenic sites) or economic value (ancient mine).

Among those showing a stratigraphical and palaeontological interest, there are some of them useful to reconstruct the geological evolution of the southern Apennines as well as to expand the knowledge of the central Mediterranean region up to Giurassic. For instance, the portion not metamorphosed of the ophiolite-bearing Ligurian unit (North-Calabrian Unit: BONARDI *et alii*, 1988), derived from basinal domains floored by the oceanic crust outcrop in the coastal geosites of Ascea and Acciaroli. The entire sequence, in spite of a strong deformation and a very early metamorphism, range from the upper Jurassic to lower Miocene and represent the highest position in the Appennine pile of nappes.

As regards the carbonate succession referable to Apenninic platform, it widely outcrops in the Alburno and Cervati massifs as well as in other mountains, lowest in altitude, such as Sottano, Soprano, Chianello and Cocuzzo mountains. In these relieves are available natural sections restricted to the range Cretaceous-Miocene, that correspond to subtidal to intertidal limestones (Cretaceous), passing to shelf-lagoon limestones (Paleocene-Eocene), followed by shallow water calcarenites, hemipelagic marls and quartzarenites (Lower Miocene) (Alburno Cervati Unit: D'ARGENIO *et alii*, 1975). The Cretaceous to Paleocene stratigraphic succession is indicative of a platform-interior environment, whereas the overlying lower Miocene deposits, rich in bryozoans and red algae, show a deepening-upward carbonate ramp. Several geosites in the area of Geopark can assist to reconstruct the evolution of the carbonate succession both in the phase of Bahamas-type and in that of temperate ramp. In this succession, moreover, there are at least four horizon rich in fossil as fishes, decapod crustaceans and plants remains, as reveal some geosites in the Alburni, Chianiello and Vesole mountains (i.e. BRAVI & GARASSINO, 1998).

In the Geopark area diverse clastic successions deposited in basins located at the rear of growing ridge (piggy-back basin). The thickest and widest succession is made up of siliciclastic turbidites with intercalations of hybrid megaturbites and olistostromes (CAVUOTO *et alii*, 2004) deposited at the base of a slope enlarged in a deep basin. It crops out mainly in the coastal areas of Stella, Gelbison and Centaurino mountains (from west to east). The megaturbidites can reach the thickness of 60 m and a continuity of more than ten kilometres in the whole Cilento area, whereas the olistostromes, observable along the eastern outcrops is characterized by a chaotic mixture of sediments from single clasts to decametric section of strata, more or less deformed, usually topped by a sequence of red clay with thin layers of cherty calcarenite and calcilutite.

Fig. 1 – The top sequence of the olistostrome in Gelbison M.

Other geological emergencies are classified as geomorphosites. In the area of Geopark are recognised karst features (active and fossil caves of Alburni M. like Pertosa and Castelcivita; coastal caves), different kind of gorges (as the spectacular examples along the Calore, Mingardo and Bussento rivers) cuesta ridges, fault scarps and fault-line scarps (Motola and Vesole-Chianello mountains), coastal landforms (as the wide terraced surface formed during the last million of year, that is middle and late Pleistocene due to eustatic oscillations; sea cliff with notches).

For instance, the Bussento fluvio-karstic gorges is a narrow and deep valley with vertical or subvertical sides with no or negligible alluvial deposits inside. The rate of incision is fasten than fluvial erosion owing to the process of dissolution of limestone IACCARINO *et alii*, 1988). This is an epigenetic gorge that was formed after the collapse of an ancient karst channel. The gorge is passable on foot or by a rail through a riparian wood up to the Oasis of Morigerati: a spectacular karst cave on the Bussento river. This is the only Italian river that flows underground for about 4 km, with a trend similar to that which can be found in a shallow gorge. The cavity, although for a short distance, is visible through a prepared path.

An other example is the Caves of the Angel in Pertosa, a karst area with various geomorphological, speleological and archaeological appearances. They present a development of about 3 km from which emerges, along a lateral branch, an underground stream. These caves, rich in stalactites, stalagmites and concretions, run in an impressive series of tunnels, that cross many natural halls, each of them with different characteristics (RUSSO *et alii*, 2005). Such caves were inhabited since the Bronze Age, and perhaps also in the Stone age. Remains of palafitte have been found ever since 1897. The geotourist tour, which is rather exiting, also for the boat run, is completed with a well organised museum.

The Caves of Camerota represent both an important archaeological area and a coastal geosite with many past sea-level traces, such as notches and limb of terraces. For instance, in correspondence of these caves (i.e. Riparo degli Infreschi) are recognised notches at 8.5 m a.s.l. with fringes of lithodomus boreholes. The presence of marine deposits and fossils (i.e. *Cladocora Coespitosa*) associated to them permit to attribute these markers respectively to the maximum position reached by sea in the Upper Pleistocene, some 125.000 years b.p. (M.I.S. 5e: ESPOSITO *et alii*, 2003). Moreover, this geosite clearly shows epigean and hypogean karst processes as well as the evidence of prehistoric settlements. The geoarchaeological sites of the Camerota coast represent an important testimony both for the density of the inhabited areas, and for the wide chronological range that they cover.

Fig. 2 – Examples of the Caves of Camerota in Riparo degli Infreschi

WHICH DEVELOPMENT?

In the territory of the Geopark, the high number of geosites, unique and scientifically valuable, as well as their geodiversity confirm the consistency of the geological heritage of this area in southern Italy. Moreover, such area presents several appearances of naturalistic importance, like the endemism of various kind (i.e. wolf and otter), thus it was involved in the 1997 in the programme “Man and Biosphere” by UNESCO. In addition, this international organization, as previously said, considered in the 1998 the archaeological sites of Paestum and Velia and the monumental assets of Chartreuse in Padula) as World Heritage.

In this context, rich in other significant naturalistic and cultural features, is easy to develop attractive routes, where the geological heritage can be connected with the life of nature and human history. Along them visitors can find many reasons to please their senses and enrich their knowledge, having predisposed structures and facilities for tourist.

However, as a member of European Geoparks Network the management of this territory can enforce the protection and the enhancement of the geosites, as well as can encourage the development of a sustainable tourism. For instance, the distribution of geosites can play an important role in directing the flow of tourists in the whole area, taking into account the reception capacity of each geosite and the correct measures to maintain them. At present, the visit and the residence in the Geopark is supported by an extensive network of accommodation (hotel, agri-touristic firm, bed & breakfast, country-hotel, mountain hut), as well as is guaranteed a great possibility to appreciate local products (handicraft laboratories, gastronomic firms, etc.).

Moreover, the Geopark authority could promote initiatives in order to support a naturalistic tourism and to favour the environmental education in the territory. In particular, a long term education programme about environment and sustainable development has been scheduled in the schools of the area. The aim of this programme is to introduce the young generations to environmental problems, helping them to understand the values of the territory in which they live and the necessary actions for the correct maintenance and utilization. In the development of this programme has been provided some classes about the basic comprehension in geology integrated by excursions on the territory for the direct knowledge of the natural beauties and particularly of the geo-diversity present.

Finally, it has to be underlined that in the territory of the Geopark there are some institutions that already promote particular geosite, also for touristic and educational tours, in agreement with the management of the Geopark, such as:

- the Foundation MIdA (Museums Integrated to the environment), whose partners are the Region Campania, the Province of Salerno and the Municipality of Auletta and Pertosa, has the aim to operate for the development of the environmental resources and the local cultural assets. It manages the famous caves of the Angel of Pertosa as well as the geologic museum of Pertosa.
- the Municipality of Morigerati manages the Oasis of Morigerati in collaboration with the WWF. The oasis is the most important project of maintenance of WWF in Italy and represents the concrete intervention in defence of the natural territory and biodiversity. It was created in 1985 and has an extension of 607 hectares. The area is traversed by natural paths that valorise the geologic uniqueness (e.g. karstic cave of the river Bussento) and the biodiversity;
- the Palaeontological Museum of Magliano Vetere where dioramas and fossils told the occurrence of environments in which animals and plants lived in the last 150 million of year.

At last, both the University of Naples "Federico II" and the University of Salerno conduct continuous scientific researches in geology, also with involvement of other European experts, and their results are published in national and international journals or books.

CONCLUSION

The Geopark of Cilento and Vallo di Diano for the territories in which it extends is the opportunity to go beyond that limit celebrated by the novel "Cristo si è fermato ad Eboli" by Levi and therefore to overturn the definition of "remote and desolated area of the country". For the management of the Geopark is a commitment to demonstrate the possibility of sustainable economic growth in this area, not only because they deliberately protected, but because it has found in rocks and landscape the reason for living and development.

Key words: *Terroirs, Vineyards, Campanian Ignimbrite*

The Campania Region is one of the areas with the highest index of geodiversity (landscapes and rock types) of the Italian peninsula, which can be frequently associated with an high quality and production of wines. The very high quality of several tipical vineyards (for example, Aglianico, Falanghina, Greco, Fiano, etc.) depends mainly by interplay of different “terroirs”, but the main rule is played by volcanic deposits of the Campanian Volcanoes (Vesuvius, Phlegrean Fields, Roccamonfina). The **latter** cover a wide part of the region both as proximal products (mainly lavas, surges, flows, etc), both as distal products (mainly ashes and pumices). The largest of these is the Campanian Ignimbrite, an eruption occured c. 39 ky BP from the Phegrean Fields. As recently demonstrated by FEDELE *et alii* (2002), the ashes covered a wide part of the Mediterranean Sea and Europe, while the pyroclastic flows occupied the main fluvial valleys of the Apennine chain. In the valleys, the “Tufo Grigio Campano” Formation constitutes one of the fluvial terrace of the valleys, generally, the most easily individuable on which many vineyards were planted since many centuries ago.

With the aim to promote the geological heritage of the the Region, the Italian Association of Geology and Tourism (hereinafter G&T), the Geological Regional Order, the Lerka Minerka Trekking Association, supported by FIST and by some local administration, organized, for the 2011/2012 years, a calendar of geotourism paths and events (see www.geologiaeturismo.it and www.geologi.campania.it) (AMATO *et alii*, 2011). The geotourism events want to envolve mainly the geologists, with the aim to provide to the their professional updating, and, secondly, the geotourists and trekking sportsman, with the aim of widely spreading the importance and the value of the geological heritage.

Within the events, one of the interests of the G&T is the interaction between Geology and Wine. In the last year we organized and promoted the Terroirs of the Greco di Tufo, where the interaction between local rocks (as the sulphur and gypsum rocks), volcanic rocks (as the Tufo Grigio Campano) and alluvial deposits allowed the development of the high quality vineyards (AMATO *et alii*, 2011).

This year the Geology and Wine will be the main theme of the G&T day, an event organized, contemporaneously in all Italian regions, by G&T Italian Association (Fig. 1).

Fig. 1 – The brochure ot the Vth edition of the G&T day in Castelvenere (BN) dedicated to Geotourism of the wine: in memory of Prof. Lucilia Gregori

In Campania region the event, included into the 2012 Calendar “Per...Corsi di Geologia e Turismo” (see CIARCIA *et alii*, in this volume), will promote and enhance the “wine landscapes” of Castelvenere, in the Benevento and Calore river district. The event will be dedicated to the memory of Prof.

(**) Ordine dei Geologi della Campania, Delegato Congresso SGI 2012
(***) Associazione Lerka Minerka

Lucilia Gregori, died prematurely, one of the scientists more active in the field of the intercation between different research fields that contribute to the wine and vineyards studies and of their terroirs.

The Castelvenere village is one of the municipalities with more vineyards of Campania Region (Fig. 2).

Fig. 2 – Touristic Sign of the Castelvenere Village: The city of the wine.

The event provides a workshop where specialists of research fields that contribute to the study and to the success of the wine and resource management of "vineyards" (as geologists, geomorphologists, volcanologists, soil scientists, winemakers, geochemists, etc.) (Fig. 1). For the choice of location has been preferred Castelvenere, in addition to the large vineyard area, because interdigitation of various terroirs in a small territory. In fact, the vineyards are found both on the terrace of Campanian Ignimbrite, both on floodplain deposits, and on flysch deposits of the foothill areas (Fig. 3).

Fig. 3 – Vineyards near fluvial terrace of the Tufo Grigio Campano Formation.

In this location, in order to offer to the municipality and to the citizens, the organizing committee identified and connected several geo-stops into a geotouristic path between the historical centre and the vineyards of the village, where are located both Middle Age buildings both the wineries, excavated directly into the Campanian Ignimbrite, just several centuries ago, by expert winemakers (Fig. 4).

Fig. 4 – The main stops of the Geotourism path of the wine in Castelvenere: in the top the Middle Age tower, today ruined, and in the bottom one of the winery directly excavated into the Tufo Grigio Campano Formation.

The invitation is addressed to all those that, in various way, deal or find relations between their interests and the wine: from the more rigorous scientific aspect to the more recreational, such as food and wine. All these aspects must be known, disclosed, and, why not,.... tasted.

In particular way, the wine and its streets, can be included into touristic paths, for which the geological and geomorphological knowledges can represent an interesting added value.

Geological landscape and crowdsourcing

MARIA ANTONIETTA ARGONDIZZA (*), DANIELA DISTILO (**), MARCELLO GACCIONE (*), GIANNI GRECO (*), GIOVANNI SALERNO (**) E COSIRA SPINA (*)

Key words: *geological heritage, GIS, crowdsourcing*.

INTRODUCTION

The Province of Cosenza and the Association Terr.A 360 are involved in the project called 'The Landscape Geology of the Province of Cosenza', based on participation and aiming at the promotion of geological heritage.

The actions of the project include the census and cataloguing of geological heritage sites of the province, in order to identify sites preserving significant geological evidence and so deserving to be protected and valorised. To identify the type of information to be connected to significant geological sites, the project team has analyzed national and international experiences and studies, and has taken account of characteristics of the area of Cosenza as well as of project objectives. The data are collected and managed by a Geographic Information System that allows an immediate reading of geographical, geological and administrative constraints of each site covering all the surveyed areas. The database can also contain images, detailed text, bibliography and will be continually updated according to developments of knowledge, the environmental dynamics and environmental changes induced by human activity. Data collection has taken place in crowdsourcing, with the collaboration of many experts who have shared their knowledge, and through a campaign of surveys conducted by a team of geologists of the Association Terra 360.

The database of geological heritage constitutes the basic tool to identify sites to be enhanced and protected, and will therefore be available to the public, schools, research centres and professionals.

THE PROJECT AND THE PARTECIPATION

The reference idea was that the census of geosites is both a moment of construction of cognitive frameworks and a chance to build a network of relationships for the overall enhancement of provincial territory. This is why the activities of the project where opened to the broader participation and contribution of both institutions and local authorities involved in the management of geological heritage, and the Community of experts, composed by universities and research institutions, professionals and professional bodies and informal groups working on environment and territory. The idea was to build a space where each person could give a contribution in terms of knowledge and skills. We are convinced that only the participation and role of professionals, academic experiences, experts, enthusiasts, interested in the physical components of the territory, can make this process efficient, offering policy makers with a contribution of knowledge, skills and incentives necessary to achieve the objectives.

This is why participative processes where carried on to define the types of geological sites to be covered during the census, to draw up guidelines for surveying sites and to identify the methods and procedures for storage of geographic databases of detected items.

The project included a series of initiatives within "The Spring of Earth Sciences", thought as a moment to deepen some issues related to the concepts of geo-resources and geo-diversity, which has allowed us to collect contributions from professionals, experts from Public Administration and academia, enthusiasts of the physical structure of the polyhedron environment.

These initiatives have represented an opportunity to consolidate the assumption of collective work put into the field, verifying progressively the shared materials, the difficulties perceived and good practices implemented.

"The Spring of Earth Sciences" has included two types of activities: a cycle of seminars with specific focuses and thematic tours aimed at setting common standards for survey of geological sites included in the census.

The seminars covered the following topics:

- "The geo-resources in territorial planning: the identification of geological sites in the experiences of the PSC";
- "The concepts of geodiversity and geological site: scientific studies and research".

The former involved mainly professionals and

(*) Provincia di Cosenza

(**) Associazione Terra 360

administrators, while the latter primarily involved the world of research.

The project also provided for the organization of onfield excursions: a first trip was made in San Lorenzo Bellizzi, an excursion to define operational standards for the survey of geological sites; a second trip was made to Malvito, where an administration - particularly careful of the importance of geo-resources - has expressed interest in regard of the project, offering active cooperation.

THE CENSUS OF GEOSITES

Among the various initiatives that "The Landscape Geology of the Province of Cosenza" project is developing, is planned to construct a cognitive framework of the geological features of the territory.

The first two knowledge tools that have been realized are:

- the complete list of geological sites;
- the collection of useful information to characterize the Geosites of interest.

The cognitive tools are created and managed using spatial DBMS technology.

In particular, the DB Geosites was realized, a geographic database containing information about geological features, and special applications for entering and accessing data.

The DB Geosites is the tool used to collect reports from people who have collaborated in the project. It can be used for simple reports, but also to define all the information needed to characterize a geological site, including spatial information.

Some sections of DB Geosites were compiled through geographical analysis (sections relating to the location, the presence of protected areas and Natura 2000 network, cartographic references, etc.). Other sections were completed by inserting the data shared by experts and enthusiasts, or through systemic work conducted by the surveyors.

The full list of geological sites should not be considered as a static product but as a work in progress to be further integrated.

According to the literature searches carried out, around sixty geological sites have been identified, through all the thematic analysis necessary for inclusion in the ISPRA national catalogue.

PLANNING THE GEORESOURCES

The Regional Planning Guidelines consider several times the themes of geodiversity and geological site, but they do so in a disarticulated manner.

On the base of the careful examination of the contents of PTCP established by the Guidelines, the provincial plans must include requirements for localization of the growth areas and infrastructure, based on exclusionary and limiting factors, the geological sites are on the lists of factors to be considered.

The project team has prepared a document that will be integrated into the provincial plan, containing a description of the methodology used and an article in support of the legislation.

The plan provides the following guidelines for the geological sites: 1) promoting actions for the protection and maintenance of physical characteristics of the sites, 2) promoting different types of visiting: scientific, social, cultural, educational, ecological, provided the maintenance of absolute integrity of the different components of landscape, 3) promote multimedia and museum exploitation of geological sites.

Access to geological sites is to be considered free subject to the rights of the landowners, where the sites fall within private property, who may provide for specific regulation of access also for tourist enjoyment.

In geological sites it is forbidden to litter, altering the water regime; to alter the morphology of the land or the condition of the premises; to remove or damage to rocky outcrops, concretions, or the elements of belowground biodiversity, plants, fossils, and paleontological palaeoethnological; to create new quarries and landfills.

The Plan also specifies the actions that municipalities will have to undertake within their planning instruments.

Stima della capacità di trasporto solido nel bacino della Fiumara Annunziata (RC)

BARBARO G. (**), FOTI G. (**) , MANDAGLIO G. (*), MANDAGLIO M*. & SICILIA C.L. (**)

Key words: *fiumara, trasporto solido fluviale, trasporto solido litoraneo.*

ABSTRACT

Termine settentrionale del centro storico di Reggio Calabria la Fiumara Annunziata si caratterizza per il brusco passaggio dalla dolce morfologia della costa alle ripide pareti vallive dell'entroterra, in un ambito fisiografico caratterizzato da un'elevata energia di rilievo e da formazioni geologiche facilmente erodibili che conferiscono al bacino ripide pareti vallive, forre e solchi calanchivi in rapido approfondimento.

Tra paesaggi aspri e suggestivi, dislivelli altimetrici accentuati (Δh = 1360 m), deformazioni gravitative di versante, frane e fenomeni di erosione accelerata la fiumara costituisce una fonte di pericolo per la città di Reggio Calabria ma anche una insopprimibile risorsa idrologica e ambientale da tutelare. Nasce da qui lo studio che oltre alle situazioni geomorfologiche, analizza il trasporto solido fluviale stimato nel bacino idrografico della fiumara lo confronta con il trasporto solido litoraneo valutato nel tratto di costa in cui sfocia la fiumara.

La fiumara Annunziata trae origine dal massiccio dell'Aspromonte, alla quota di 1360 m s.l.m. Le caratteristiche morfometriche, calcolate utilizzando le carte 1:25'000 dell'IGM, sono riportate nella Tab. 1. Dopo un percorso di circa 20 km, che si sviluppa in massima parte tra zone di altopiano e di versante, raggiunge la pianura costiera per sfociare sulla sponda calabra dello Stretto di Messina, nei pressi del porto di Reggio Calabria. Nell'asta principale del torrente confluiscono numerosi, ma poco estesi, valloni tra i quali i più importanti solcano il versante destro idrografico.

Il trasporto solido fluviale è stato calcolato mediante il modello multiparametrico di GAVRILOVIC (1959), modificato da ZEMLJIC (1971). Si tratta di un modello sviluppato in ambiente mediterraneo, su bacini poco estesi a carattere torrentizio come quello preso in esame,

Il trasporto solido litoraneo è stato valutato mediante l'espressione BARBARO & MARTINO (2008):

La calibrazione e l'analisi dei fattori da cui dipende K sono state effettuate mediante 4 database contenenti 170 rilevazioni di portata di materiale solido longshore. I database di riferimento sono: SCHOONEES & THERON (1993), WANG ET ALII. (1998), SANDYDUCK (MILLER, 1999) e DUCK85 (KRAUS ET ALII., 1989).

Geoheritage, professional updating and geotourism paths in the Campania Region (southern Italy)

CIARCIA SABATINO (*), AMATO VINCENZO (**), PELLINO ROBERTO (***), BENEDETTO LORENZO (****) & CAMPANELLI LUCIANO (*****)

Key words: *Geotourism, Geosites, professional geologists, Campania.*

INTRODUCTION

Since 2011, the Order of Geologists of the Campania Region, in collaboration with the Italian Association of Geology and Tourism, and the association Lerka Minerka, organized a variety of geotourism initiatives, aimed at professional geologists with the purpose of contributing to their professional updating. These initiatives also involve walkers, excursionists and geotourists, in order to promote, enhance and raise awareness the diversified geological heritage of the region. The places of field trip were chosen through a careful selection of sites where the geological heritage of the region is mixed with natural elements and cultural and archaeological sites of great value.

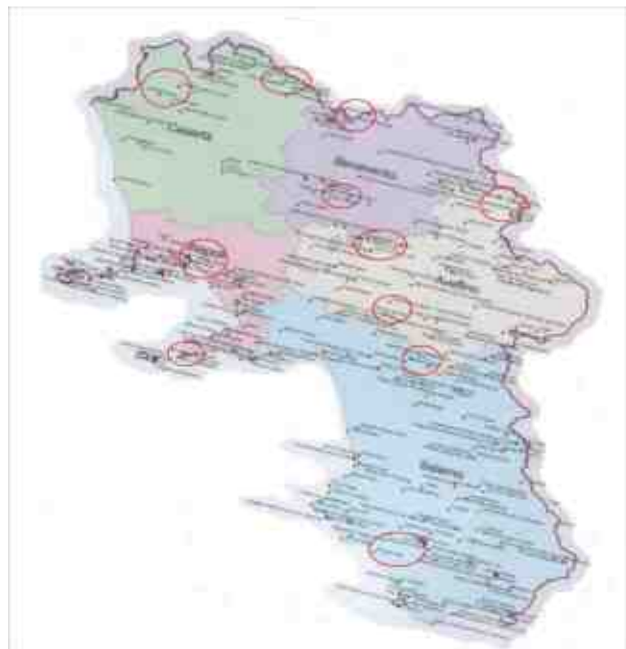

Fig. 1 – Campania Region geosites map showing the locations (in circle) of 2011 excursion calendar.

GEO EXCURSIONS OF 2011

The excursion calendar of 2011 has involved the main geological sites of the Campania (geo-sites), especially those representatives of the main rocks and landscapes of the region, as well as those relating to the most important stages of the geological and geomorphologic evolution (Fig. 1). Many of these geo-sites were chosen because they fall within natural areas like national and regional parks, SIC and ZPS areas, as well as in archaeological parks and sites (geoarchaeo-sites). Itineraries and reports of 2011 geo-tourism trips, are online on the websites of the Order of Geologists (www.ordinegeologicampania.it) and of the involved associations (www.geologiaeturismo.it and www.lerkaminerka.com) and have been object to presentations in national conferences (AMATO *et alii*, 2010, AMATO *et alii*, 2011) and in local initiatives, as the GTday 2011. Each of the trips, lasting about 4 hours, involved a geological theme based on the scientific and educational interest of visited geo-sites (Fig. 2):

- Geo-tourism of the Fossils: the bauxite quarries and mines of Cusano Mutri and the Pietraroja Geopalaeontologic Park (Benevento);
- Geo-tourism of the Health: Ichthyol mines and fish fossiliferous rocks in Giffoni Valle Piana (Salerno);
- Geotourism of the Gas : the volcanoes in the Malvizza bubbles and the prehistorical archaeological site of La Starza of Ariano Irpino (Avellino);
- Geotourism of the Water: the springs of Lete River, the historical centre of Letino village and the Matese Lake and surrounding fossiliferous rocks (Caserta);

(****) Ordine dei Geologi della Campania (Tesoriere).
(*****) Ordine dei Geologi della Campania (Consigliere).

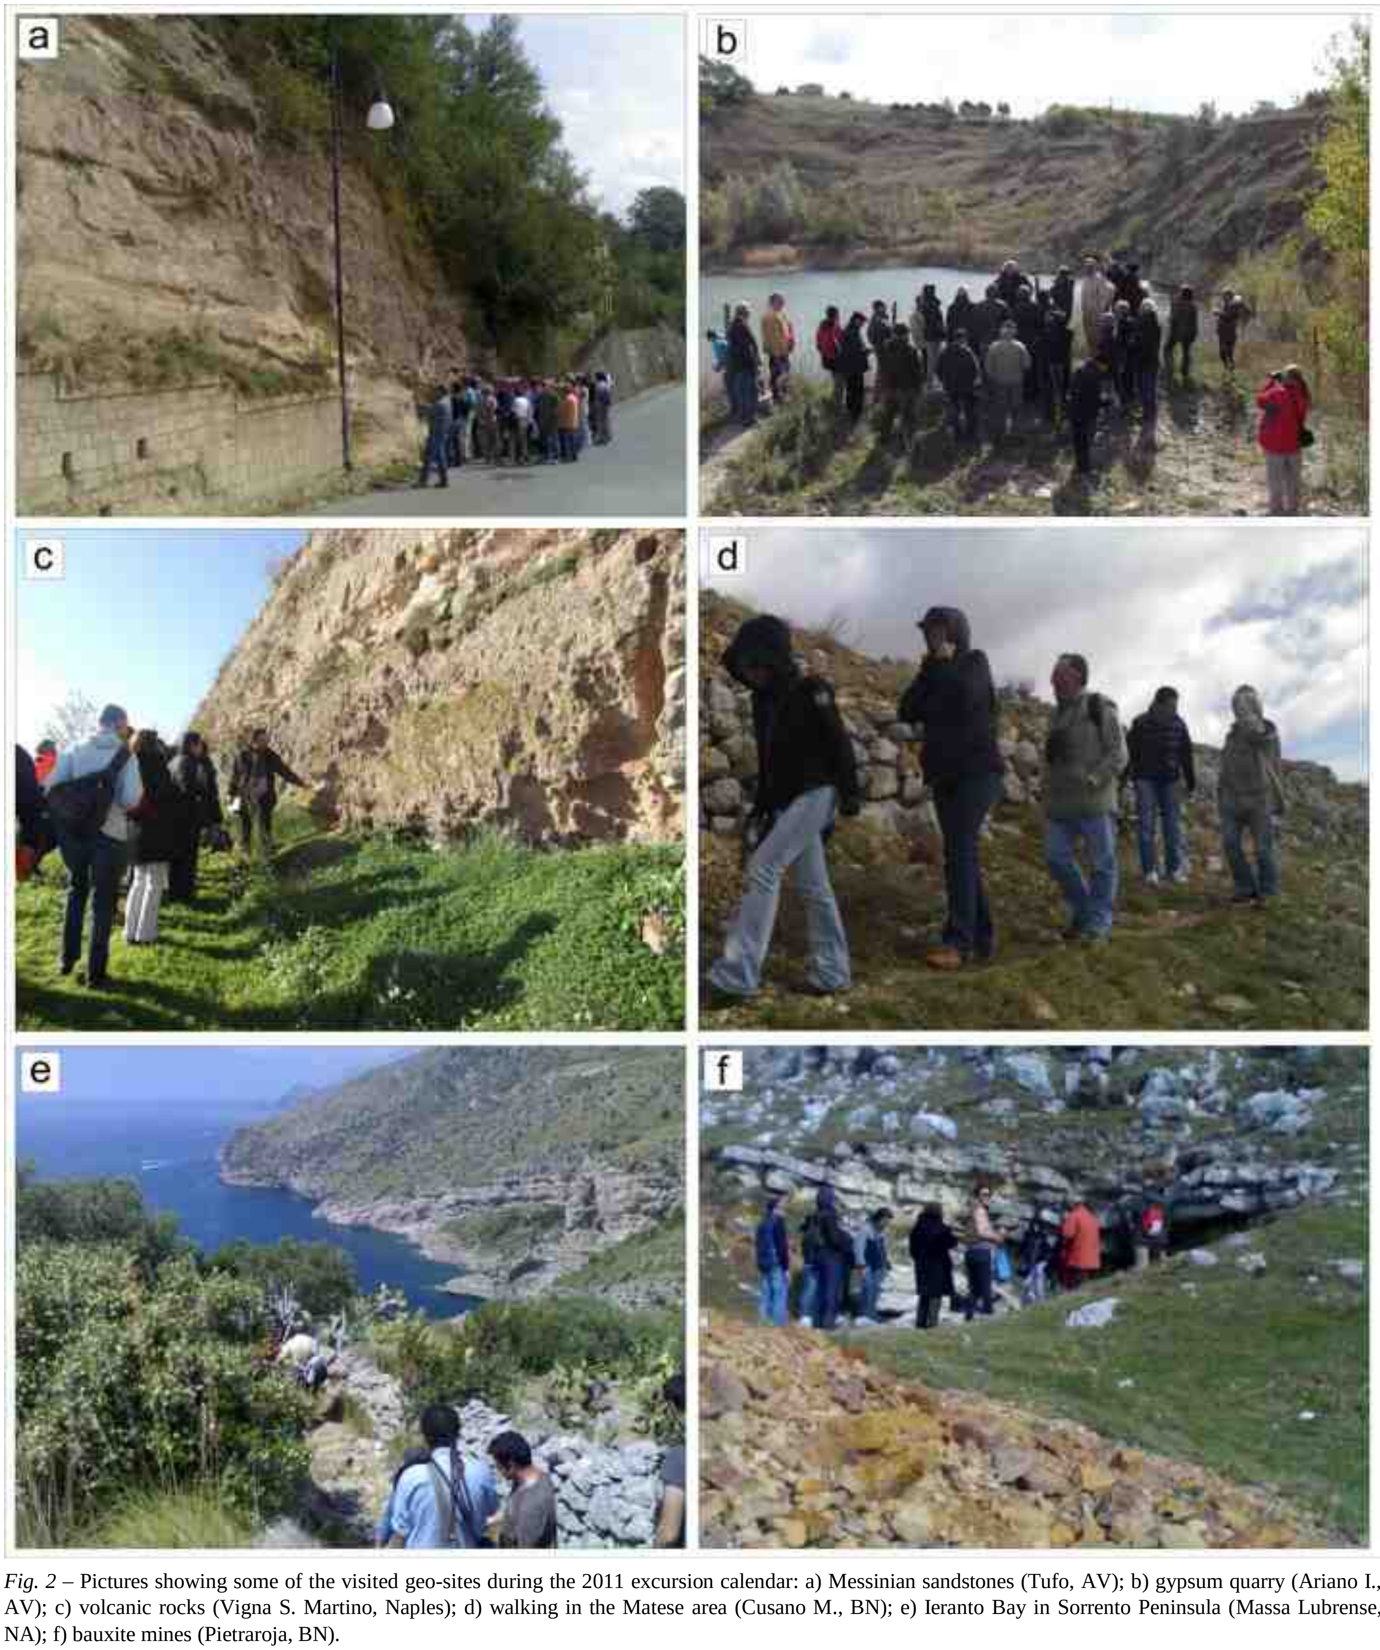

Fig. 2 – Pictures showing some of the visited geo-sites during the 2011 excursion calendar: a) Messinian sandstones (Tufo, AV); b) gypsum quarry (Ariano I., AV); c) volcanic rocks (Vigna S. Martino, Naples); d) walking in the Matese area (Cusano M., BN); e) Ieranto Bay in Sorrento Peninsula (Massa Lubrense, NA); f) bauxite mines (Pietraroja, BN).

- Geotourism in Town: the paths of the historic center of Naples, with its volcanic rocks outcroppings, its remnant wineyards of Vigna S.Martino and the ornamental stones of the main churches and buildings;

- Geotourism of the Wine: the terroir of the Greco di Tufo wine and the gypsum and sulphur outcroppings and mines in

Tufo village (Avellino);

- Geo-archaeo-tourism: the Archaeological Park of Elea-Velia (province of Salerno), a site where the palaeonvironmental and palaeogeographical are an unicum in all the region because the man-induced impacts started since 2.5 ky ago.

GEO EXCURSIONS OF 2012

During 2012, the program targets certain areas of the Campania region, with geotourism vocation, but often lesser-known, but worthy of more promotion, development, divulgation and fruition.

The new geotourism trips are located in the districts of: Roccamonfina volcano, Central Irpinia, Calore Valley (Castelvenere, G&Tday), National Park of Cilento and Vallo di Diano, Sele Plain, Ofanto Valley, Fortore area, Sele Valley and Phlegrean Fields (Fig. 3). Within these districts were chosen to visit several locations, as steps of the geotourism itineraries. In fact, the excursions lasts 8 hours, with packed lunch, and the subjects of interest are of geological, geomorphological, stratigraphic, hydrogeological and various combinations of these as well as interdisciplinary links with archeology, history, wine, etc.

The excursions of 2012 provide a path in the following districts:

- Roccamonfina Volcano: the site of anthropological-volcanological interest with the oldest human footprints named "Ciampate del Diavolo", the megalithic walls of the Garden of the Queen and the crater rim of Santa Croce Mount;

Fig. 3 – Campania Region map showing the locations (spirals) of the 2012 excursion calendar.

- central part of Irpinia: Mefite in Rocca S. Felice, characterized by carbon dioxide and sulphur dioxide exhalations, the Fontanarosa Stone and Alabaster of Gesualdo quarries,;

- Calore Valley (Castelvenere): the IV edition of G&T day "Geology and Wine"(for detail see this volume);

- Cilento and Vallo di Diano Geopark: the Alburni massif, the Castelcivita caves and the Roscigno landslide;

- Sele River plain: the S. Cecilia-Gromola and Campolongo-Spineta Lido coastal dunal ridges, the Paestum travertines , the springs and the oasis of Capodifiume River;

- Ofanto Valley: the Samnitic, Roman and Modern Archaeological Parkof Compsa, the ornamental stones of St. Andrea di Conza, the landslide and the old town of Calitri;

- Fortore area: the river, the fossils of Baselice and the Montefalcone Valfortore Museum of Paleontology;

- upper part of Sele Valley: the thermal mineral waters of Contursi Terme, the oasis of Valle della Caccia and the Senerchia landslide;

- Phlegrean Fields: the Serapeum of Pozzuoli, the "Area Flegrea and Monte di Cuma" regional forest and the Cuma Archaeological Park.

CONCLUSIONS

The promotion, the enhance and the raise of the geoheritage of the Campania Region must be realized also by professional geologists. The latter must update their professional experiences bag, by means detailed and scientific knowledges of the territory, where they work.

At the same time the geoheritage of the region must be spread and promoted toward a more wide interested audience (natural scientists, human scientists, etc.).

Adding geological criterion VIII to the dossier for nominating the sila national park to the unesco world heritage list

CRISCI G. M. (*), CRITELLI S. (*), DE ROSA R. (*), MARABINI S. (*), PROCOPIO F. (*), & VAI G. B.(**)

Key words: *Geological heritage, Protected area, Sila*.

The Convention for Protecting the World Heritage is the most popular challenge in terms of international visibility and local favourable impact. The Unesco World Heritage List sums up a total of 936 sites, as of August 2011, among which 725 are cultural, 183 natural, and 28 mixed, based on cultural (criteria I to VI) and natural criteria (VII to X) in 153 out of 183 Member States having ratified the 1972 Convention.

Acceptance and registration into the List of Goods concerning the World Heritage is a long process of selection for the high value of the criteria recognized (which have to be unique not only at national level but also at global scale), the severe integrity condition required in the Operational Guidelines, and the rigorous managing models needed to assure due protection. Inclusion of a site in the Unesco List is focussed in the definition of "outstanding universal value" (OUV) of the site through ten criteria, among which the Sila National Park has deemed to highlight also criterion VIII which says: be outstanding examples representing major stages of Earth's history, including the record of life, significant on-going geological processes in the development of landforms, or significant geomorphic or physiographic features.

As a matter of fact, the nominated property Sila National Park (73.695 ha) is located in the Sila, a vast rectangular shaped plateau, 1200 to 1500 m in elevation, punctuated by several mountains up to 1929 m in the northern part of Calabria (South Italy), geologically including a variety of metamorphic, plutonic and sedimentary rocks spanning from early Paleozoic to Quaternary and representing a unique geological archive, highlights the uniqueness concept proclaimed by the Operational Guidelines.

In detail, the Sila mountain plateau forms the northern part of Calabria which is placed on the leading SE tip of the Apennines, a mountain chain constricted between the jaws of the moving macroplates of Eurasia and Africa. The geology of the Calabria Region, expressed by rocks, mountains and landforms is milestone for reading a long history of events occurred within the Mediterranean Region. The geological archive within the Calabrian Mountain Ranges includes a long history of about 500 My, and Calabrian rocks and landforms represent a innovative laboratory at every scale of learning the archive of planet and to know the geological heritage of a region. In this frame, the Sila Mountains and their "terranes" consitute a key geological fragment within the Mediterranean Region. A terrane is defined as a block of Earth lithosphere exotic, sharply different from and accreted onto the adjoining areas after long horizontal displacement (hundreds of km or more) related to plate tectonics. Terranes are associated to many mountain belts but occur in places rarely easy to walk on.

The geology of the Calabria Region, expressed by rocks, mountains and landforms is milestone for reading a long history of events occurred within the Mediterranean Region. The geological archive within the Calabrian Mountain Ranges includes long history of about 500 My including:

(1) a nearly complete Paleozoic section from Cambrian to Permian (550-275 My) culminated with the Hercynian Orogenesis (assembling Gondwana with Laurussia and forming the supercontinent Pangea); (2) fragmentation of Pangea and forming the Mesozoic (180-65 Ma) Tethyan Ocean; (3) Closure of Tethyan Ocean and Alpine Orogenesis (60-45 Ma); (4) Apennine Orogenesis (25-3 Ma); (5) dissection of the Mediterranean Region and formation of Evaporite successions (5.75-5.30 Ma); (6) Opening of Tyrrhenian Sea (12 Ma-Present); (7) Ionian Lithosphere subducting beneath Calabria and forming Peri-Tyrrhenian Magmatic Arc; (8) Abrupt Uplift (c. 1 mm/yr) of Calabria Mountain Ranges); (9) huge sedimentary discharge to the marine basins; (10) intense rainfall, landslides, flooding; (11) changing nature of climate (paleo), vegetation, biology, hydrology and rock response. All of this natural archive of living planet are reading and visible to fashinating observation of key natural geological sections that immense energy of planet preserved to us. Field trips in key "Geosites" represent a innovative laboratory at every scale of learning the archive of planet and to know the geological heritage of a region.

(a) What makes the Calabria and Sila terranes unique is a series of special circumstances making them of outstanding universal value: Sila is a block of the Alpine chain comprised of different nappes some made by Precambrian to Palaeozoic rocks folded and metamorphosed during the Carboniferous Period (Hercynian orogeny c. 330-300 Ma) and others made by Mesozoic rocks, all in turn folded and metamorphosed during the Cretaceous Period (eo-Alpine orogeny c. 100-80 Ma, reactivating also the Hercynian nappes).

(*) Dipartimento Scienze della Terra Università della Calabria, Italy.
(**) Museo Geologico Giovanni Capellini Università di Bologna, Italy.

(b) Late Palaeozoic to Mesozoic extension and crustal listric fault denudation supplied to the following eo-Alpine convergence conditions favorable to emplace lower crustal granulites on top of the nappe system, which are widely outcropping in the Mount Gariglione unit of the Sila plateau.

(c) As a whole the Sila and Calabria terranes involved in the eo-Alpine orogeny are bounded N and S by the much younger Apennine chain made by Mesozoic to Tertiary rocks folded and partly metamorphosed only in Neogene times (c. 20-1 Ma). On both sides of Calabria the Apennine nappes plunge beneath the Alpine terranes which appears to have superseded the Apennines. Once attached to Spain, Sardinia and Calabria rotated anticlockwise from c. 20 to 15 Ma. Then Calabria detached from Sardinia being displaced east and southeastward for more than 600 km mainly in the last 2 Ma, following the opening of the Tyrrhenian Sea. At the same time, this enormous displacement and the Tyrrhenian Sea opening were driven by rapid westward subduction of the old (Permian) and cold Ionian oceanic lithosphere beneath the Calabria terranes and the Tyrrhenian area.

(d) Fast subduction of the Ionian lithosphere enabled the displacement of the Calabria terranes from Sardinia to the present position and their accretion on top of the Apennine chain, both occurring mostly in submarine condition and conveyed in the geotectonic depression as wide as the downgoing Ionian slab. Slowed or stopped subduction resulted in the Middle Pleistocene to Present fast uplift of Calabria and its Apennine margins at a rate of over 1mm/a or 1Km/Ma.

(e) The two basic driving forces enabling the Calabria terranes to be displaced are thus depending on subduction of the Permian oceanic lithosphere of the Ionian Sea, the oldest known in the whole Earth, and the spreading of the Pliocene-Pleistocene small Tyrrhenian ocean basin, one of the youngest oceans in the world. This is a really unique coincidence of extreme plate tectonic processes.

(f)Individual or associate occurrences of features similar to those described above, when available somewhere in the world, are found in isolated, far, and strenuous mountain chain difficult to be reached and visited. In the Calabrian Sila case, instead, the access and visibility are easy for everybody and provided with all facilities by the existing national parks.

The rocks presently exposed in N Calabria, and in particular in the Sila Mountains, have been deposited and/or emplaced in (1) a Jurassic to Cretaceous ocean (known as the Ligurian-Piedmont palaeo-ocean) extending southeastward to (2) a Mesozoic to Miocene deep pelagic basin on attenuated crust (the Sicilian to Lagonegro palaeo-basin) in turn passing to (3) a late Palaeozoic to Present deep basin on oceanic crust (the Ionian basin). (1) and part of (2) have been involved in the Alpine orogeny at the end of Cretaceous (thus becoming part of the Alps). The remaining part of (2) and (3) have not, allowing for Neogene drift of the Calabria terranes from Sardinia and Spain to the Southern Apennines.

The Sila plateau uplift, that occurred about 7 Ma ago as a single block, makes Sila an area favourable to the conservation of important geomorphic and pedostratigraphic proxies of the climatic evolution of the planet in the last millions of years. A good example is the wide up to tens of m thick weathering horizon on top of the crystalline rocks, enhancing the relevant biodiversity and ecological significance of the Sila forest ecosystem. In detail, crystalline rocks of the Sila Massif experienced intense weathering processes, evidenciated by isolated large boulders of plutonic rocks, vaste boulder fields, and thick weathering profiles, representing a residual well preserved evidence of intense interaction between lithospere and climate changes during last milion of years.

In view of preparing the second and final step for the inclusion in the Unesco *Worl Heritage List*, the Sila National Park has submitted its nomination to the global Biosphere Reserve Net and to the Global Geoparks Network.

The memory of mountains using Geosites. A tool for understanding natural culture and learning Earth Science.

A geologic archive in the Mediterranean Puzzle (Calabria)

SALVATORE CRITELLI (*), GINO MIROCLE CRISCI, ROCCO DOMINICI, FRANCESCO MUTO, ANTONIO PISCIUNERI, FABIO PROCOPIO,

Key words: *Geosites; Mediterranean Region; Mountain Chains; Calabria.*

SUMMARY

"Geological heritage" is the memory of our planet. Landforms and mountains preserve elements that, as such as a book, testify the history of Earth. In the last decades, is growing the idea of preserve not the "wonders of nature" but a system of organic and organised blocks of information revealing the story of the Earth of the life forms that have lived upon in the various regions that have yielded key clues to the fascinating history of its evolution as a planet. Even today this signal resource is still glimpsed through static perceptions–natural monuments, quirks of geological forces and events–that in any event see a given formation as something separate, detached from the surrounding landscape. Geosites include numerous meanings and potentialities that go far beyond such a museological vision, and a natural laboratory for each learning at each level of culture or curiosity. Indeed, it constitutes at once an essential resource for scientific and economic development, a habitat, landscape, an element of geodiversity, a source of knowledge about the Earth's dynamics and past history, the memory of biological evolution and of mainkind's origins and development, and a exceptional laboratory for environmental education. As far as other scientific methods, it is fundamental to develop understanding and bringing geology within the ken of society at large. Any geological subject is an integral part of mankind's common heritage, albeit the object becomes part of our cultural trust only when knowledge of it is shared and it is accesible. An example of the Memory of mountains (the "Calabria Region" , a peace of an "Orogenic Belt" within the core of the Mediterranean Region), is here discussed and illustrated using geosites as a tool for understanding natural culture and learning Earth Science at every level of knowledge.

(*) Dipartimento di Scienze della Terra, Università della Calabria, 87036 Arcavacata di Rende (CS)

CALABRIA, SOUTHERN ITALY

The geology of the Calabria Region, expressed by rocks, mountains and landforms is milestone for reading a long history of events occurred within the Mediterranean Region. The geological archive within the Calabrian Mountain Ranges includes long history of about 500 My including: (1) a complete Paleozoic section from Cambrian to Permian (550-275 My) culminated with the Hercynian Orogenesis (assembling Gondwana with Laurussia and forming the supercontinent Pangea); (2) fragmentation of Pangea and forming the Mesozoic (180-65 Ma) Tethyan Ocean; (3) Closure of Tethyan Ocean and Alpine Orogenesis (60-45 Ma); (4) Apennine Orogenesis (25-3 Ma); (5) dissection of the Mediterranean Region and formation of Evaporite successions (5.75-5.30 Ma); (6) Opening of Tyrrhenian Sea (12 Ma-Present); (7) Ionian Lithosphere subducting beneath Calabria and forming Peri-Tyrrhenian Magmatic Arc; (8) Abrupt Uplift (*c*. 1 mm/yr) of Calabria Mountain Ranges); (9) huge sedimentary discharge to the marine basins; (10) intense rainfall, landslides, flooding; (11) changing nature of climate (paleo), vegetation, biology, hydrology and rock response.
To confirm this national park sila, recently, has been included in UNESCO World Heritage tentative list to the criterion VIII which says: be outstanding examples representing major stages of Earth's history, including the record of life, significant on-going geological processes in the development of landforms, or significant geomorphic or physiographic features. All of this natural archive of living planet are reading and visible to fashinating observation of key natural geological sections that immense energy of planet preserved to us. Field trips in key "Geosites" represent a innovative laboratory at every scale of learning the archive of planet and to know the geological heritage of a region. Here are illustrated six peculiar geosites illustrating complex history of mountain formation, that are fruible for each kind of interesting people and, particularly, for students at each level of formation from primary to University. Case history 1-to-5 are located in eastern portions of Calabria along the piedmont, and near the coast, of the Ionian Sea. These geosites document the past geological history of the Ionian Sea, from deep-marine basin fill sequences of 15-5 Ma (Case 1-Crucoli, KR), to evaporitic rocks (gypsum, halite) of 6-5 Ma (Case 2- Verzino, KR, and

Case 3- Zinga, KR) testifying Messinian salinity crysis of the Mediterranean basin, to 3-1.5 Ma deep-marine basin-fill recording boundary between Cenozoic to Quaternary (Case 4-Vrica, KR), and finally preserved coastal dune having typical biogeographical Mediterranean habitat (Case 5-Marinella, KR). The last case history 6 (Ciminà, RC) is a remnant of plutonic rocks (granite) having a Late Paleozoic age (Permian; 290-275 Ma). These plutonic rocks were formed during the last orogenesis of the Paleozoic age, the Hercynian or Variscan Orogenesis, that was responsible of the continental collision between Gondwana and Laurussia supercontinents, resulting in the formation of the Pangean Supercontinent.

CASE HISTORIES

Case 1.-:*Crucoli (Kr): Deep-marine basin fill of the Paleo-Ionian Sea Late Miocene (15-5 Ma)*

During late Miocene, the Ionian Sea basin, was subdivided into several sub-basins following growth of the Southern Italy orogenic system. These Neogene basins were filled by deep-marine clastic strata, and/or abruptly perturbated by accommodation of "thrust systems"displaying thick Tectonic Nappes. The area of Crucoli reflects both deep-marine (Middle-Upper Miocene in age of conglomerate and sandstone) basin-fill examples, and accommodation of Nappe sequences (Cariati Nappe). Walking along a rural road, in 3 STOP, we observe a paleo-basin fill sequence, similar to that occurs in the Modern Ionian basin.

Case 2.-: *Marinella Coastal Dune (Kr): Late Quaternary-Holocene Coastal Dune*

They are well-sorted medium-fine dunal sand deposits, stabilized by vegetation. This is a "protected area" for the typical flora of the biogeographical Mediterranean Habitat. The age of the dunal sand is Late Pleistocene-to-Holocene.

Case 3.-: *Verzino (Kr): Caves in Karst Evaporitic Rocks*

The Messinian (late Miocene) evaporitic succession of the Peri-Ionian Crotone Basin, experienced intense karst morphologies, including karren and sinkholes from hydrosolution of halite and gypsum. This morphological selective erosion generated an epigean karst system within halite and gypsum strata. In the Verzino Area, are present 13 caves. One of these, the Grave Grubbo Cave is one of the most spectacular caves in evaporitic rocks in Italy, develop with over than 2 km in length of passage and galleries, 150 m in diameter and 56 m of drop.

Case 4.-: *Zinga (Kr): Halite and Salt Diapir- A memory of the Messinian Salinity Crysis in the Mediterranean*

The Salt, is a great geo-resource for our planet. From domestic to industrial uses, the salt represents, one of the most useful natural products of our lithosphere. Literally is a mineral and a rocks, the Halite, and it has very unusually properties with respect other rocks. It is impermeable, incompressibile until high burial (6-8 km), constant density (2,2 g/cm^3), high viscosity, termal condicibility, and a thermal gradient of 20°C. If load conditions vary, the Halite can flow forming vertical structures named diapir, that have great economic importance,

Fig. 1 – Halite deposits outcrop by small dipapirs (KR)

because they form salt domes trapping petroleum and natural gas. The Geosite of Zinga shows a series of medium-small-scale diapirs, where all physical-chemical behaviors of salt diapirs are observed, such as the columnar structure of salt, a caprock of insoluble minerals and rocks, and internal deformational structures (fold). At regional scale, the Geosite include salt diapir and the related evaporitic succession of the Messinian (5.75-5.32 Ma), representing a stratigraphic record of the Mediterranean salinity crysis.

Case 5.-: *Vrica (Kr): Stratotype of the Pliocene (Cenozoic)-Pleistocene (Quaternary) boundary*

The Vrica section consists of open sea deposits preserved in the emergent portion of the late Cenozoic Crotone sedimentary basin. The rocks are bathyal, marly and silty claystones with interbedded, fairly conspicuous, *sapropelic* marker beds. Some very thin sandy horizons and a volcanic ash layer also occur within the section. Sedimentation rates through the section range from 310mm to more than 750mm per thousand years. The base of the Pleistocene Series is defined as the base of the marine claystones conformably overlying the sapropelic Marker Bed "e" in the Vrica Section. The Plio–Pleistocene sequence of deep-water marine beds at Vrica, Calabria, Italy, was proposed by INQUA and by the IGCP as the location for a physical boundary-stratotype for the base of the Pleistocene, according to modern chronostratigraphic guidelines. The recommended level has been adopted formally by the IUGS.

That section is herein characterized in terms of sedimentology, paleoecology, biostratigraphy, biochronology, and magnetostratigraphy, based on a decade of studies by stratigraphers in different countries. According to criteria established by prior recommendations, the physical location of

Fig. 2 – Vrica Section (Kr).

the Pleistocene boundary-stratotype is identified with the base of the claystone conformably overlying marker bed *e* of the Vrica section. This level is very close to the Olduvai normal-polarity subzone and is approximately coeval with the beginning of a cold-climate phase marked by the first appearance of the "northern guest" *Arctica islandica*, a mollusk confined to boreal waters during interglacial periods.

Case 6.-: *Ciminà-Tre Pizzi (RC): A LATE PALEOZOIC GRANITE (275 Ma) during last (Pangea) Supercontinent Assemblage*

The Geosite of the "Tre Pizzi" is a remnant of plutonic rocks (granite) having a Late Paleozoic age (Permian; 290-275 Ma). These plutonic rocks were formed during the last orogenesis of the Paleozoic age, the Hercynian or Variscan Orogenesis, that was responsible of the continental collision between Gondwana and Laurussia supercontinents, resulting in the formation of the Pangean Supercontinent. Following the Hercynian Orogenesis, involving southern and Central Europe and northern Africa, large quantities of plutonic and metamorphic rocks are now preserved in diverse mountain belts along the Mediterranean perimeter. In Calabria, these plutonic and metamorphic rocks are well preserved and testify the record of the Hercynian orogenesis assembling the last supercontinent of the planet. After that, the Pangean experienced rapid and abrupt fragmentation, forming, in the last 200 My, the modern continent and related ocean basins.

Fig. 3 – Cimino Tre Pizzi (RC)

The "Geosite of Tre Pizzi" testify, in several stop, this long history of the Earth (since 300 or older Ma), from Hercynian Orogenesis and more recent geological history of the Mediterranean region in a fashinating observation of natural and extreme landscapes. The difficult to walk and visit the geosite is low.

CONCLUSIONS

The geology of the Calabria Region, expressed by rocks, mountains and landforms is milestone for reading a long history of events occurred within the Mediterranean Region. The geological archive within the Calabrian Mountain Ranges includes long history of about 500 My including:
(1) a complete Paleozoic section from Cambrian to Permian (550-275 My) culminated with the Hercynian Orogenesis (assembling Gondwana with Laurussia and forming the supercontinent Pangea); (2) fragmentation of Pangea and forming the Mesozoic (180-65 Ma) Tethyan Ocean; (3) Closure of Tethyan Ocean and Alpine Orogenesis (60-45 Ma); (4) Apennine Orogenesis (25-3 Ma); (5) dissection of the Mediterranean Region and formation of Evaporite successions (5.75-5.30 Ma); (6) Opening of Tyrrhenian Sea (12 Ma-Present); (7) Ionian Lithosphere subducting beneath Calabria and forming Peri-Tyrrhenian Magmatic Arc; (8) Abrupt Uplift (*c*. 1 mm/yr) of Calabria Mountain Ranges); (9) huge sedimentary discharge to the marine basins; (10) intense rainfall, landslides, flooding; (11) changing nature of climate (paleo), vegetation, biology, hydrology and rock response. All of this natural archive of living planet are reading and visible to fashinating observation of key natural geological sections that immense energy of planet preserved to us. Field trips in key "Geosites" represent a innovative laboratory at every scale of learning the archive of planet and to know the geological heritage of a region.

Naftah: a town in the region of mirages, between brittle morphotypes and geological-technical problems*

GIUSEPPE MANDAGLIO (°) & MICHELE MANDAGLIO

Key words: *brittle morphotypes, geological-technical problems historical value, mirages.*

Naftah is an ancient caravan town of Roman origin (Nepte) located in the western of Tunisia, in an area where at least four morphotypes converge: the Sahara dunes, the desolate landscape of the sebka, the apparent immobility of the Chott and the full of water Jerid oasis. Other morphotypes, of anthropogenic origin with important aspects of naturalness, are represented by the same city with the Corneille basin which, taken together, constitute a historical pattern of land use between the desert and the intensively cultivated oasis and today declining. This part of Tunisia is characterized by the domain of the Saharan platform that extends across the Maghreb. The sedimentary covers have reacted to the tectonic thrusts from NW assuming the folds structure that characterizes the heights at north of Chott, while the contrast between the Atlas reliefs and the carbonate formations of Saharan platform has involved the vast depression which extends from the Algerian Sahara to the Gabes Gulf. Here the persistent subsidence has originated the succession of the Chott. In this geological context, the geomorphic processes have originated some morphotypes in brittle dynamic equilibrium and sometimes evanescent such as the dunes, the sebkha, the Chott, the Oasi, Naftah and the Corbeille. The geo-environmental characteristics are reflected on the city generating numerous problems which endanger the existence of parts of the landscape, monuments and buildings, and are repeated in the Naftah center where instabilities are observed even where major restoration works in recent times were carried out. Moreover, the development of Naftah town is related to water and especially to the ability to preserve it both qualitatively and quantitatively, using an integrated cycle and experimenting with new energy sources to purify and to reuse. On the other hand, new experiments seem necessary for the buildings whose rapid degradation is due to the climate and to the construction techniques, which should be maintained for the historical value, but to which must be made substantial improvements. In particular the foundations of the buildings have its defects due to lack depth and binders which are exhausted and due to external agents, such as especially the water discharged by the characteristic protruding, and to the absolute lack of effective techniques of interruption of the capillary.

The recovery of the San Niceto Castle between geostatic instabilities and geoenvironmental singularity

GIUSEPPE MANDAGLIO (*), MICHELE MANDAGLIO & CRISTINA AMBROGIO

Key words: *recovery castle, landscape, geostructural survey, rock mass.*

The San Niceto Castle (XI century) and its geological bedrock are in an advanced instability state due to different phenomena and to long years of neglect. This situation has defined a particular landscape for both intrinsic aspects depending on the geomorphological site context in the Aspromonte and for aesthetic aspects including a single glance the Strait of Messina with Peloritani and the Etna Volcano. The restoration works, that recently (2004) have affected the castle, do not have interested the western side of the cliff where major geostatic problems and broad landscape persist. Anyway these works have allowed to the recovery and the reclassification of some internal works (Mastio tank) and of a part of the wall belt. In order to define the lithological structure and the geomechanical behavior of the bedrock and of the castle works, a geognostic investigation to complete the previous investigations has been carried out. The investigations performed (refraction seismic, MASW, laserscan, ecc.) and a detailed geostructural survey allowed to characterize the rock mass and to define the kinematisms governing the evolution of the slopes. In particular, the laser scan technique allows to the examination at distance of the steep slopes and to identify the discontinuities, the orientation discontinuities and the fracturation degree where the topographic conditions do not permit the access. Petrographic analyzes and tests have completed the geological knowledge and the physical properties of the rock. The obtained results, together with the geological knowledge previously acquired, have allowed to establish the feasibility conditions and the type of geostatic restoration needed to return the San Niceto Castle to contemporary civilization as a heritage and a resource for development.

Geodiversity: concepts, methods, examples and management

MARIO PANIZZA (*)

Key words: *geodiversirty, geomorphodiversity, management, world heritage, geopark, dolomites, emilian Apennines.*

PANIZZA (2009) defined geodiversity as: "the critical and specific assessment of the geological features of a territory, by comparing them in a way that is both extrinsic (with other territories) and intrinsic (with the territory itself). It takes into account the level of their scientific quality, the scale of investigation and the purpose of the research".

It should noted that some authors consider the number and variability of "geological" elements to be the basic parameters on which the quantitative and qualitative assessment of geodiversity should be founded; they use also mathematical indexes and formulas. This procedure can be considered as a mere statistical elaboration of geological data which, in most cases, had been previously collected: it seems an unfruitful exercise, simple spatial statistics that add nothing either from a conceptual viewpoint or regarding content.

Two examples of application of the concept of geodiversity are presented: the first concerns the Dolomites, the second the Emilian Apennines.

The Dolomites have been included in the UNESCO World Heritage List (GIANOLLA, MICHELETTI & PANIZZA, 2008) because of their exceptional beauty and unique landscape (criterion VII), together with their scientific importance from the geological and geomorphological point of view (criterion VIII).

In order to acquire correct geomorphological understanding of these mountains, an original interpretation has been introduced, that is "geomorphodiversity" (PANIZZA, 2009) derived from the concept of geodiversity. First of all, they have monumental, original and spectacular qualities distinguishing them from all other mountains in the world (extrinsic geomorphodiversity on a global scale). Furthermore, in the context of the alpine environment, but not only, they offer a particularly varied, complex and emblematic range of morphological features (extrinsic geomorphodiversity on a regional scale), with structural forms linked above all to distant and more recent movements of the earth's crust. On account of their variety and complexity, these phenomena are superimposed on other forms which offer an almost complete educational and scientific case study within the Dolomites (intrinsic geomorphodiversity at regional scale). The morphology is linked either to present climate conditions or to processes taking place during recent geological periods. On a local scale, another example of intrinsic geomorphodiversity is offered by the wide range of karst formations, both epigeal and hypogeal.

Referring to "geological" values in a broader sense, subdividing them into extrinsic and intrinsic values (geodiversity), the stratigraphic-type geological values, like the various layers or formations whose names are derived from the Dolomites, such as "Ladinian" or "Dolomia principale", should be mentioned among the extrinsic values. The peculiarities of palaeogeographic and palaeontological-type, the Triassic reefs made up of 200 million year-old corals, algae and sponges or the "San Cassiano" fossils could be quoted as intrinsic values; also mineralogical-type values such as "monzonite", which got its name from the Monzoni chain, should be mentioned.

Concerning the Emilia Apennines, a dossier is being prepared to present a portion of these mountains as a candidate for enrolment in the list of European Geoparks. Also for this area the concept of geodiversity has been applied (PANIZZA & PIACENTE, 2008).

In the case of extrinsic geodiversity, the area selected can be considered as an exemplary case in the Apennines owing to its typical geological features: it is in fact an educational example for illustrating tectonic evolution, stratigraphic sequences and lithological peculiarities in this chain compared with other mountains in the world. On the other hand, intrinsic geodiversity concerns first of all the complexity and variety of geomorphological features: LGM glacialism, karst landforms in the gypsum formation, the spectacularity of badlands and high frequency of landslides, which are also a sort of outdoor laboratory for investigations on their hazard. Other characteristics of intrinsic geodiversity are related to mineralogy (e.g., baritine, which Goethe defined as "phosphoric stone"), or petrography, such as the ophiolites (known also as the "Devil's stones") or palaeontology, including some specific types of fossils.

Finally, it can be observed that, considered from the standpoint of geodiversity, the territory of this poprtion of the Apennines shows a multifaceted and complex image, depending on the various points of view of scientific observation. In order to carry out a thorough territorial analysis, it is therefore of

(*) Dipartimento di Scienza della Terra, Università degli Studi di Modena e Reggio Emilia.

paramount importance to first choose the goals of our investigations and, consequently, the most appropriate conceptual and methodological path also for applied purposes.

As for the management of these mountains, a conceptual path is suggested and illustrated, following the phases of knowledge, communication, awareness, protection and appraisal (PANIZZA & PIACENTE, 2011).

Knowledge should be based on a strict analysis of the particularities typical of the Dolomites and of the Emilian Apennines, avoiding the use of project schemes developed for other geological realities. Communication must be comprehensible in order to enrich knowledge; it cannot be a simplification of complex problems. Therefore, specific communication skills are needed, together with clear cultural and social responsibility. Any geological context can become common heritage and therefore a "cultural asset" in all its values only when communication leads to a shared awareness; not only would this allow participation but would also approve territorial management choices. As for protection and appraisal, the idea is "not planning in order to protect and protecting in order to manage" but "planning in order to disseminate knowledge and develop awareness in order to appraise and self protect" (PANIZZA & PIACENTE, 2003). In short, not a top-down planning (passive approach) but a bottom-up planning (active approach) with self involvement.

In order to attain positive results, it is necessary to adequately tackle the problem concerning the relationship between the above mentioned phases and the political choices – that is, management – and establish not only constant dialogue between the various sides involved but also constant, indispensable involvement of public opinion. Therefore this sort of management must be linked to an "open network", intended as a cultural network of all the physical, biological and cultural elements of the territory.

The San Carlo mine: an archeological tour in the Sicilian mining industry (Peloritani Mountains, NE Sicily)

SACCÀ C.*, SACCÀ D.*, CIRRINCIONE R.**, FIANNACCA P.**, MILITELLO G.**, NUCERA P.*, ORTOLANO G.**

Key words: *Geoarcheology, mining industry, San Carlo mine, Peloritani, Sicily*

The evidences of mining activities in Sicily are as old as the history of the civilizations who inhabited the island starting, at least, from the Greeks. The Peloritani area, with the crystalline nature of the outcropping rocks, has always been generating a considerable interest in this regard although, in different centuries, moments of great enthusiasm have been alternating with moments of almost total neglect. Notary's documents and research permits attest to a flourishing mining activity throughout the fifteenth and sixteenth centuries, a period in which the Aragonese domination and later the Spanish one encouraged mining, not only for civilian but also military purposes (BAVIERA ALBANESE, 1974). That was the period, in fact, when a large furnace went into operation in the Fiumedinisi ironworks, where artillery bullets were mainly produced. The lack of documentation for the seventeenth century, most likely coincides with a reduced industrial vitality. The activity resumed in 1728 with the dispatch by Charles of Habsburg of a group of Saxon miners whose job was to investigate the potential of the mineral resources distributed in the Peloritani Mountains. With the establishment of the Bourbon dynasty, the mining activity in the peloritanian area achieved the greatest development. In this period, eighteen mines were active in the Fiumedinisi area and, to optimize the exploitation, expert miners, metallurgists and mineralogists were sent from Germany. In the first half of the nineteenth century, were the English that, at various times, took up the exploitation of the peloritanian mineral resources, in some cases deliberately concealing the true economic extent of the plants. Finally, in 1951, the "Azienda Mineraria Siciliana" took care to restore some mine galleries thanks to permission of resource exploitation. These activities, however, lasted only a decade (Diana, 1999). Therefore, the millenary history of the mining activity in the Peloritani Mountains ended just a few years ago, leaving behind a historical past that is itself an important scientific document if all the involved mineralogical, petrographic and chemical aspects of the extracted products are considered, but also an important historical record if the attention is focused on the cultural, economic and social vicissitudes that have marked the whole area of production, as well as on the technological innovation, considering the industrial plants designed for the extraction and exploitation of the mineral resources. Of all the mines that dot the peloritanian slopes, the San Carlo mine, located near the village of Fiumedinisi along the right side of the homonymous torrent, is considered the most important. In it were extracted tetraedrite, sphalerite, chalcopyrite, pyrite from which were obtained lead, copper, tin, zinc, silver and gold (Saccà et al, 1992). In the Fiumedinisi area, mineralisations contain the highest silver concentrations of the whole Peloritani Belt. Indeed, galena from San Carlo mine reaches concentrations above 2000 ppm and even tetraedrite, also extracted there, is argentiferous (Saccà & Saccà 1993). With good reason De Borch (1780) stated that the San Carlo mine produced 19 ounces of silver (one ounce equals 26.45 grams) and 6 rolls of copper (a roll is equivalent to 30 ounces) per ton of raw material extracted. There is no doubt about the scientific value of the mine: metalliferous veins are still present and clearly observable through the narrow and often barely viable tunnels (Fig. 1).

Fig. 1 – Mineralisation within the San Carlo mine, Fiumedinisi

But what makes this site unique and worthy of restoration and valorisation is also its historical message. In it are preserved fragments of the history of the mining activity and, at the same time, glimpses of the social and economic life in Sicily in different historical periods. At present, the site pays in deplorable conditions and lacks of access path; the only way to get to the tunnel entrances is on a steep and rough slope; the entrances are in turn often obscured by dense vegetation or filled with debris (Fig. 2 and 3); finally the vaults and the floors of the tunnels are often unsafe (fig. 4). This work is aimed to sensitize the scientific community towards the preservation of valuable scientific and historical heritage, often harmed by the severe state

Fig. 2 – Entrance to a tunnel of the San Carlo mine, partially obscured by dense vegetation.

Fig. 3 – Entrance to a tunnel of the San Carlo mine, partially obstructed by debris.

Fig. 4 – Interior of a tunnel of the San Carlo mine.

of neglect and abandonment in which many important sites of historical and scientific interest pay in the Italian territory. More specifically it wants to represent a proposal for the construction of a project finalised to restoration and valorisation of an archaeological mining site, which is considered a cultural asset in actual fact, of considerable importance for the scientific aspects related to the still present mineralisation, as well as for the socio-cultural aspects that it continues to preserve.

The effects of the different chemical-physical properties of the natural and artificial soils on the nutritional quality, flavour, and yield of the PGI Pachino cherry tomatoes (south-eastern Sicily)

ROBERTA SOMMA (*), NICOLA CICERO (*), GIACOMO DUGO (*), CARMELO PANDOLFO (**), GIUSEPPE SABATINO (°) & ANDREA SALVO (*)

Key words: *agricultural geology, bedrock, food chemistry, pedology, PGI Pachino cherry tomato fruit, X-ray powder diffraction.*

Pedologically, PGI (Protected Geographical Indication) Pachino cherry tomato (*Lycopersicon esculentum* cv. Shiren) would be expected to be cultivated (in greenhouses) on the very fertile soils belonging to the autochthonous pedological cover cropping out within the territory of Ragusa and Syracuse (Pachino, Portopalo of Capo Passero, and part of the territory of Noto and Ispica, SE Sicily).

Most of the soils sampled in the pedogenic superficial horizons of the above-mentioned areas contain a skeleton of fine sands composed of quartz and calcite (with minor silicate mineral phases). Due to the calcite, these soils have an alkaline pH ($8.2 \leq pH \leq 8.6$ in H_2O). These soils derive mainly from weathering of thin alluvial and coastal deposits overlying non-deformed thick calcareous successions (prevailing Mesozoic-Cenozoic limestones and marls) belonging to the Hyblean plateau of the Maghrebian chain (LENTINI *et alii*, 1987).

In a few cases, X-ray powder diffraction analysis showed these soils to be composed of vermiculites and organic matter (peat moss), with a minor presence of quartz.

Soils with these features prove to have a dubious origin, being characterized by mineral composition and pH quite similar to those of the artificial soils.

A multidisciplinary study on the Pachino cherry tomato fruits and soils where this horticultural product is grown has been begun by a staff of geologists, food chemists, and natural science researchers to analyse the possible relationships between the chemical-physical characteristics of the PGI Pachino cherry tomatoes (CIAMPA *et alii*, 2010) and the main sedimentary and geological features of the bedrock and of different soil types. Particularly, in order to define electrical properties and thickness of the pedogenic cover penetrated by roots and providing macro- and micronutrients to the cultivar studied, and the occurrence of geological discontinuities in the bedrock, a campaign of superficial geophysical survey is planned.

The main aim of this research is to examine how different characteristics of the natural and artificial soils influence, positively or negatively, nutritional quality, flavour, and the yield (several hundreds of tonnes/year) of the PGI Pachino cherry tomato fruits cultivated following the PGI production disciplinary code (Commission disciplinary CE 617/03, 4 April 2003).

This research indicates that the autochthonous pedological cover cropping out within the PGI Pachino cherry tomato cultivation area, having very good chemical-physical properties, represents an important geological heritage and resource to protect.

It would be desirable for the PGI Pachino cherry tomato to be cultivated exclusively on these natural soils and that the PGI autochtonous soils should be included in the PGI coded production disciplinary.

AKNOWLEDGEMENTS

We are grateful to Giovanni Randazzo for providing the sieves of the sedimentological laboratory of the Earth Science Department of the Messina University.

Sharing data and interpretations of geological maps on the web: the example of the CNR-IGGTO geoportal

G. BALESTRO (*), F. PIANA (**), G. FIORASO (**), G. PERRONE (*) & S. TALLONE (**)

RIASSUNTO

Condivisione dei dati e delle interpretazioni delle carte geologiche in rete: l'esempio del geoportale CNR-IGGTO

Le Tecnologie dell'Informazione (IT), permettendo l'applicazione di nuove metodologie di rappresentazione del dato e favorendo la condivisione delle informazioni, rappresentano un'opportunità per superare alcuni limiti nell'utilizzo e nella diffusione delle carte geologiche. Per trarre effettivi vantaggi dall'utilizzo di tecnologie quali i Sistemi Informativi Geografici e i servizi di *web-mapping*, è però necessario che le informazioni contenute nelle carte geologiche siano specificatamente strutturate e standardizzate. In questo ambito, i protocolli WMS (*Web Map Service*) e gli standard previsti dalla direttiva INSPIRE (*Infrastructure for Spatial Information in Europe*) rappresentano importanti strumenti per la creazione e il mantenimento di geoportali contenenti informazioni geologiche interoperabili. Il geoportale dell'Unità di Torino dell'Istituto di Geoscienze e Georisorse del CNR (CNR-IGGTO) è un esempio di condivisione delle banche dati delle carte geologiche attraverso l'utilizzo di servizi standard di *web-mapping* e la compilazione di metadati con contenuti geologici.

Key words: *GIS, INSPIRE, geological map databases.*

Maps are a key-method for the representation of geological information but they could transfer more information than those communicated through traditional paper-based methods. An opportunity to improve use and spreading of geological maps is given by IT applications such as Geographic Information Systems (GIS) and web-mapping services. As a matter of fact, geological maps are widely shared over the Internet and spatially discovered through Web-GIS applications but, in order to actually take advantage of systems-aided representations, information has to be specifically structured according to technical and geological standards.

A great amount of geological knowledge is now available on geoportals and spatial data infrastructures that are built on standard technical specifications, enabling interoperability of systems and ensuring accessibility of information. Geological maps are increasingly spread through the WMS protocol, that allows sharing information independently from systems and platforms, whereas the need of methods for storing and homogeneously describing spatial information is particularly faced by the INSPIRE (Infrastructure for Spatial Information in Europe) European directive.

Two INSPIRE implementing rules are relevant for encoding and sharing interoperable geological information:

- the "Data Specification on Geology" (INSPIRE TWG-GE, 2011), providing a conceptual data model and a language (the GeoSciML) for representing geological knowledge in an interchange format;

- the "Metadata Implementing Rules" (INSPIRE DTM, 2009), providing a form for representing the meta-informative component of information through the ISO 19115 metadata standard for spatial data sets.

The IGGTO Geoportal (the Geoportal of the Torino Unit of the Institute for Geosciences and Earth Resources; http://server21.to.cnr.it/geonetwork/srv/en/main.home) is an example of a local web-infrastructure built on the application of existing standards. It consists of a catalog service and a web map service:

- the catalog service allows finding information and is managed by the GeoNetwork open source software (a platform-independent application that provides MD editing and web-search functions);

- the web map service allows publication and configuration of maps and is managed by the Geoserver software (a standard-based and open source application for displaying and sharing spatial information via WMS).

The most meaningful data shared in the IGGTO Geoportal come from geological maps, and correspond to field data and map features extracted from large GIS databases. Each shared datasets is described through metadata that provide different information concerning contents, quality and provenance of data. Metadata particularly allow giving knowledge about the different processing steps from original field data to map representation, and can be used for explaining geological interpretations.

(*) Università degli Studi di Torino - Dipartimento di Scienze della Terra, Via Valperga Caluso, 35 – 10125 Torino, Italia

(**) Consiglio Nazionale delle Ricerche, Istituto di Geoscienze e Georisorse, Unità di Torino, Via Valperga Caluso, 35 – 10125 Torino, Italia.

The IGGTO Geoportal is on the whole an example of geological maps sharing via standardised metadata and geoportals. Map information is harmonized by standard MD compilation and datasets are shared by interoperable web-mapping technology. These IT applications enhance dissemination of geological maps and improve reading of maps through the meta-description of geological interpretations.

ABSTRACT

The Geological Survey of Italy in order to make available relating to geological data and maps, in the geoportal SGI has built a series of tools that allow access to all information stores of several databases, developed inside, and meet different users.

The SGI has realised a first version of Geoviewer with flex technologies (flash builder) which was presented within the Geoportal SGI during the 2010, has also developed an evolution of the same viewer. The new version of the viewer is due to two reasons: from technological point of view in order to make available a more friendly interface to the user that has more tools like analysis widgets; from the other point view to re-organise the contents of data based on the great feedback received over time by the uses.

In particular the new geoviewer is structured in three thematic sections related to the geological content: the geological data where is stored all the data that represent map distribution of the geological data or the data that have generic content. The second theme is represented by the Geologic resources like prospection, boreholes or quarry and the third theme is represented by the hazard events, like landslide, active faults, sinkholes, etc. To support the data is realised a set of tools to query and analyze the data: for each layer discoverable in each web service has been developed a specific query window and for some data is possible to operate a combo advanced query to highly the geologic results. Otherwise to easily manage the extra external data an "Add Widget" to manage the web service in several standard (WMS, KML, ArcGIS Server, ArcIMS, Image) has been developed.

Moreover in the viewer the major base maps has been integrated and now are available OpenStreetMap, Google Map, the Environmental Ministry Ortho-images together at the previous Esri and Geological Survey of Italy base maps.

INTRODUZIONE

Nell'ultimo decennio l'esigenza da parte di utenti esperti di avere a disposizione un modo semplice ed interattivo per la consultazione di dati e mappe via web, ha fatto crescere il settore della geovisualizzazione, in concomitanza con la comparsa di innumerevoli interfacce grafiche che consentissero via web la gestione di informazioni geografiche e l'utilizzo di strumenti di analisi.

In quest'ottica il Servizio Geologico d'Italia ha realizzato all'interno del portale SGI una serie di strumenti così da mettere a disposizione dei diversi utenti tutto il patrimonio delle informazioni archiviate nei molteplici database realizzati dallo stesso. fornire

In particolare dopo aver realizzato una prima versione di visualizzatore con tecnologia flex (flash builder) presentata in coincidenza della pubblicazione del Portale SGI nel maggio 2010, è emersa ben presto la necessità di predisporre una nuova versione sulla base di due motivi fondamentali: da una parte per mettere a disposizione un applicativo di più facile utilizzo e più ricco di strumenti, anche di analisi, rispetto al primo; dall'altra la necessità di riorganizzare i contenuti sulla base dei numerosi feedback ricevuti dagli utenti stessi.

Il geovisualizzatore del Servizio Geologico, denominato GeoMapViewer, è realizzato con tecnologia Adobe flash 4.5, utilizzato le specifiche librerie flex di Esri nella versione 2.4; sulla base di tale piattaforma è stata eseguito uno sviluppo specifico per mettere a disposizione dell'utente i contenuti organizzati per widget tematiche al fine di fornire strumenti di interrogazione, anche attraverso query combinate, e per estendere l'interfaccia al caricamento di dati esterni.

SVILUPPO DEL VIEWER E ORGANIZZAZIONE DEI CONTENUTI

Il geovisualizzatore del Servizio Geologico, denominato GeoMapViewer, nella prima versione si basava sul visualizzatore Esri flex 1.3 tramite l'utilizzo di librerie nella versione 1.3 sviluppate per il flex builder 3.0 con compilazione in SDK (Software Developers Kit) 3.3. La nuova versione viceversa sfrutta le nuove librerie Esri flex 2.4 che mettono a disposizione molteplici nuove funzioni e necessitano di un ambiente di sviluppo Flash builder 4.5 con SDK 4.1 o superiore.

La scelta di sviluppare una nuova versione del visualizzatore, come è stato detto in precedenza, è dettata principalmente dalla necessità di organizzare i contenuti ma anche per la presenza di ulteriori funzionalità messe a disposizione dalla nuova piattaforma software.

La prima parte del lavoro di sviluppo è stata orientata all' organizzazione dei contenuti, ovvero i dati geologici suddivisi in differenti aree tematiche con lo scopo di facilitare all'utente la ricerca di quelli d'interesse. In tal senso si è cercato di organizzare le informazioni individuando tre aree tematiche di maggior importanza: Dati geologici, Risorse e prospezioni geologiche e Eventi pericolosi. Nel primo gruppo "Dati Geologici" sono stati accorpati tutti i servizi di dati relativi a dati di mappe geologiche, geofisiche e geotematiche nonché quei dati che per caratteristiche dei contenuti non potevano comunque essere inseriti nelle altre aree. Nel secondo gruppo "Risorse e Prospezioni Geologiche" sono stati inseriti tutti i servizi che si riferiscono a dati prevalentemente puntuali che forniscono informazioni relative alle condizioni del sottosuolo, quali sondaggi profondi e non, risorse idrogeologiche, cave e località d'interesse geologico. L'ultimo dei contenitori presenta i dati relativi a servizi che identificano quei fenomeni che possono dar luogo ad eventi pericolosi sul territorio, quali frane, faglie attive, sprofondamenti, terremoti (catalogo multiplo ottenuto da dati INGV, ex-SSN e DPC).

Per facilitare la fruizione dei dati, le tre aree sono state rappresentate attraverso dei contenitori (widgets) in cui è consentito lo spostamento dei singoli servizi, la definizione del livello di trasparenza del layer, la consultazione di informazioni associate ad ogni layer e, attraverso l'attivazione di un bottone (check box), la visualizzazione delle legende dei singoli strati.

In aggiunta, per poter permettere agli utenti una consultazione integrata dei dati disponibili via web è stata realizzata ad hoc una widget che permette di caricare servizi esterni e sovrapporli a quelli già presenti nel visualizzatore. Tale strumento permette di scegliere tra diversi standard WMS, WFS, KML, ArcGIS Server (Tiled, Dynamic, Image) e ArcIMS; una volta inseriti i parametri il servizio verrà aggiunto alla lista dei servizi web personali. Successivamente, questa lista può essere salvata e caricata come un progetto locale, facilitando all'utente l'uso di dati selezionati per successive applicazioni.

Sempre sulla base di quanto emerso dai suggerimenti inviati dagli utenti sono state ottimizzate le funzioni d'interrogazione delle informazioni relative ai singoli elementi geometrici di ogni strato, pertanto sfruttando le nuove funzioni delle librerie nella versione 2.4, per ogni strato di ogni servizio (nel visualizzatore sono disponibili 24 servizi per un totale di 276 strati) è stata creata una finestra di consultazione dei dati per l'interrogazione della singola feature.

E' stato eseguito inoltre un enorme lavoro relativo all'implementazione della funzione di query. Sulla base della tipologia di dato da interrogare, sono state predisposte query specifiche sul singolo dato, oppure mediante una widget viene reso disponibile un sistema d'interrogazione avanzata che permette di eseguire combo-query sugli strati.

La seconda parte del progetto di sviluppo e miglioramento del visualizzatore si è orientata nel fornire una serie di funzioni che tendono o a migliorare le precedenti o addirittura ad inserirne delle nuove.

In particolare è stata migliorata la ricerca delle località geografiche, la modalità realizzazione di misurazioni (measuring) e disegni (drawing) salvabili in locale, la modalità di consultazione dei metadati in cataloghi standard con servizio CSW 2.0.2 e la modalità di consultazione di eventi d'interesse. Inoltre è stata implementata una funzionalità che offre la possibilità agli utenti di segnalare eventi naturali avvenuti sul territorio cliccando sulla carta: verrà inviata in automatico una e-mail al Servizio Geologico con la segnalazione e le coordinate di riferimento dell'evento in oggetto.

La veste grafica rinnovata resa più accattivante e innovativa dal punto di vista tecnico, permette all'utente di raggiungere facilmente tutte le funzioni nonché di selezionare in modo rapido un ampio elenco di mappe di base da sottoporre ai dati visualizzati nel GeoMapViewer.

In questa nuova versione del visualizzatore sono state integrate oltre a quelle già disponibili ed erogate dalla Esri e dal Servizio Geologico d'Italia stesso, anche altre basi di uso comune come: le Ortofoto del MATTM, OpenStreetMap e Google Map.

CONSIDERAZIONI

La nuova versione del GeoMapViewer che rappresenta lo strumento integrato del Portale SGI per la consultazione dei dati geologici è, con le nuove funzionalità, uno strumento che si rivolge sempre più ad utenti non solo esperti della materia facilitando la consultazione delle informazioni geologiche ma diventa strumento di supporto per la comunità geoscientifica che, all'interno di questo applicativo vede il concretizzarsi della completa integrazione delle informazioni ivi presenti con quelle erogate esternamente da altri enti oppure presenti in locale sul proprio pc.

Pur riconoscendo le limitazioni di tali strumenti in analisi di dettaglio poiché l'uso inappropriato di dati non sovrapponibili può indurre in erronee valutazioni da parte degli utenti è pur sempre una apertura al cittadino alla consultazione di dati che facilitano la consapevolezza delle ricchezze presenti nel proprio territorio e dei fenomeni naturali che possono costituire evento di pericolo per lo stesso. Con la nuova funzionalità relativa alla segnalazione di un evento sul territorio il geomapviewer si configura per il professionista o il cittadino un importante strumento web 2.0 di conoscenza del territorio italiano, nonché di controllo nei confronti di quegli eventi il cui monitoraggio nel corso degli anni è stato disatteso, in relazione alla sempre più frequente mancanza di fondi indirizzati alla prevenzione e mitigazione del rischio idro-geologico.

Il Portale del Servizio Geologico d'Italia accessibile all'indirizzo http://sgi.isprambiente.it/geoportal dispone di un catalogo di metadati nel quale è possibile ricercare le informazioni anche mediante i canali tematici, ossia risorse informative relative a contenuti di particolare interesse che il Servizio Geologico mette a disposizione attraverso dati e prodotti cartografici, documenti, servizi informativi.

Per l'organizzazione in canali tematici si è partiti dall'analisi del contenuto informativo dei dati disponibili al fine di riconoscere delle "categorie" di riferimento nelle quali fare confluire le informazioni di diversa natura, sia quelle di proprietà del Servizio Geologico che quelle acquisite da terzi. Sono state ad oggi individuate cinque categorie di dati all'interno delle quali sarà possibile consultare non solo i metadati afferenti ai contenuti del portale e relativi a progetti presenti su scala nazionale, ma anche quelli più specifici che comprendono, ad esempio, elaborati di dettaglio, sia a livello regionale che locale.

I canali tematici identificati sono i seguenti: Dati geologici, Pericoli naturali, Monitoraggio, Risorse e Idrogeologia.

Nei Dati geologici, ad esempio, è possibile consultare i dati del Servizio Geologico relativi alle informazioni geologiche del territorio italiano disponibili a diversa scala cartografica, a partire da 1:1.000.000 fino ai fogli geologici del Progetto CARG, in scala 1:50.000, seppur in fase di completamento, alla Carta litologica d'Italia alla scala 1:100.000 e altro ancora.

Nella voce Pericoli naturali si ha accesso alle informazioni riguardanti alcuni eventi naturali che si verificano sul territorio italiano; si possono infatti consultare i dati del Progetto Sinkholes, ossia la banca dati dei fenomeni di sprofondamento censiti sul nostro territorio nonché quelli del Progetto IFFI (Inventario dei Fenomeni Franosi in Italia), realizzato dall´ISPRA e dalle Regioni e Province Autonome, che ha raccolto ad oggi 485.000 fenomeni franosi su un´area di 20.721 km2, pari al 6,9% del territorio nazionale e rappresenta, quindi, uno strumento conoscitivo di base per la valutazione del rischio da frana, per la programmazione degli interventi di difesa del suolo e per la pianificazione territoriale a scala nazionale e locale.

Per quanto riguarda la categoria Monitoraggio all'interno di questa si reperiscono i dati del Progetto ReNDiS (Repertorio Nazionale degli interventi per la Difesa del Suolo) sviluppato per raccogliere le informazioni su tutti gli interventi finanziati dal MATTM, a partire dal 1999 ad oggi per monitorare il territorio, attività che l'ISPRA svolge, per conto del Ministero dell'Ambiente e della Tutela del Territorio e del Mare, al fine di attuare i piani e i programmi di interventi urgenti per la mitigazione del rischio idrogeologico finanziati dal Ministero stesso. Il Repertorio fornisce un quadro unitario, sistematicamente aggiornato, delle opere e delle risorse impegnate, condiviso tra tutte le Amministrazioni che operano nella pianificazione ed attuazione degli interventi, proponendosi come uno strumento conoscitivo potenzialmente in grado di migliorare il coordinamento e l'ottimizzazione della spesa nazionale per la difesa del suolo, nonché di favorire la trasparenza e l'accesso dei cittadini alle informazioni.

Nel canale Risorse, invece, sono disponibili i dati dell'Archivio nazionale delle indagini nel sottosuolo (Legge 464/84) e quelli del Progetto Sondaggi profondi in cui sono contenuti i dati dell'attività di Esplorazione e Produzione degli idrocarburi in Italia depositati presso l'UNMIG dal 1957 a oggi, e che per legge possono essere resi pubblici dopo un anno dalla cessazione del titolo minerario della società che li ha realizzati.

Una particolare attenzione è stata posta nella creazione di una newsletter denominata Geonews accessibile da una sezione del Portale. Riservata agli Utenti registrati viene diffusa per divulgare approfondimenti e notizie relative al Portale del Servizio geologico d'Italia oltre ad una selezione di eventi, notizie e altre iniziative riguardanti l mondo delle Sciense della Terra e dei Servizi geologici del mondo.

Si articola in sei sezioni tematiche ed ha lo scopo di tenere aggiornta la comunità delle geoscienze anche in relazione alle iniziative che si svolgono a livello regionale.

The application of the INSPIRE Directive on hydrogeological risk data for civil protection activities: the case of the DORIS Project

CARA P. (*), CORAZZA A. (*), DURO A (*)., PAGLIARA P. (*), PROIETTI C. (*) & VALGIMIGLI G. (*)

Key words:, *Civil protection*, *Hydrogeological risk, landslide, INSPIRE*, *metadata*, *network services*.

INTRODUZIONE

Italy's national territory is exposed to a broader range of natural hazards, including landslides, that cause every year fatalities and a large economic damage. The vulnerability of its population and built environment is often severe and has in some cases been exacerbated by human activities. In this perspective, within the National Civil Protection Service (Law 225/95), the Italian Department of Civil Protection (DPC) operates according to the following lines: prevention, forecast and assessment, early warning and alerting, emergency response and recovery from emergency.

DPC daily supports research efforts on the assessment of vulnerability and exposure to landslide of population, buildings and critical infrastructures also by the involvement in international project. The DORIS project (Ground Deformation Risk Scenario: an Advanced Assessment Service) is an advanced downstream service for the detection, mapping, monitoring and forecasting of ground deformations, that integrates traditional and innovative earth Observation and ground-based data and technologies. DPC, in close collaboration with the other partners, have the objective to design and develop an efficient interface between the user domain, the existing European level core service and the individual downstream service modules. In order to assess the performance of the developed interface, DPC has detected many assessment tools. One of them is the translation of the service specifications detected by the user's domain into requirements. In particular, the INSPIRE Directive compliance is requested among DORIS's "Product requirements", according to the Regulations for Metadata (1205/2008), Network Services (976/2009) and Interoperability (1089/2010 and 102/2011).

The preliminary methodology of the application of the INSPIRE Directive on hydrogeological risk data for the whole emergency cycle for civil protection activities is presented.

GeoSciML: il modello dati per l'armonizzazione e condivisione delle informazioni geologiche

CARLO CIPOLLONI & MARCO PANTALONI

Key words: *modello dati, GeoSciML, armonizzazione, banca dati.*

INTRODUZIONE

L'importanza di un linguaggio comune per le informazioni geologiche risulta fondamentale sia per poter aderire agli standard internazionali quali INSPIRE, sia per la sempre crescente domanda di dati geologici disponibili via web. Il Servizio Geologico d'Italia in tal senso ha maturate grandi esperienze sia realizzando e partecipando al progetto OneGeology-Europe che collaborando come membro del Gruppo di Lavoro sull'interoperabilità del IUGS-CGI (Commissione per la gestione dell'informazione geologico-scientifica). Questo gruppo di lavoro internazionale ha sviluppato un modello dati geologico comune denominato GeoSciML (GeoScience Mark-up Language – IUGS-CGI, 2008) che è corredato al momento da 27 vocabolari di termini geologici e da un linguaggio di "encoding" per la condivisione digitale delle informazioni attraverso la rete internet.

Sono stati sviluppati diversi casi di studio su cui gli autori hanno applicato e tarato il modello GeoSciML, analizzando alcune parti del modello dati che risulta composto nella versione attuale (3.0) da una parte centrale (GeoSciML-Core) e da 12 pacchetti di informazioni collegate che trattano sia le informazioni base come l'età dell'evento geologico o le caratteristiche tettonico-strutturali, sia informazioni molto più dettagliate quali le analisi geochimiche o le caratteristiche geotecniche di una unità/formazione geologica.

I casi di applicazione si possono suddividere in tre categorie: quelli relativi al progetto OneGeology in cui i dati geologici sono stati uniformati nei contenuti rispetto al modello GeoSciML 2.1.1 e a specifici vocabolari che tengono in considerazione le specificità dell'Europa. Un secondo gruppo relativo alla applicazione del modello GeoSciML sviluppato come modello nella Direttiva europea INSPIRE e un classe relativa all'uso del modello GeoSciML 3.0 in fase di sviluppo.

Lo scopo di questo lavoro è quello di mostrare le potenzialità del modello unico sia ai fini dell'armonizzazione dei dati che vengono condivisi via web, sia per semplificare la fruizione dell'informazione geologica attraverso l'uso della semantica che sfruttando i vocabolari di termini viene in aiuto dell'utente favorendo percorsi semplificati di lettura dei dati.

SINTESI DEL MODELLO GEOSCIML

Il modello dati GeoSciML nasce nel 2004 come risultato dei primi lavori del Gruppo di Lavoro sull'interoperabilità dello IUGS-CGI con lo scopo di avere un modello dati unico con cui rappresentare le informazioni geologiche 3D derivanti da cartografie e/o dati geologici digitali. Nel 2007 il Servizio Geologico d'Italia entrando a far parte del gruppo di lavoro, ha iniziato una fase di test del modello che incomincia ad essere più complesso e articolato in pacchetti di informazioni.

Fig. 1 - Esempio di risposta in linguaggio GML3.1.1/GSML2.1.1 secondo lo schema dati utilizzato nel progetto OneGeology-Europe.

La versione 2.1.1 è stata applicata nel progetto OneGeology-Europe, questa versione risulta ancora composta di pacchetti collegati direttamente alla geometria, pertanto come mostra la

figura 1 il linguaggio di scambio informazioni si presenta come un blocco con un tag univoco.
Con la necessità di definire meglio il modello dati per la Direttiva INSPIRE e per rispondere ad esigenze sia di gestione informatica che di contenuti, la nuova versione 3.0 è stata ri-disegnata, definendo un pacchetto di contenuti base, identificato con GeoSciML-Core, in cui oltre alle informazioni relative alle geometrie vengono inseriti gli attributi identificativi di base, quali ad esempio l'Unità geologica, le caratteristiche di stratificazione e etc. A questo pacchetto sono associati con delle relazioni geologiche/logiche le altre informazioni supplementari secondo quanto espresso nello schema sintetico di figura 2; maggiori informazioni sono reperibili nel sito istituzionale del modello GeoSciML (http://www.geosciml.org).

Il modello di dati per il tema Geologia di INSPIRE (EC-JRC, 2010), utilizza oltre alla parte di base del modello suddetto, anche la parte geomorfologica, introdotta specificatamente proprio per le richieste venute dalla comunità geoscientifica di INSPIRE. Inoltre nello stesso tema ricadono informazioni relative alla geofisica e all'idrogeologia che però sfruttano altri modelli collegati al GeoSciML (es. GWML).

Il nuovo pacchetto geomorfologia in corso di sviluppo è disegnato per codificare tutte le informazioni relative alle forme del territorio, mentre quelle più squisitamente geologiche dei depositi risiedono negli altri pacchetti del modello GeoSciML 3.0.

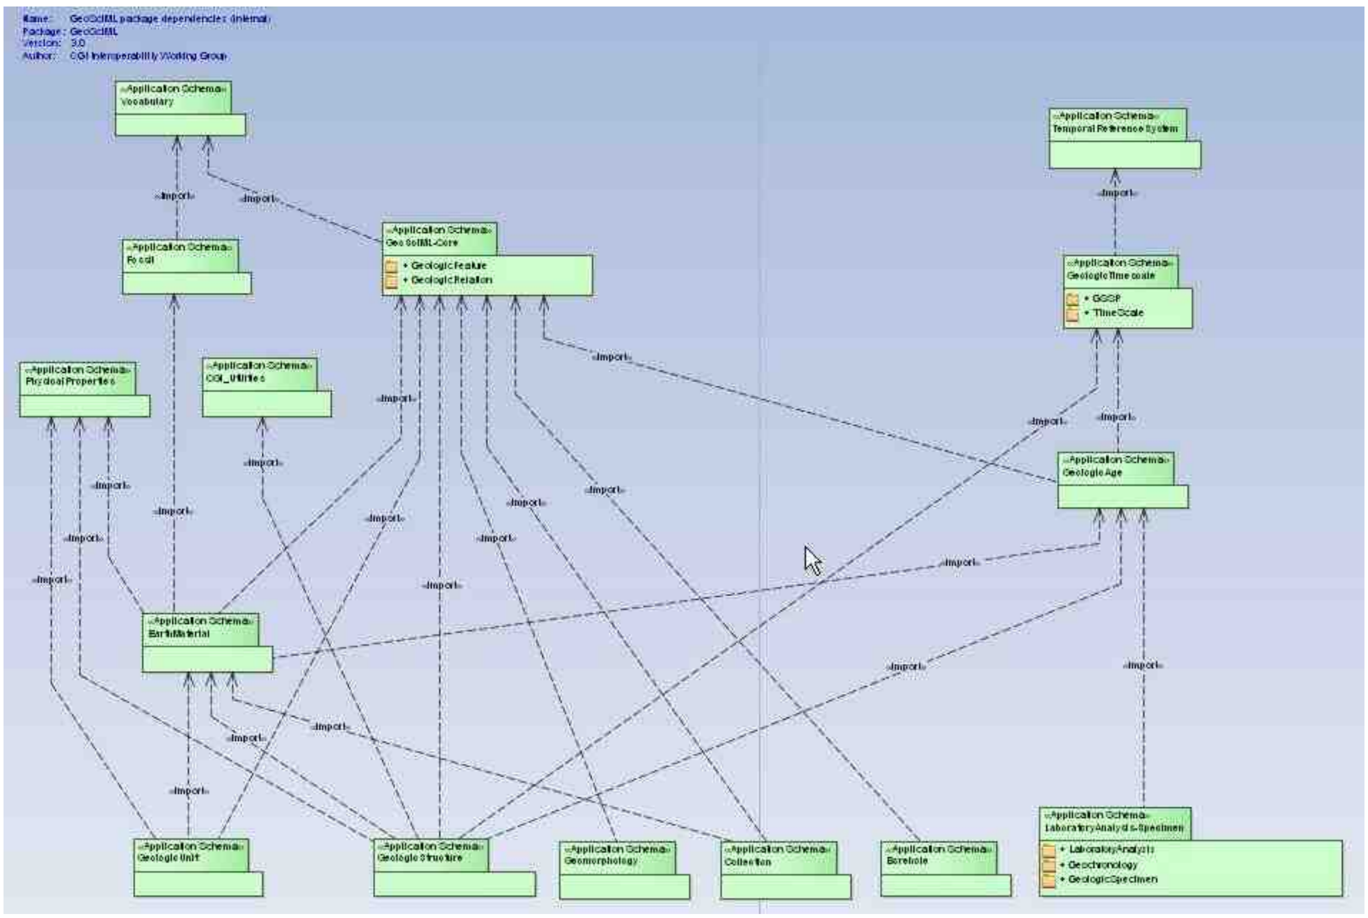

Fig. 2 - Schema sintetico del modello dati GeoSciML versione 3.0.

DATI UTILIZZATI PER L'APPLICAZIONE DEL MODELLO

I casi di applicazione del modello GeoSciML sono principalmente tre: il progetto OneGeology-Europe, il Test del modello dati INSPIRE e le attività di sviluppo dell'IWG che implementa il modello dati stesso.
Nel progetto OneGeology (http://www.onegeology-europe.eu) si sono utilizzati i dati della Carta Geologica d'Italia alla scala 1:1.000.000; il database Geo1MDB (CIPOLLONI et alii, 2009; CIPOLLONI et alii, 2011) si basa sulle descrizioni della legenda della carta associate ad ogni unità geologica (es.

litologia, cronostratigrafia, ciclo orogenetico, eventi geologici, eventi tettonici, caratteri strutturali, ambiente deposizionale, petrografia, grado e facies metamorfica). Nel progetto durato due anni si scelto di armonizzare i contenuti semantici degli attributi primari come: età, litologia, ciclo orogenetico, grado metamorfico e tettonica, sia per la ristrettezza temporale del progetto sia perché erano quelli in cui l'azione di armonizzazione risultava più semplice, senza per questo aver risolto tutti i problemi di armonizzazione nelle aree di confine.

Nel progetto di valutazione e applicazione del modello dati INSPIRE, invece il modello è stato applicato per valutare le difficoltà nell'armonizzazione a livello di contenuti su dati geologici di maggior dettaglio. In particolare è stato applicato ad un subset di dati del database dei sondaggi profondi, dove un operazione di allineamento ai vocabolari CGI è stata fatta con le informazioni relative all'età e alla litologia di una formazione. Nel database sono archiviate, ma non ancora armonizzate, tutte le informazioni relative alla cronostratigrafia, biostratigrafia, presenza di acqua e/o idrocarburi, nonché tutte le informazioni sulle caratteristiche della perforazione.

Un altro set di dati utilizzato per validare e testare il modello INSPIRE sono, per una porzione limitata di territorio, i dati del progetto CARG, relativi alle formazioni e alla geomorfologia.

L'applicazione di alcuni pacchetti presenti del modello GeoSciML 3.0 completo è stata fatta solo sui dati delle carte Geologiche alla scala 1:500.000 e 1:1.000.000, sia perché di più facile standardizzazione nei contenuti sia perché questi database sono di più facile gestione.

Il lavoro di armonizzazione dei contenuti, semplificato dalle nuove tecnologie di condivisione dei dati via web, non sarebbe comunque possibile senza specifici vocabolari comuni di termini. A tal fine gran parte del lavoro di applicazione e conversione dei propri dati verso il modello GeoSciML, nelle varie versioni valutate, ha richiesto grossi sforzi nel identificare le corrispondenze tra vocabolari di termini, realizzati all'interno del IWG del CGI e i dati dei propri database.

CONDIVISIONE DEI DATI GEOLOGICI

Il semplice esercizio di applicazione e valutazione del modello dati, nonostante rappresenti un'importante processo di analisi atto a migliorare ed integrare il modello e comunque suscettibile di nuove migliorie ed integrazioni, trova la sua massima espressione quando il dato via web diviene fruibile da più utenti.

L'accesso ai dati geologici del Servizio Geologico d'Italia si ha attraverso il Portale SGI (http://sgi.isprambiente.it/geoportal) e tramite servizi web di mappa (WMS) e d'interrogazione (WFS) attraverso una piattaforma multifunzionale (CAMPO et alii, 2011). Tali servizi dialogano tramite linguaggio di "encoding" GeoSciML in virtù dello sviluppo di connettore java (sviluppato dal BRGM nell'ambito del progetto OneGeology-Europe) che decodifica le richieste in entrata e uscita dal linguaggio standard GML a quello specifico GeoSciML.

Un ottimo esempio di integrazione di dati, omogeneizzati e armonizzati secondo il modello dati geologico, è fornito dal portale di OneGeology-Europe dove la web semantica supporta l'utente nell'interpretazione dei contenuti geologici.

RING and ReCal GPS networks: two Italian geodetic infrastructures and their data management, sharing and dissemination

ELISABETTA D'ANASTASIO (*), GIANPAOLO CECERE (*), CIRIACO D'AMBROSIO (*), LUIGI ZARRILLI (*), VINCENZO CARDINALE (*), FELICE MINICHIELLO (*), NICOLA D'AGOSTINO (*), ANTONIO AVALLONE (*), LUIGI FALCO (*), GIUSEPPINA ANTONELLA SETTE (**)

Key words: *GPS and GNSS networks, infrastructures, database and knowledge management.*

ABSTRACT

Geographic data sharing and collection are becoming key activities among geological and geophysical studies worldwide, and the recent increase of infrastructures is demanding to scientific and civil community an effort to manage and disseminate their products as efficiently as possible.

With this effort in mind, INGV (*Istituto Nazionale di Geofisica e Vulcanologia*) began some years ago to collaborate with civilian and commercial subjects in order to promote the integration and sharing of data from GNSS (*Global Navigation Satellite System*) networks existing in Italy.

Since 2004, INGV deployed a permanent, integrated and real-time monitoring GPS network (RING, *Rete Integrata Nazionale GPS*, http://ring.gm.ingv.it), which is now constituted by about 170 stations all over Italy (SELVAGGI *et alii*, 2006; AVALLONE *et alii*, 2010). All stations have high quality GPS monuments (D'AMBROSIO, 2007; MINICHIELLO *et alii*, 2010) and most of them are co-located with broadband or very broadband seismometers and strong motion sensors. This scientific network is aimed to monitor crustal deformation in Italy in order to study earthquake deformation processes, from interseismic strain accumulation to rupture processes, and is giving an effective contribute to Italian Civil Protection for seismic hazard monitoring.

Moreover, in the last years, local Authorities, nation-wide industries and other scientific institutions started to establish GPS/GNSS networks all over the Italian territory mainly for cartographic and positioning purposes. More than 500 CGPS stations are actually operating in Italy.

The INGV acquire and analyze most of these networks, promoting at the same time actions to integrate the RING with the ones managed by regional and national data providers (D'ANASTASIO *et alii*, 2010).

The Regione Calabria in 2009 planned and established a network of 17 GPS stations for cartographic and civil protection purposes covering the Calabria region (hereafter ReCal network). The GPS stations are good quality monument connected in real time and, in the next future, will start to furnish to the civil community a positioning service.

In order to share the RING and ReCal data and relative products, a synergy between the CNT-INGV (*Centro Nazionale Terremoti* of INGV) and the Regione Calabria started in 2011. An official agreement between the two institutions state the sharing of GPS data, the collaboration between CNT-INGV and Regione Calabria to test the efficiency and the positioning service of ReCal network, and the contribution of ReCal network to scientific monitoring of Calabria, one of the most seismically active region in Italy. Moreover, this agreement included also the commissioning of the ReCal network and of its positioning services performed by CNT-INGV.

Figure 1 shows the GPS and GNSS stations currently operating in Italy. In the inset it could be noticed how the RING and ReCal networks are integrated in order to have the best spatial coverage of the Calabrian territory.

We will present the first results of the agreement between INGV-CNT and Regione Calabria, and of the commissioning of ReCal network.

Moreover, we will focus on the infrastructure already existing and developed by CNT-INGV to manage data acquisition, storage, distribution and access (CECERE, 2007; CARDINALE *et alii*, 2010; FALCO, 2006; 2008; MEMMOLO *et alii*, 2010; PIGNONE *et alii*, 2009). INGV developed dedicated facilities including new softwares for data acquisition and a web-based collaborative environment for management of data and metadata. These facilities are used to manage data coming from the RING as well as from agreements with ReCal and other GPS/GNSS networks in Italy.

We believe that this infrastructure represents an important

Management and deployment of rock-analysis data from thin section - to field-scale

GAETANO ORTOLANO (*) & LUIGI ZAPPALA' (*)

Key words: *Database management, Geochemical and isotopic data analysis; Minerochemical data elaboration, Petrophysical properties; X-ray Map.*

INTRODUCTION

The acquiring, storing, processing and deployment of geological data, from syntax to conceptual point of view, have not always respected the harmonization rules. This is because, ample amount of freedom have been adopted responding to the various logical methods, which characterize still today the various schools of thought.

It is not uncommon, in fact, find today's heterogeneous systems where the various thematic mapping is not uniquely expression of the significance and/or of the complexity of information that is hidden behind the symbol, which should unambiguously represent field reality.

Information data lexicon and structures need now of a major harmonization in order to satisfy requirements of compliant between different systems of data mining. This is useful also to avoid the prevalence of a specific scientific culture, ensuring at the same time the usability and reliability of representation as well as the correct scientific rigor.

In order to realize a well organized system for Geoscientific Knowledge Management, the inspiration to the Australian project Auscope (i.e. auscope.org.au) is more than suggested. It is thus necessary to look at standard conceptual and logical schemes, where each geological feature is related to the others according to shared rules defined by international working groups for standardization.

In this view, the present contribution, largely based on the principles of the Geo-Scientific Mark-up Language (GeoSciML) (Laxton et al., 2010), intends to propose a logical model for rock-analysis data infrastructure able to allow: **a**) data storage based on more widely shared correlations lexicon; **b**) pyramidal views of differential scaled data; **c**) more reliable data comparison. GeoSciML proposes indeed a conceptual model that, following IUGS guidelines by means of international committee working group such as CGI (Commission for the Management and the Application of Geoscience Information), explores ontological, semantic and lexical aspects, in order to protect cultural pluralism, respecting at the same time the researcher intellectual rights.

DATABASE INFRASTRUCTURE

This project intend to streamlining and designing a GIS based information system applied to the field of petrochemical and petrophysical rock data analyses, able to integrate several types of geological data source differently obtained as for instance from: **a**) direct detection and measurement; **b**) remote sensing; **c**) instrumental analytical devices.

This project has the main aim to correlate and process field-derived and laboratory data analyses deriving from different scaled rock specimens, from mesoscale to several types of micro-analysis, such as SEM EDS (Energy Dispersive X-ray spectroscopy), EPMA (Electron Probe Micro Analysis), or isotopic analysis at the SHRIMP (Sensitive High Resolution Ion Microprobe), passing through thin section analysis via optical devices (i.e. optical microscope or high resolution scans).

With such a system could be possible to obtain, for instance, derived geothematic maps where each piece of information becomes usable even by remote systems, in respect of recent interoperability schemes proposed by CGI. In this view the interaction with other remote systems from which to draw and overlay mapped feature (e.g. Web Map Service) or alphanumeric data (e.g. Web Feature Service) can useful to complete correlation between multidisciplinary geological data sources (e.g. Lehnert et al., 2000; Spear et al., 2009) .

The conceptual scheme upon which is based the present proposal can be extrapolated by the GeosciML 3.0 application schema. As shown in Fig.1a, it is well defined the conceptual generalization of the Class "Mineral" in "Earth Material", where it is evident the correlation between the mineral and its physical-chemical attributes. Furthermore, these data types is now linked to the feature type "Observation and Measurements" (Fig.1b), which rigorously define the entire processes of laboratory analysis. In this way can be also possible to correlate all information about the analytical procedures, including also data instruments, operators, etc…, enhancing the objectivity and confidence of data output.

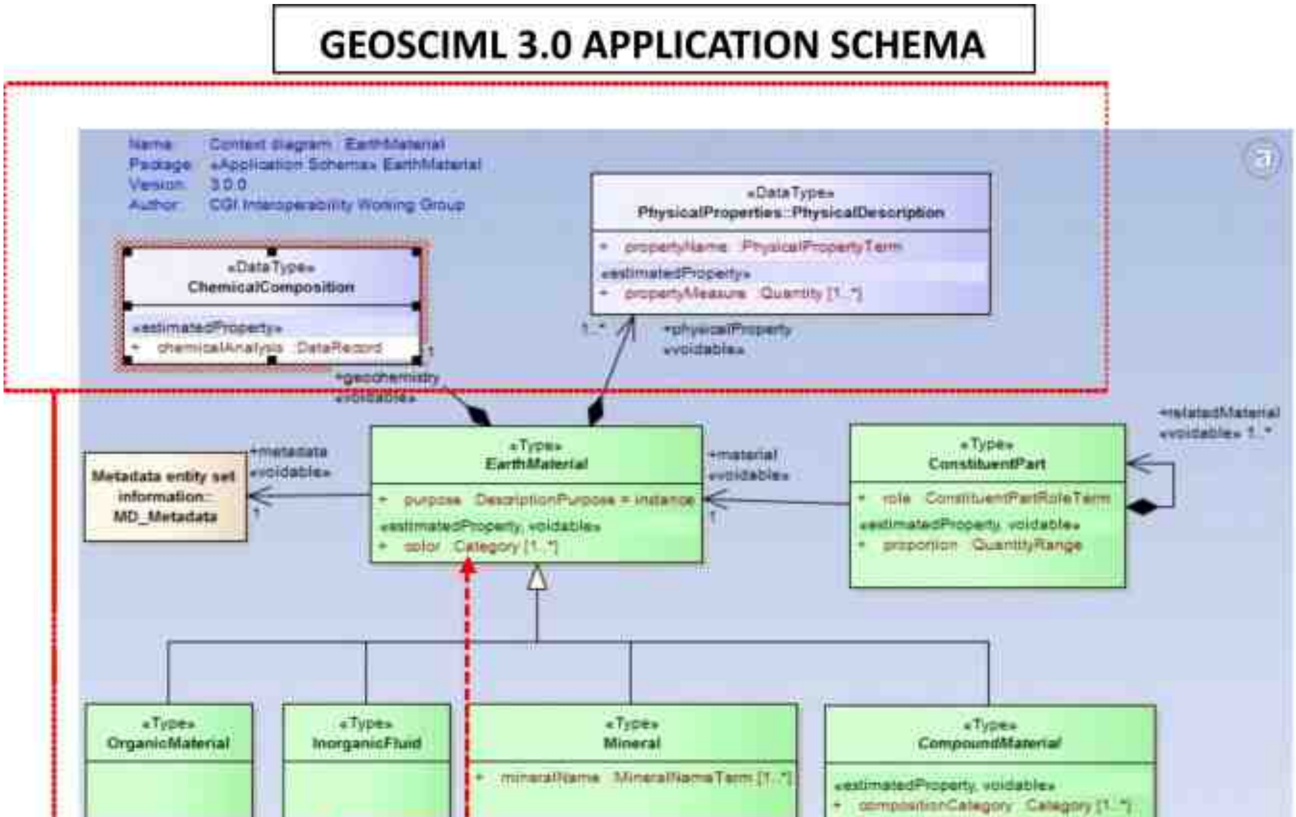

Fig. 1 – GeosciML conceptual model for the Earth Material class. **a**) Generalization of the class “Mineral” in “Earth Material”, where it is possible toobserve physico-chemical attributes. **b**) Conceptual Model of the class “Laboratory Analysis-Specimen”. This class extends the ISO19156 scheme “Observations, Measurements and Sampling”.

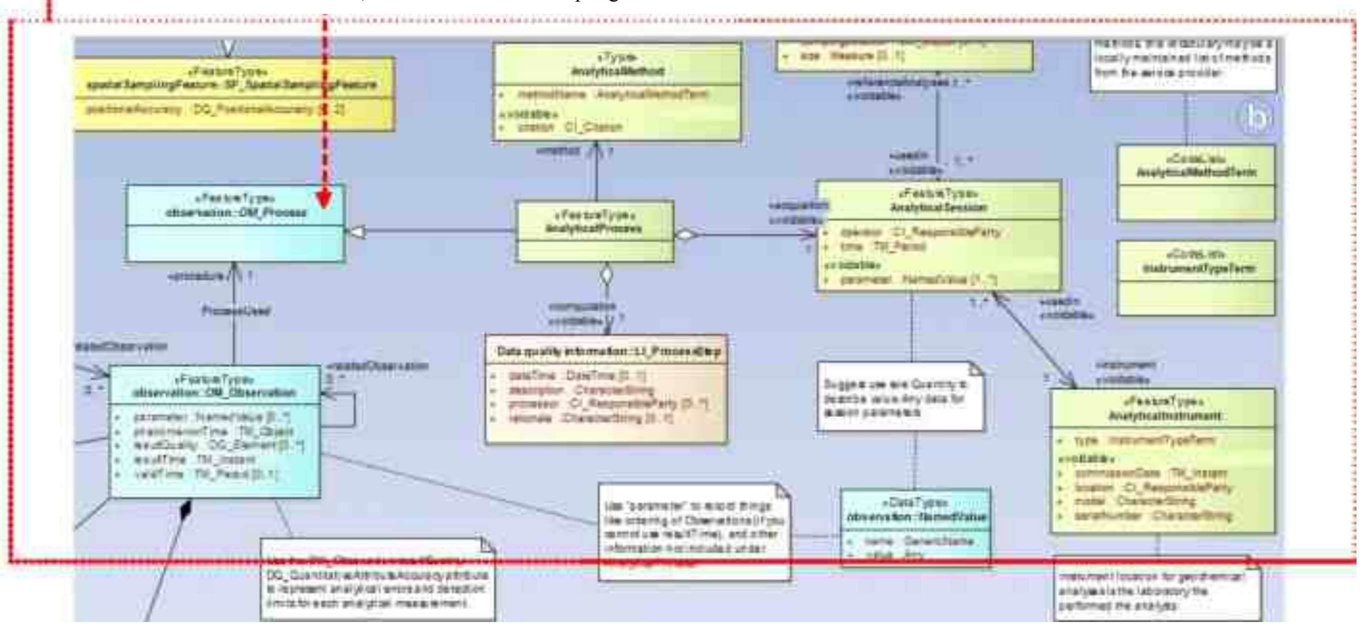

CONCLUSION

The infrastructural database model which would be propose with the present contribution (Fig.2) have the aim to correlate sampling collection activity, contextualized within field investigations job, to the more or less routinely performed rock analytical methods. This can permit to obtain useful correlation between environmental and geological phenomena linked for instance, at the occurrence of particular minerochemical-related geological activity (e.g. anomalous CO2 emmission). Such a model is indeed able to store and manage GIS based minero-petrographical data which have point sampling as geographic primitive, and a self-referencing system, provided by high resolution scanning of the thin section, as one of the starting point of data analysis (Fig.3). On the thin section are indeed possible properly identified domains for which can be performed mineral-chemical and isotopic data analysis as well as to make a series of calculations based on the statistical data handling of X-Ray Map (Fig.3).

Geodatabase: a tool for managing geological and geophysical data

E. PARTESCANO (°)

Key words: *relational geological database.*

ABSTRACT

The increasing necessity, to share data and metadata, at European scale, has pushed the European community to develop common rules. In this context the INSPIRE directive has grown.
Therefore, the growing need to standardize geological information, leads to develop an informatics tool, as a relational database, that allows to catalog and manage a large amount of data that can be used in a number of fields as to solve environmental or civil problem (CHANG & PARK, 2004).
In addition, a relational database gives the opportunity to join geological and geophysical information, this allows to have a global view of a complex geological area, as the Sicilian area (fig. 1), developed from a complex deformative events as consequence of the convergence between the African and European plates (LENTINI *et alii*, 1990; LENTINI *et alii*,1996).

The primary aim of this work is to build a tool finalized to collect

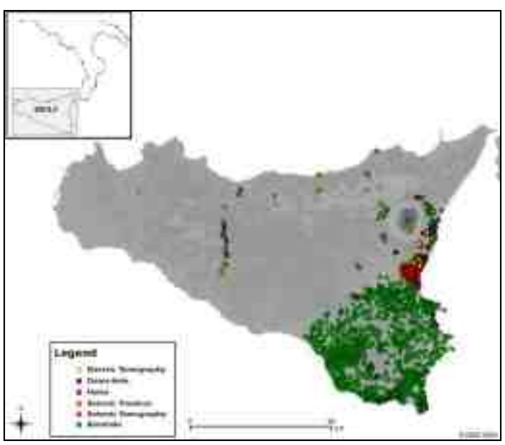

Fig. 1 – Geographical data distribution.

and manage several data, acquired using different methods (geological and geophysical), adopting Microsoft Access 2003.
The possibility to join geophysical and geo-lithologic elements gives the opportunity to focus the attention on the study of the recent tectonic processes and to study the morpho-structures of the Sicilian area.
The Geodatabase has a complex and unique architecture based on the features of the data entered and the search required.
The application allows to catalogue geognostic data (borehole data) and geophysical data (electric tomography, down-hole, noise data, seismic tomography, seismic traverse), using a relational system.
The creation of the application followed different phases, all of them had the objective to create a structure (tables, query, forms, macros) capable of managing the data.
The planning included five phases:
-the choice of the kind of the database (relational or not);
-realize the tables and the join between them (fig. 2);
-insert the records;
-test the recovery operations using the macro and the query

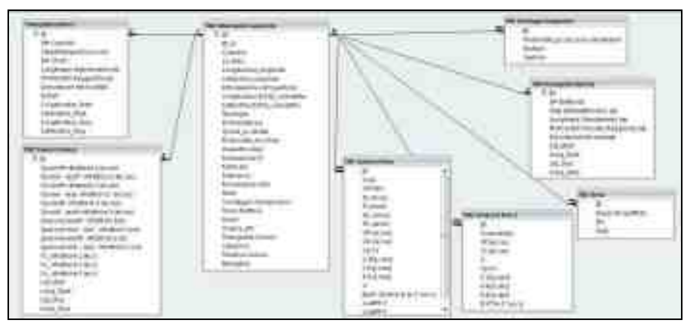

Fig. 2 – Relations among tables (PARTESCANO *et alii*, 2008, mod.).

expressed in a language such as SQL (Structured Query Language);
-realize an interface to extract and insert the data (PIRIOU & TRIPOLINI, 2004) (fig. 3).

In this Geodatabase, 3773 georeferenced geological and geophysical data were inserted: 81% of them are boreholes and

(°) Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS

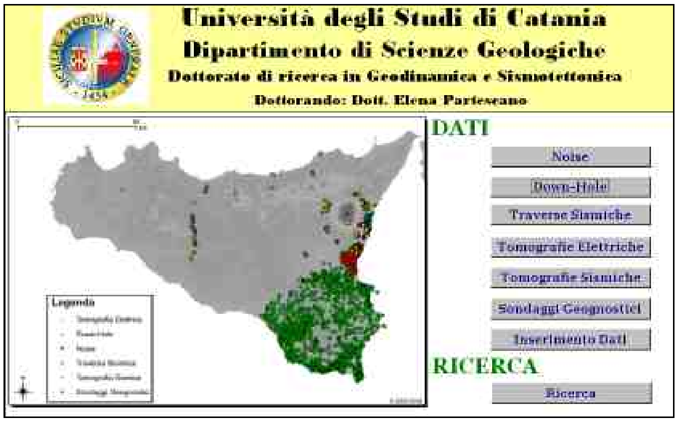

Fig. 3 – Database interface.

the 19% are geophysical data (fig. 4), principally localized in the eastern part of the Sicily (fig. 1).

Some applications of the database concerned: the use of the boreholes to invert 294 horizontal to vertical spectral ratio (H/V)

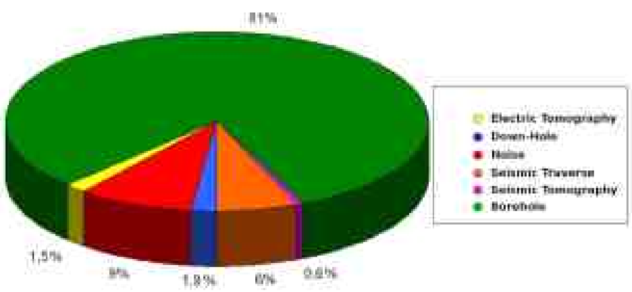

Fig. 4 – Data inserted into the database (expressed in percentage).

curves and study the seismic noise in the studied area (CASTELLARO *et alii*, 2005); the use at the same time of the geological and geophysical data to realize 19 geological cross-sections, to define the discontinuities in the substratum (PIERI, 2008); the database was an useful tool to extract all the boreholes contained information about the marly clay, the clayey bedrock, to study the different uplift rates in the area and propose a morpho-structural model, useable to study the volcano –tectonic evolution.

At last, using the values of the shear wave velocity (vs) inserted in the database, we calculated the average shear-wave velocity in the first 30 m of subsoil (vs30) and mapped the areal distribution of the parameter.

They are some examples of the use of the database, but many others could be the fields of applicability.

ACKNOWLEDGMENTS

Thank is due to the University of Catania in particular to Professor G. De Guidi and Professor S. Imposa. I thank to local municipalities and Dr. A. Privitera that contributed to improve the number of the data used in this work.

INTRODUCTION

The Garigliano Plain, located between Latium and Campania, has a surface of 240 km^2 and is an coastal/delta plain that filled up a graben generated by some anti-Appennine faults in the early Pleistocene. The same faults originated the uplift of the mesozoic carbonate massifs of Monti Aurunci (north-west) and Monte Massico (south-east) , while, eastward is present the Roccamonfina pleistocenic volcanic district. The fluvial discharge gradually filled up part of the graben and during the Tyrrhenian time shoreline was characterized by beach ridges that closed a wide bay with lagoons and marshes. During the following glacial phase, the sea level fell to about 120 m under the present one, and the Garigliano river locally eroded the ancient beach ridge. After the last glacial maximum the sea level rose approaching the present sea level about 6000 B.P. In this period new beach-dune ridges developed near the new mouth of the river and along the coast, and the area between the new and the old dunes was characterized by lagoons and marshes. During the last 6000 years a wave dominated delta developed at the Garigliano mouth.

At present the Garigliano delta plain (Fig. 1) is characterized, from the sea to landward, by an holocenic strand plain, by low and wet areas and by the Eutirrenian dune ridges, that separates the delta plain from the alluvial one (ABATE *et alii*, 1998). Remains of the colony of *Minturnae* are present on the Eutyrrhenian dune ridges at the inner margin of the low area present on right side of the Garigliano distributary. The ancient literature describes the landscape during Roman times indicating that the city was at the edge of a lake created by the river. But what was the real nature of the area between the shoreline and the city? There was a lagoon with an harbor? Which may have been the evolution of the area before, during and after the life of the Roman colony of *Minturnae*?

METHODS AND MATERIAL

The present multidisciplinary study is based on the following materials and methods:

- geomorphologic analysis from sets of aerial photographs and ancient cartography ;
- several cores carried out using a manual auger to acquire a first information about the thickness and the nature of sediments;
- drilling of three cores (up to 4.5/6 m depth), located according to previous investigations (point b), by means of an AF coring system produced by AFgtc s.r.l. (AMBROSIO *et alii*, 1999). Both equipment and technique were suitable for recovering continuous cores with preserved sedimentary structures;
- grain size analysis of the collected sediments by means of mechanical sieving and laser diffractometry for > and < 62µ fractions, respectively;
- ^{14}C datings, ^{13}C/^{12}C and C/N ratios, measured on specimens of the cored sediments selected according to the nature of the organic relics, stratigraphy and environmental implications;
- pollen analysis: 11 samples from top of core C1;
- analysis of archaeological and historical sources.

MORPHOLOGICAL FEATURES

Morphological elements characterizing the Garigliano plain consist: two system of beach ridges, trending NW-SE direction and referring to the Eutirrenian and to Holocene time and two different depressed areas between ridges. These depressed areas are separated by the Garigliano channel. The northern area on whose banks stood the town of Minturnae, has the shape of a triangle, with the minor cathetus that extends parallel to the river for about 800 meters and the major stretches, parallel to the Holocene beach ridge, about 1400 meters long. The bottom of the depression is about -1.5 meters above sea level. The analysis of historical maps showed that depression was partially submerged until the eighteenth century. The southern depression is shaped like a trapezoid that extends parallel to the coast for about 5 km with a maximum width of about 1200 meters. This depression, which locally reaches -2.8 m above mean sea level, was partially submerged until the nineteenth century. Both depressions are currently kept dry by land reclamation.

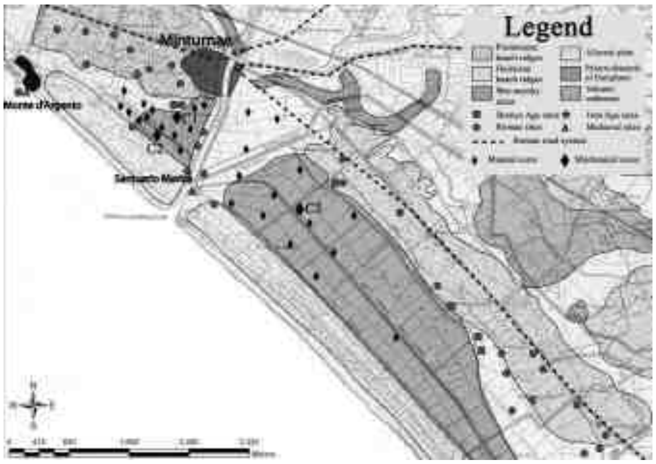

Fig. 1- Planimetric view of the Garigliano river mouth area (from FERRARI *et alii*, 2011).

STRATIGRAPHIC DATA

The sedimentary succession of the northern depression is recorded by cores C1 and C2 while the core C3 records the succession of the southern depression (Fig. 2).

The succession of the northern depression is characterized by lower unit, five meters thick, formed by soft peat with wood remains. Locally, thin silty-sandy level with rare mollusc fragments are interbedded. In core C2, the fauna present at about – -4 meter indicates a fresh/brackish environment. Peat pass upward, with sharp contact, to silt brown with rare remains of fresh gastropods. Thick of this member change from -75 to -165 cm. The age range of the peat member, measured by radiocarbon in core C2, is comprised between 8000 and 3000 years BP. In the central part of the northern depressed area (core C1), age of the top of peaty member is about 4000 years BP. Sedimentary succession of the southern depression is formed from a lower silty, about 2 meters thick, characterized by levels with abundant mollusc fragments that record a brackish to fresh/brackish environmental change from bottom to the top. Range of the age in this member is comprised between 8000 and 5500 years BP. To the basal member, follows, with sharp contact, a peaty member, 1.5 meters thick, settled between 5500 and 3500 years BP. Finally follows with transitional contact a silty member, about 1 meter thick. Silt is peaty at bottom and brown upward and it is settled in the last 3500 years.

PALINOLOGY

The most representative pollen belong to hygrophilous plants (like *Salix* and *Alnus*) and to hygro - hydrophilous plants (like Cyperaceae). The deeper samples, collected at the top of the lower unit, contain an epiphytic alga on macrophyte (Coleochaete) and plant tissues that indicate a eutrophic basin with fresh water and decaying vegetation. At about -165 cm (base of the upper unit) is recognizable a drainage event indicated by the drastic diminution of these plants. This phase correspond to change from peaty to silty units. Above this point we find still aquatic plants, but the context is quite different. The presence of *Myriophyllum alterniflorum* at -95 cm indicate that there is a basin with limpid and oligotrophic water. Just upon and below this deepness is present *Myriophillum verticellatum* that indicates respectively the beginning and the end of this period with water rich in calcium carbonate (PIGNATTI, 1982). Very few indicators of cultivations are recognized: some cereals (like *Hordeum* or *Avena-Triticum*), *Juglans*, *Morus*, *Vitis* and *Olea*. Sediments close the top conserve some pollens of Cichorioideae; Poaceae, Fabaceae and traces of *coprophilous fungi* that are indicators of pasture activities (MERCURI *et alii*, 2010).

HISTORICAL AND ARCHAEOLOGICAL DATA

Apart from a few witnesses, attributed to the Palaeolithic, recognized into the sand of the pleistocenic beach ridges and to remains of the Middle Bronze age located on the top of the *Monte D'Argento* (a promontory on the sea 2 km north of the river), many remains testify the human settlement close to Garigliano river mouth. On the right bank of the river, on the top of the Holocene dune and near the ancient marsh was built, in VII-VI century b.C. the Sanctuary of *Marica* where they were worshiped divinity linked to water and marshes (ANDREANI, 2003). The roman expansion, started in the region during the IV century bC., led to the foundation of colonies of *Minturnae* and *Sinuessa*, respectively north and south of the point where the *Appia* road crossed the river. Latin authors indicate the presence near *Minturnae* of an harbour and a wide lake. After the abandonement of *Minturnae*, the area was sparsely populated for many centuries (ARTHUR, 1991). The toponyms like *Pantano di Traetto* or *Pantano di Sessa* indicate that in the Middle Ages or later were present marshes and wet zones.

FINAL REMARKS

The analyzed data so far allow assume that during the last phase of sea level rise (8-6 ky BP) a bay/estuary developed in the southern area while further north developed a marsh. At the end of the postglacial sea level rise (about 6 ky BP) the fluvial sediments were sufficient for a more continuous development of the beach ridge, so also the southern area was isolated and brackish environment change in a fresh marsh. Both marshes (to the north and south respect to the fluvial channel) remained practically isolated, from the sea and the river, until about 3 ky BP (peat only occasionally interbedded by thin clastic levels). After, the peaty sediments were replaced by river silt releted to overbank events. During the Roman period *Minturnae* faced on a

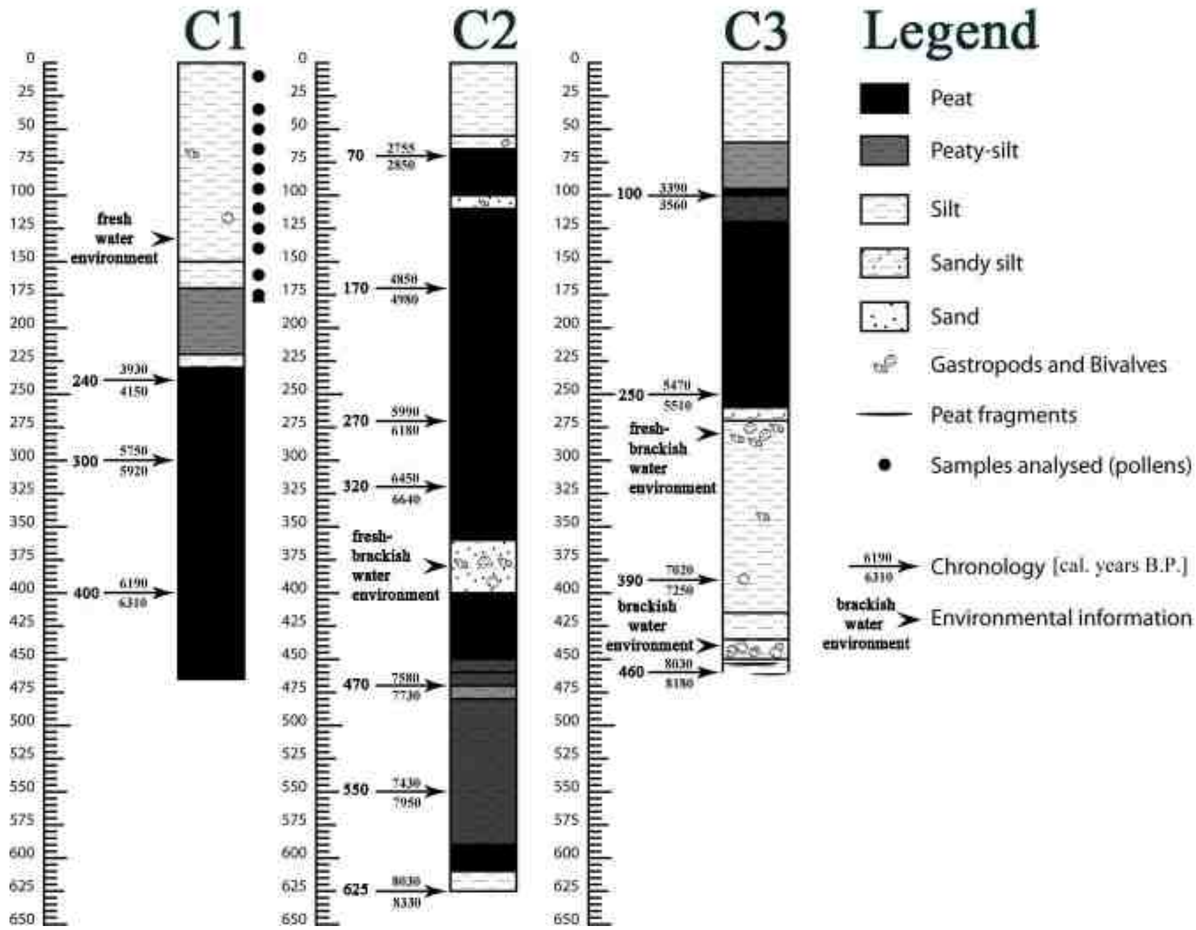

Fig. 2 – Stratigraphy of the three mechanical cores. (Modified from FERRARI *et alii*, 2011

fresh coastal lake with limited depth (< 2m) and, periodically, clear and oxigenated. These characteristics suggest a dock suitable for fishing, but not to a port use. Moreover, the presence of the remains of the Sanctuary of *Marica* on the rigth levee suggests that the river channel has not been significant shifts in the last 2700 years, according to the distributary dynamics in wave dominated delta. In Roman times the cultivated areas appear to be far away from coastal lake, from the Middle ages the area was mainly used for grazing.

The "Geological Heritage" of the Palatino Hill (Rome, Italy): landscape evolution, rock slope instability and anthropic modifications

BIANCHI FASANI G. (*), BRETSCHNEIDER A. (**), DI LUZIO E. (***)

Key words: *Geological Heritage, landscape evolution, row materials, rock slope instability, Palatino, Rome*.

INTRODUCTION

The Palatino Hill is among the main sites of the Roman antiquity. The western side, bordering an ancient tributary stream of the Tiber River - i.e. the Velabrum Valley - was occupied since the Iron Age, hosted the main settlements at the time of foundation (VIII cen. BC) and became an important religious and public area during the Republican and Imperial ages.

The original geological landscape of the area has been modified by almost 3000 years of urban development. Few evidence can still be observed on isolated outcrops (Fig.1), while well data archives can give some further insights.

In this work we try to outline the "Geological Heritage" of the site, this meaning we highlight the main aspects of the interplays between the geological characteristics of the area, the landscape evolution, and the site development during the Roman civilization.

Since the Middle Pleistocene the landscape evolution of the area was controlled by the eruptive volcanism from the Albani and Sabatini districts and the dynamics of the Tiber River (FUNICIELLO et al., 2008; KARNER et al., 2001; MARRA & ROSA, 1995; MARRA et al., 1998). Erosive fluvial process shaped sub-vertical rock slopes around the Velabrum Valley into the volcano-sedimentary multilayer. Using well data provided by the Archaeological Board and by VENTRIGLIA (2002) we reconstructed the main steps of slope erosion and valley infilling in the Velabrum Valley. This was useful to understand the main factors determining rock slope instability in the area.

After we analyzed the geological aspects and reconstructed the landscape evolution of the area, we collected evidence - on the Palatine western slope - of anthropic slope modifications. In particular, hole prints of Iron Age huts can be observed on a terraced surface close to the present slope edge, while ruins of restraining walls of different ages are found at the slope base. Such evidence suggests a long history of slope modifications, while the use of different rough materials reflects the development of the Roman civilization. Finally, we present the result of a recent study for the site remediation of the area, aimed to the reduction of the present rock fall hazard.

Fig. 1. Picture from the archive of the Archaeological Board (courtesy of C. Del Monti) showing the western edge of the Palatine Hill in the 30's. Tuff rock masses can be observed lying over sedimentary terrains on the right (southern) side of the slope

REMNANTS OF THE ORIGINAL GEOLOGICAL LANDSCAPE

Along the edges of the Palatine and Capitoline Hill few sparse outcrops remain as a witness of the geological evolution of the. We reconstructed the local stratigraphy by means of field survey and analysis of well data and old documents such as maps and pictures (Fig. 1).

Grey and white layered siltstones found at the slopes base testify to a fluvial-marshy environment in the Middle Pleistocene developed before the deposition of the volcanic units (since 0,6 Ma onward). Massive grey and red-brownish tuffs (the Palatino and Villa Senni unit, respectively) originated from pyroclastic flows erupted by the Albani Hills. These are inter-layered with air-fall deposits and layered tuffs from the Sabatini Mts. and with coeval sedimentary deposits. Sharp thickness variations of the pyroclastic units reveal paleo-valleys orientations.

LANDSCAPE EVOLUTION

Several cycles of valley erosion and deposition alternated in the peri-Tyrrhenian areas during the Middle Pleistocene-Holocene following sea level lowstands and highstands during glacial and inter-glacial periods, respectively. These processes featured also the dynamics of the Velabrum Valley, an ancient and no more existing left tributary of the Tiber River.
We reconstruct the main phases of the local landscape evolution basing on outcrop analysis and well data. The geological evolutionary model was adopted for the reconstruction of a multiple-step numerical model representing the stress-strain condition on rock slopes bounding the valley. This allowed us to investigate the reason s of slope instability in the area.

ANTHROPIC MODIFICATIONS

The oldest evidence of the site occupation are few circular hut print hole dated to the Iron Age. According to local archaeologists villages were placed on a terraced surface which was carved within the uppermost tufitic unit in the area after the removal of a thin, overlying clayey level. Moreover, remnants of three orders of retaining walls can be observed at the slope base. The first one can be dated back to the Royal Age (VIII-VI cen BC) and is made by 1 feet-squared blocks of grey tuffs from local quarries. Few elements of this ancient wall are preserved. A second order of retaining walls was built in the IV cen. BC during the Republican Age using "allochtonous" raw materials, such as 2 feets-squared tuff blocks coming from quarries in northern Latium ("Tufo Rosso a Scorie Nere" and "Tufo di Grotta Rossa"). These materials became available during the Republican Age after the Roman expansion in the Etruscan territory of Veio. Ruins of the Republican wall (Fig. 2) are found at different sites along the western slope of the Palatine Hill. Such outstanding opera was of a great meaning for the development of an area that, since the IV cen. AD, became the main religious site of Rome with the construction of new temples in the Hellenistic period (as the Vittoria Temple and the Magna Mater temple).

The last order of retaining walls was built during the Early Imperial Age (II cen AD), when the area of the Palatine western slope further developed with the construction of new buildings. Unlike to the dry-stone walls of the Royal and Republican ages, the Imperial wall was built using basaltic blocks cemented by a concrete containing volcanic ashes ("pozzolane").

Fig. 2. Ruins of the Republican Wall at the base of the Palatine western slope, right beneath the tuff rock slope..

PRESENT ROCK SLOPE INSTABILITY

Today the Palatine Hill is part of a wider archaeological area including the Roman Forum and the Coliseum. The western edge of the hill is restricted to visitors due to local hazard determined by potential rock falls from tuff rock masses. Rock fall hazard is a serious threaten to the local Cultural Heritage also, since the Royal Wall and the Republican Wall are in the close proximity of the slope (Fig 2).

Therefore, the last part of this study regards the analysis of the present-day slope instability investigated by means of kinematic analysis and a numerical model of the stress-strain slope conditions. (Fig.3). This effort was finalized to a non-invasive work for site remediation that could also be in harmony with the local environment, for the valorisation and future fruition of the area.

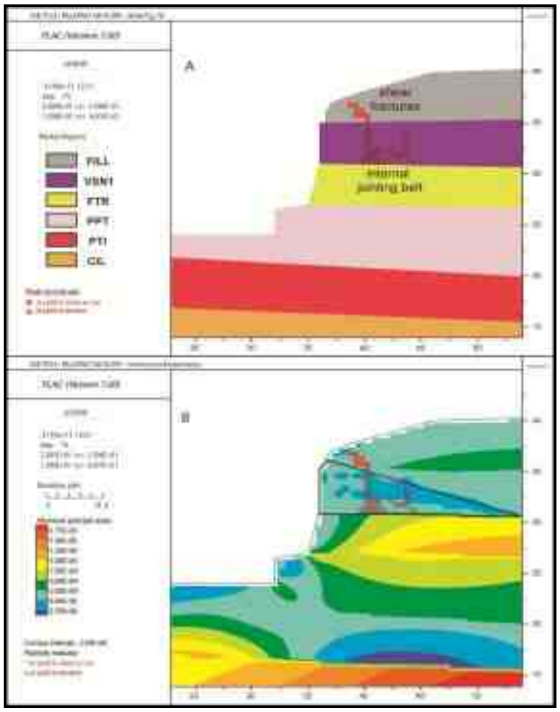

Fig. 3. Stress-strain numerical model of the Palatine slope behind the ruins of the Republican Wall.

CONCLUSION

In the area of the Palatine Hill several evidence of a strict relationship between the geological environment and the anthropic modification of the site over the centuries can be observed. Outcrops of tuff rocks provided the rough materials in the earlier moment of site development. Nevertheless, the instability of the rock slope made necessary the construction of retaining walls at different times. Even today, care must be taken to reduce the local rock fall hazard.

This evidence let us to use the term "Geological Heritage" to underline how even the geological and natural aspects of an archaeological or historical area can be considered part of the Cultural Heritage. For this reason, new preservation and valorisation strategies should be imaged.

Water supply and water circulation in ancient Pompeii: resource management and catastrophic events in the past as in the present

ANNAMARIA CIARALLO (*), ERNESTO DE CAROLIS (**) & MARIA ROSARIA SENATORE (°)

Key words: *Water supply, water circulation, resource, geologic hazard, Pompeii settlement.*

INTRODUCTION AND METHODS

One of the biggest problem to be addressed for the protection of Pompeii (Fig. 1), even in the light of the ongoing climate changes, is to regulating the water flow, that has affected the development of the city before the AD 79 eruption and today represents an hazard to the conservation of the archaeological site.

If the urban arrangement of the ancient city took into account the impact on the surrounding area, especially for what concerned the flowing of surficial water, it was only after the discovery of Pompeii, and especially since the second half of 1800, when the stratigraphic excavations brought to light several buildings, that the relationship between the ancient city and its surroundings deeply transformed by AD 79 eruption, began to be a problem. Each sector of the ancient city became a sort of well drilled in the pyroclastic deposits. Also when, with the widening of the excavations, the excavated sectors were connected to each other, the surficial water that flowed on the old topographic surface could not find its natural course toward the present-day surrounding area especially after the deep changes that occurred over the centuries following the other eruptions and the man actions.

The work here presented is part of a wider research which aim is to reconstruct, through integrated studies on stratigraphy, sedimentology, flora and archaeology, the natural landscape prior to the eruption of Vesuvius in AD 79 (CIARALLO *et alii*, 2003, 2007; PESCATORE & SENATORE, 2005; PESCATORE *et alii*, 199, 2001; SENATORE *et alii*, 2009, 2012). This research was performed using 28 drill cores carried out over a wide area around the ancient city. Using the stratigraphy of these new drill cores as a reference, about 400 stratigraphies of old drill cores have been re-interpreted. One archaeological dig in the archaic city and one section located laterally to the Guard Tower n. 10 along the northern city walls were also studied. Data deriving from digs and the section, integrated with archaeological information, were very important for the final interpretation. Two samples were dated by AMS radiocarbon analysis using animal bones recovered one in the dig in the archaic city the other from the section at the Guard Tower n. 10. A walking survey in the ancient city has allowed to reconstruct the organization of the water circulation in Pompeii before the AD 79 eruption.

BRIEF HISTORY OF THE EXCAVATIONS

In 1748 the direction of the excavations, episodic and aimed to look for the beautiful object, was assigned to the engineer J. de Alcubierre: the Villa of Cicero and the Herculaneum Gate to NW, and the *praedia* of *Julia Felix* to SE were discovered. In 1764, the direction of the excavations passed to Francesco La Vega, which focuses its research in the Street of Tombs, discovering Villa of Diomedes, and in the south of the city, bringing to light the Odeon, the Grand Theatre, the Triangular Forum and the Temple of Isis. The link between the two areas began with the French period (1806-1815) by Antonio Bonucci, who brought to light all the area of the Forum and the adjacent buildings. The land under which the ancient city was buried, was also acquired, and the surrounding walls were fixed.

The return on the throne of Ferdinand of Bourbon hampered the extensive program launched by the French, but some stunning discoveries, such as the baths of the Forum, the House of the Tragic Poet, and especially the House of the Faun, aroused the interest of Francis I, ascended the throne in 1830, who gave new impetus to the excavation campaigns, especially along major roads, for connecting the upper part of the city with the Forum.

With the unification of Italy the new Director Giuseppe Fiorelli, organized a comprehensive program of excavations carried out with the new methods of the archaeological research, ie removing the eruptive materials, going down in the stratigraphy, allowing the recovery of all data related to buildings. In the following decades, the direction of the Pompeii excavations was characterized in particular by Michele Ruggiero (1875-1893) and Antonio Sogliano (1905-1910), who, in addition to continuing the excavation campaigns, began a comprehensive restoration of buildings and decorations of the ancient city, seeking also to make

Fig. 1 – Ancient Pompeii today. The unexcavated northeastern side of the city is visible.

understandable the town, gradually unearthed, at scholars and visitors.

Further progress in the research was conducted by Vittorio Spinazzola (1911-1923) by digging Abundance Road, to link the Civil Forum to the Amphitheatre, located at south-eastern end of town. In 1923 the direction of the excavations passed to Amedeo Maiuri (1923-1961), who undertook the last excavation campaigns on a large scale in the city, in particular with the discovery of the House of Menander and neighborhoods next to the Great Palaestra, and the continuation of excavation of the Villa of the Mysteries.

RESULTS

The meandering course and delta of the ancient Sarno channel, identified by boreholes was located at least 1 km south of the ancient city walls like the modern river channel. Furthermore a difference in altitude of about 30 m had to be present between the edge of the ancient city and the alluvial plain. Following these data the Sarno does not seem to be a possible source of water for the city.
Our research leads to find out that another fluvial system once reached the town by a channel directed toward Pompeii from the base of surrounding hills located about 14 km to the NE. Boreholes data collected N and W of the city indicate that the channel was artificially cut toward the W, supplying the city with water. Evidence of this western flow course is also provided by the pollen spectra in borings and excavations N and W of Pompeii, including poplar, willow and cultivated plants, which required water supply. That channel flowed then toward Villa of the Mysteries, and finally to south along the western city margin likely collecting the city's waste-water before discharging in a delta formed on the coastal margin SW of Pompeii.

The water circulation inside of the city had a strict organization with built structures diverting the water flow toward specific neighborhoods (*regiones*) and blocks (*insulae*).
In the boreholes we also identified three units referred to volcaniclastic flood deposits. Root structures between units indicate that some time may have passed between flood events. They reached probably the city by way of the artificial channel and overflowed hitting and damaging Pompeii before its final disappearance because of the Vesuvius eruption.

CONCLUSIONS

Our research shows that catastrophic events have occurred in the Pompeii territory in the past. The connected deposits are very close to the sediments related to the alluvial flows that have affected in the last fifty years the Campania region, and that are linked to episodes of high rainfall.

These events make the area with very high hydrogeological hazard. The recent collapse that occurred in the ancient city induces to take steps to protect the excavated structures. In any case the protection of Pompeii from the hydrogeological hazard cannot be solved if it is not put in relation the evolution of the excavations with that of the surrounding area starting by the definition of the state of the sites before the transformations made by the eruptions.

Exploring the landscape of Northern Campania in Roman times and the route of the Appian Way from Sinuessa to Capua

CLELIA CIRILLO[1] GIOVANNA ACAMPORA[2] LUIGI SCARPA[3] & UGO ZANNINI[4]

Key words: *Ancient Topography, Landscape, Modeling, Roman Age*.

The present study aims to contribute to the knowledge of historical and topographical landscape of Northern Campania starting from the section of the Appian Way passing through the heart of Campania Felix. Having been the Appian Way almost completely abandoned during the early Middle Ages and restored only from the late eighteenth century, studying the eighteenth-century maps we can obtain useful information for the reconstruction of places. The route of the Appian Way between Sinuessa and Capua has long been among the least known and most problematic traits of the Queen of the Regina Viarum despite being the most described road section by the ancient literature; throughout history various studies have been performed to reconstruct this section of the Appian Way, but only in the second half of the twentieth century the correct reconstruction of the entire path of the Appian Way between Sinuessa and Capua is reached, thanks to the topographical studies carried out by Antonio Sementini. The valuable information provided by Sementini, confirmed by Guadagno investigations were complemented by the studies of Ugo Zannini which with further archaeological and documentary evidence made it possible to substantiate and clarify the reconstruction carried out by Sementini. The realization of this important road artery represented for the Roman civilization the birth of the complex and efficient road network that connected Rome to the whole Mediterranean basin, thus becoming not only indispensable for the wide ranging territorial accessibility but also a fundamental element of the anthropic landscape.

The road infrastructure in Roman times becomes one of the main tools to organize man's space not only from the physical point of view; all the roads become in fact the grid by which the human life develops altogether. Considered the extension of the road network in Roman times, it can be easily imagined how the landscapes have evolved over the centuries with distinct modes depending on places, populations and ages; the ancient road networks have structured and influenced the transformation of landscapes being crossed by their road layouts. The section of the major road artery being considered in this study is that referred to the hinterland located north of the Campania region; after having crossed Minturnae, city of Ausone origin on the border between Lazio and Campania, the Appian Way, passing over the bridge over the River Liri -Garigliano and wedging in the narrow strip of land between the sea and Monte Massico, reached Sinuessa, maritime colony located at the southern edge of Liri plain. In Sinuessa the Appian Way turned away from the coast towards the inside of Campania Felix through the ager Falernus, unique countryside where orchards, vineyards, olive groves, wheat fields and woods outlined a landscape of high environmental interest. After crossing the ager Falernus, in Casilinum on Volturno river, the river port of the city of Capua, the Appian Way joining the Latin Way crosses the big bridge heading straight over the west gate of Capua. From this city, in a second step, the Regina Viarum continued to Calatia, Vicus Novanensis and Benevento in to reach in 190 BC the most important seaport connecting Rome to Greece and the East. The landscape of Northern Campania, already characterized by the work of the Italic people, was strongly characterized by the Appian Way, whose path appeared full of rustic villas, vici, pagi and fora as shown by the archaeological remains from the Roman Age. The poster shows a thematic map aiming at representing the reconstruction of the historic landscape of Northern Campania crossed by the Appian Way; the maps being realized in GIS environment were built using an interdisciplinary approach. It should be premised that the researches referred to the environmental characterization of this part of Campania rely on a broad enough knowledge as the area has been subject of several topographical studies; to support the knowledge of the landscape of Northern Campania in Roman times as well as of the section of the Appian Way from Sinuessa to Capua, a study was carried out focusing on the location of the archaeological finds and monitoring the landscape of ancient footprint; then a map was realized to define the shape of the landscape of historical origin,

using historical maps; the reconstruction of the morphology of the sites was made based on the existing land use in the eighteenth century resulting from the analysis of the historical maps and according to the reconstruction of the Appian Way between Sinuessa and Capua realized on a scale of 1:25.000 by Ugo Zannini (Zannini, 2002).

Sea level changes, ground deformations, human settlements in the bay of Naples

ELENA CUBELLIS (*), ILIA DELIZIA (°) GIUSEPPE LUONGO (°), FRANCESCO OBRIZZO (*)

Key words: *Bay of Naples, Ground deformations, Human settlements, Sea level changes, Neapolitan volcanoes.*

Ground deformations (soil uplifts) in active volcanoes are considered precursors of eruptions according to the most tested models; therefore monitoring networks of ground deformations are installed on inhabited dangerous volcanoes. Direct measurements of such deformations are carried out since 1861 when Luigi Palmieri monitored the eruption at Mt. Vesuvius with levelings along the shoreline near the town of Torre del Greco. Relative sea level changes were measured at Serapeo in Pozzuoli in the middle of 19^{th} century to record soil uplifts which are locally known as bradyseism. To enlarge the time series of data on these phenomena it is necessary to utilize historical and prehistorical informations on the location of shore-line of human settlements. It is common practice to spread to research on earthquakes, tsunamis, eruptions, by analyzing documentary fonts and relics left by ancient peoples. When the historical data are poor, to enlarge the time series of events for deeper knowledge of the natural history of investigated sites, the research is devoted to geological processes and particularly to the location of marine terraces in respect to present sea level.

As regards the regions of active volcanoes as the Neapolitan one three processes contribute to sea level changes as eustatism (LAMBECK *et alii*, 2004), regional tectonics and local intrusive and effusive phenomena. Therefore at the same time the relative sea level should be different at far-away places only few kilometres according to the volcanic activity. In fact eustatic and tectonic processes contribute to sea level changes with very lesser rates than volcanic activity.

The Neapolitan region for its geological history is an excellent laboratory for testing the validation of new paradigms for some natural phenomena. The geological structure of the Neapolitan area, located in Campania Plain, at the margin of Tyrrhenian Basin, is formed by the succession of effusive and explosive rocks as lavas and pyroclastic products erupted by polygenic and monogenic volcanoes. Moreover this area is characterized by shallow seismicity capable to produce high intensities in small epicentre areas.

The whole range of phenomena observed, in particular the present stress field, as is amply shown by seismicity, recent tectonics and chemism of magmas feeding active and recent volcanoes can be accounted for in relation to a local mantle upwelling, a lithosphere plate bending and subsequent collapse. The measure of tectonics contribution to relative sea level changes is obtained by the velocity of sedimentation of rocks forming Campanian Plain due to tensile processes during quaternary time (LUONGO et *alii*, 1991 a). This value is of about 1-2 mm/yr in accordance with the results observed in other areas characterized by active tectonics. It is $10\text{-}10^3$ times less than that observed in active volcanoes (Figg.1,2).

Eruptions and earthquakes occurred in the Neapolitan area, have produced myths, legends, historical documents, archaeological findings.

The name Campi Flegrei (Fields of fire) of the district including the town of Naples with its western suburbs suggests that manifestations of volcanism were evident in Ancient Times. This area was once a preferred location to the entrance to Hades. It is caldera complex, formed by collapse of the ground following two giant eruptions (Campanian Ignimbrite, 39 ka and Neapolitan Yellow Tuff, 15 ka). Part of the structure is submerged to form the Pozzuoli Bay; the landward floor is peak marked by tens of volcanic cones (D'ARGENIO *et alii*, 2004). Campi Flegrei attracted special attention during the nineteenth century, thanks to the Serapeo, ruined roman market in Pozzuoli, which had been submerged by slowly sinking and re-emerged from the sea, due to a rapid rising of the land before 1538 Mt. Nuovo eruption and the well known 1970-72 and 1982-84 crises (Bradyseism) (LYELL, 1872; BERRINO *et alii*, 1984; LUONGO *et alii*, 1991 b) (Figg.3,4).

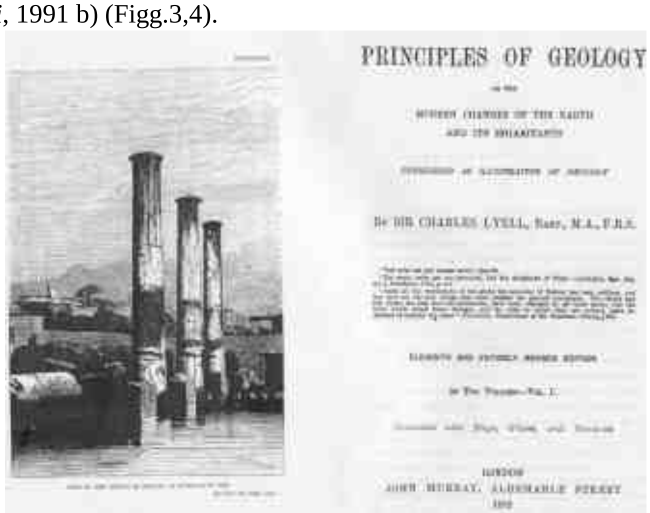

Fig.3 - View of Macellum (Temple of Serapis) in 1836. Frontispiece of "Principles of Geology" by Charles Lyell.

The investigation of submerged roman ruins at many places round the bay of Pozzuoli let us to reconstruct the ancient coast line which had fallen some meters but it was rising to the present level as recorded upon columns of the Macellum (Temple of Serapis) by the hollows of the lithodomi in historical times, and by geometrical levelings in recent times. In the environs of Pozzuoli the land within short distance of the coast terminates in a cliff of moderate elevation (30-40 m). It is interpreted as an ancient coast line and the inland marine terrace, called "La Starza", evidences a ground inflation which occurred 8-4 ka ago (OBRIZZO *et alii*, 1991). Evidences of the subsidence of the Phlegrean area derived also from the investigation on the ancient harbours of Puteoli, Avernus, Misenum, Nisida, located at short distance one another along the coast of the Bay of Pozzuoli. The largest and best known roman breakwater is that of Puteoli, called "The bridge of Caligola". This consist of tall piers which must originally have been at a convenient height above the surface of water, while they were 1-2 m below it at the beginning of XX century (GÜNTER, 1903). Now the piers are concealed from view with the new breakwater of the harbour.

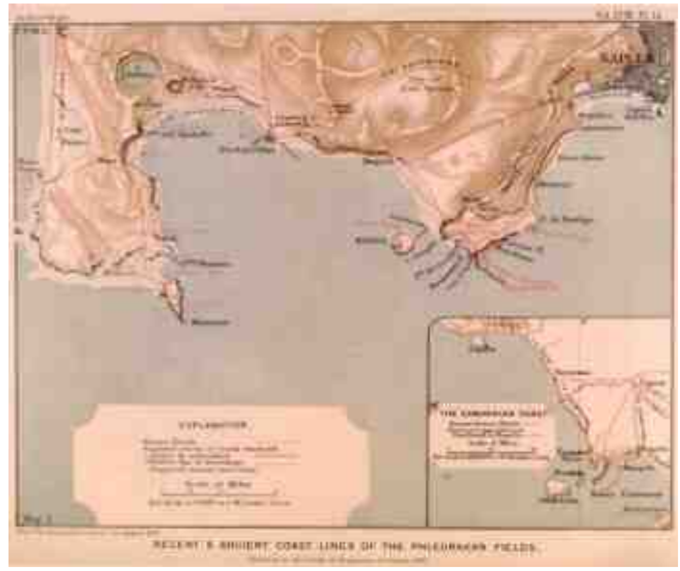

Fig.4 - Coast line of Campi Flegrei in Roman times. «The discovery that one submerged "rock" after another showed clear signs of artificial origin was so fascinating, opening as it did a new field for research, that we were led to add to our geographical investigation a survey of the sunken antiquities» (GÜNTER, 1903).

Vesuvius has acted like a powerful magnet from time immemorial, drawing people to settle on the fertile soils (Bronze Age), to wonder at the beauty of the landscape as tourists, or to undertake scientific investigations. Eruptive activity in Vesuvius area dates back about 400 ka according to the stratigraphic and radiometric data on volcanic products and paleosoils from the borehole drilled down to depth of 2200 m b.s.l. in the southern side of the volcano for geothermal exploration. The volcano edifice formed only in the last 25 ka when the volcano produced at list five large-scale plinian eruptions and smaller scale subplinan eruptions. Some archeological relics of the Bronze Age in the eastern part of the Campanian Plain are covered by fall products of the plinian eruption of 3800 yrs BP, known as Avellino eruption. Instead the eruption of 79 AD, is described in the letters of Pliny the Young; at present quantitative analysis models of the mechanism of this eruption utilize the detailed descriptions of Pliny. Before the 79 A.D. eruption Tacitus and Seneca wrote about the damage caused by the strong earthquake which struck the town of Pompeii and surroundings in A.D. 62 (CUBELLIS *et alii*, 2007). In light of recent archaeological and epigraphic evidences this earthquake with the subsequent low-moderate energy seismic swarms have been considered as precursors of the A.D. 79 eruption, responsible for the destruction of Pompeii and Herculaneum and of the displacement of the coast line offshore, of about 400 m, by the occurrence of dense pyroclastic currents which reached the sea.

Archaeological and geological surveys carried out onland and offshore between Herculaneum and Pompeii show that at present the coast line at the time of 79 AD eruption have sunk of about 4 m. As the eustatism contributes to this value only for an amount of about 1 m, the large part of the subsidence was caused by the long term tectonics of Campanian Plain and volcano dynamics with uplift before large eruptions and sinking afterwards.

The island of Ischia was the site of the earliest known Greek settlement in Italy. Strabo mentions that Greek colonies abandoned the island repeatedly in consequence of the violents of the eruptions, earthquakes and tsunamis that took place in Pythecusa since the 6th century BC. Pliny the Elder, in his Naturalis Historia writes that on the island of Ischia, the earth swallowed up a town and that after this catastrophe a lake was formed (Lago del Bagno?). This eruption was dated by the 6th-5th century BC pottery remains (BUCHNER, 1986). About historical seismicity more comprehensive accounts are available for Ischia island since 1228.

We have considered a possible relationship between volcanic activity in the island and large sea level changes during the late Quaternary. Eruptions may be triggered by loading and unloading the crust owing to change in sea mass. Seven phases of activity have been distinguished in the Island since 150 ka B.P. Two major activity phases (1 and 7 in fig.5) occurred between 140 and 123 ka and in the last 18 ka when there was a continuous sea level rise of about 130 m and 125 m, respectively. Instead at 55 ka B.P., when the catastrophic caldera forming Mount Epomeo Green Tuff (MEGT) eruption occurred, the sea level showed some oscillations up to 50 m (4 in Fig.5).

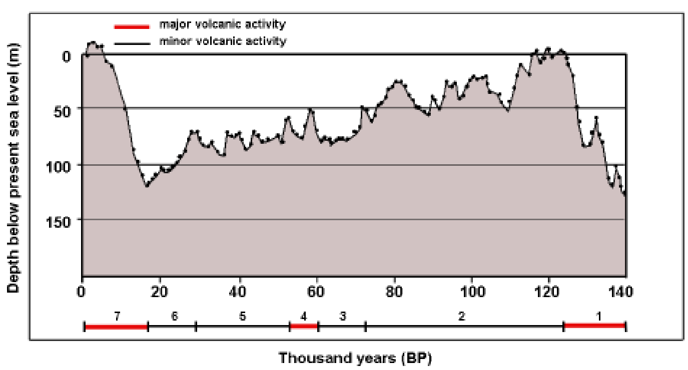

Fig.5 - Late Quaternary sea-level variations (after SHACKLETON, 1987, modified) and volcanic activity of Ischia Island since 140 ka B.P.

The caldera depression was filled – at first in sub-aerial and subsequently in submarine conditions – by the MEGT and pyroclastic deposits of the eruptions occurred in the island between 44 and 33 ka B.P. These deposits were involved in an uplift process starting between 33 000 and 28 000 years ago, forming the Mount Epomeo block. Total uplift, deduced from the present height of marine deposits and eustatic variations, is 710 m on the southern flank and 920–970 m on the northern flank, with an average uplift rate of 2.3 and 3 $cmyr^{-1}$ respectively (BARRA *et alii*, 1992; TIBALDI & VEZZOLI, 2004). Today Greek and Roman ruins may be observed along the island coast line, submerged under the sea. According to archaeologist the ruins have sunk by about 2 m. Geographers comparing 16th century and current maps of the island infer coastal subsidence of about 1 m (FRIEDLAENDER, 1938; CARLINO *et alii*, 2006).

Molecular analysis of ancient Greek human remains

STEFANIA DEL GAUDIO (*), ALESSANDRA CIRILLO (*), GIOVANNI DI BERNARDO (*), UMBERTO GALDERISI (*), THEODOROS THANASSOULAS (*), THEODOROS PITSIOS (°) & MARILENA CIPOLLARO (*)

Key words: *Ancient DNA, DNA typing, Real-time PCR.*

One of the applications of molecular biology techniques is represented by the possibility to study ancient DNA (aDNA) recovered from human, animal and vegetal remains (HOFREITER *et alii*, 2001). Huge collections of materials from these sources are available in European Museums and Superintendences. They contribute considerable knowledge to our cultural heritage when considered to serve both as cultural-archives and as bio-archives. Much literature has been produced on aDNA, spanning from the origin of the humankind (KRINGS *et alii*, 1997), the arise of ancient societies, spreading of disease, alleles haplotyping (DI BERNARDO *et alii*, 2002, 2004, 2009), museum collections classification and conservation genetics (LEONARD, 2008).

Studies of DNA in archaeological remains are based on the Polymerase Chain Reaction (PCR) amplification of molecules that have not been destroyed over time by diagenetic processes (PRUVOST & GEIGL, 2004).

The object of this study are nine human bone fragments of skeletons collected in the in Greek Museum of Anthropology of University of Athens (Fig. 1).

DNA was extracted from bone powder using a guanidinium and silica-based method (BOOM *et alii*, 1990; DI BERNARDO *et alii*, 2009).

We confirmed the ethnic origin of the remains analysing the human mitochondrial control region (ANDERSON *et alii*, 1981), the most variable region of the mitochondrial genome. Most polymorphisms are concentrated in two hypervariable segments (HVS1 and HVS2) of the control region, one of which encompasses the origin of replication, while the other lies within the (D) loop itself. We amplified and sequenced a region spanning from nucleotide 16022 to 16424 of the HVS1 (Table 1).

We also determined the biological sex of five bone remains by amplification of amelogenin (AMG) alleles located on both X and Y chromosomes (ANDREASSON *et alii*, 2002) (Table 1).

Since previous anatomical studies on these skeletons indicated the possible presence of β-thalassemia, the β-globin gene will be amplified and sequenced screening for the many mutations that account for β-thalassemia in order to confirm the presence of the disease. In the countries bordering the Mediterranean basin, the most common β-globin variants are IVS I-1, IVS I-6, IVS I-110, CD-37 and CD-39 (MORENO *et alii*, 2002). We designed primer pairs to amplify the specific DNA fragment

Fig.1: some of the skeletal materials object of this study.

Sample	mtDNA polymorphisms	Probable haplogroup	Sex (AMG alleles)
B1	NT	/	-
B2	16093 T>C 16311 T>C	K	XX

Holocene episodic subsidence and steady tectonic motion at the ancient Sybaris (Calabria, southern Italy)

LUIGI FERRANTI (*°), ROSSELLA PAGLIARULO (**), FABRIZIO ANTONIOLI (***),

ANDREA RANDISI (****)

Key words: *Relative sea-level changes, tectonic displacement, boreholes, archaeological markers, Holocene, Calabria.*

Intense Holocene subsidence is documented at the ancient Sybaris (GUERRICCHIO & MELIDORO, 1975; CHERUBINI *et alii*, 2000; Pagliarulo, 2006), one of the most powerful among the Greek colonies collectively known as *Magna Greacia*. Sybaris flourished along the Ionian Sea coast of north-eastern Calabria since 2.7 ka BP and lasted until the end of the Roman empire, when it went progressively concealed below the ground (PUGLIESE CARRATELLI G., 1974; PALADINO & TROIANO, 1989; GUZZO, 1998; GRECO & LUPPINO, 1999).

This site, however, represents an anomaly in the regional tectonic frame of Calabria, which is characterized by strong uplift since the Middle Pleistocene (for a review see FERRANTI *et alii*, 2010). Large uplift is also well documented in north-eastern Calabria around Sybaris (CUCCI, 2004; FERRANTI *et alii;* 2009; SANTORO *et alii*, 2009). The anomalous subsidence at this site was previously explained as the product of localized compaction of peat and mud levels (CHERUBINI *et alii*, 2000; PAGLIARULO, 2006), which overwhelmed the effect of regional uplift and coastal aggradation and progradation (CUCCI, 2005). Existing models for the RSL history at Sybaris, however, have made use of average rates for individual processes, rates which in some cases were extrapolated from regional estimations.

Our study of the Latest Pleistocene-Holocene evolution of Sybaris (FERRANTI *et alii;* 2011) , that we summarize and expand in this contribution, involved analysis of the relative sea-level history for individual borehole logs, based on re-calibration of published ages and stipulation of nominal sea-level positions related to each marker. For investigation of the shorter-term (historical) evolution, we undertook a novel compilation of geological and archaeological sea-level markers supported by new radiometric ages.

Appraisal of the position of dated markers, when compared to a sea-level curve built on purpose for this coast using an updated glacio-hydro-isostatic (Lambeck) model, indicates a locally intense difference in vertical motion between boreholes located away from, or close to, the ancient town. Specifically, whereas data from the basement of the archaeological layers document large subsidence, more distant sites behaved differently. A site ~2 km to the NW of the settlement was apparently stable throughout the Holocene, and a site ~6 km to the SE experienced uplift at ~1.5 mm/yr since 0.6 ka BP.

In addition, our analysis reveals temporal changes in subsidence pattern in the archaeological area. Large (5-6 mm/yr) Early Holocene subsidence at Sybaris slowed down to ~1.5 mm/yr during the middle part of the Holocene. The slowing-down trend continued during and after historical occupation at ~0.8 mm/yr, a value similar to the long-term (35-40 ka BP) rate established upon the deepest boreholes samples. These data are interpreted as suggesting that sediment compaction affected the basement of Sybaris during the Early Holocene, and progressively ceased during historical times, when a tectonic signal prevailed.

Although the possibility of extensional collapse of the central part of the plain, and/or of a negative gradient in regional uplift toward the coastline should not be discarded and possibly contributes to the displacement budget, the historical vertical motion appears controlled differential growth of active folds documented by morpho-tectonic studies on-land and seismic profiles analysis in the offshore of Sybaris (FERRANTI *et alii;* 2009; SANTORO *et alii*, 2009). Whereas location above a syncline caused tectonic subsidence at Sybaris, the regions to the north and south record stability or uplift that reflects transition to growing anticlines.

Although Greeks and later on Roman colons were attracted by the estuarine environment of the Crati river for settling, because of the suitable conditions for navigation and trade, in the ultimate they choose an unfavorable location. River flooding was certainly important and possibly entailed the tale of destruction of the archaic Sybaris by hands of Crotonians enemies in 510 B.C. (Herodotus, *Histories*). However, the inescapable punishment for Sybaritic sins so remarked in the literary tradition was accomplished by growing folds.

Palynology of archaeological sites: the example of economy and human impact of the Metaponto area (6th-1st century BC)

FLORENZANO A., MERCURI A.M.

Key words: *cultural landscape reconstruction, archaeological sites, Metaponto area, palynology.*

INTRODUCTION

Most of the biological archives, including pollen, upon which past environmental reconstructions are based, responds to both climate change and human impact. The latter is clear and visible by definition in layers from archaeological sites thanks to the plant remains trapped in sediments.

According to Faegri *et alii* (1989), plant remains help to recognise different types of land use: a) exploitation of plant resources; b) cultivation, i.e. the planting and care of useful plants; c) breeding carrying out the increase of pastures and selection of unpalatable plants by animal browsing; d) settlements with spreading of ruderal and nithrophilous plants, or of plants preferably living in trampled areas.

Pollen and Non Pollen Palynomorphs - NPPs (a set of other microscopical records of biological origin, mainly including fungi and algae) are especially useful to discriminate these types of actions. Moreover, the comparison between off-site and on-site data provides more detailed information about the impact of the human activities in shaping the natural environment settled by human groups (MERCURI *et alii*, 2011).

The Metaponto area has been investigated since the '70s by the Institute of Classical Archaeology of the University of Texas, under the direction of Prof. J.C. Carter. The area is a good example of the continuous interaction between humans and environmental setting that is at the base of the development of an agricultural civilization. In the Hellenistic period, this area was occupied by the *chora* of Metaponto, the agricultural hinterland of the ancient Greek city, with an organized road network, as well as of an efficient irrigation and drainage system (CARTER, 1980, 1987, 1996, 2008; DE SIENA, 2001).

In the Metaponto area, the palynological research has been carried out on samples collected from archaeological contexts, mainly farmhouses and rural settlements. This allowed to improve the knowledge of plant species present and / or used in the sites, and environmental and land-use changes during the Hellenistic period and in following phases of occupation.

Materials and methods

Samples for pollen analysis were collected during surveys or excavations in the Metaponto area, between the rivers Bradano and Basento (Basilicata, southern Italy). Particularly, samples were taken from 4 sites situated in the *chora* and dated from the 6th to the 1st cent. BC (Fig. 1):

- Fattoria Fabrizio (FF; farmhouse to host one family) - 12 samples;
- Pantanello (PNT; Greek spring-sanctuary and Roman farmhouse with a tile factory) - 13 samples;
- Pizzica (PZZ; rural necropolis) - 5 samples;
- Sant'Angelo Vecchio (SAV; large farmhouse) - 95 samples.

Fig. 1 – Location map of the archaeological sites of the *chora* of Metaponto (Basilicata) studied for pollen analysis.

The samples are sediments collected from layers of exposed sequences opened within the archaeological structures, taking into account both stratigraphy and archaeological phases.

In some cases, besides pollen samples, carpological samples of about 5 l were taken from the stratigraphical

Laboratorio di Palinologia e Paleobotanica, Dipartimento di Biologia, Università degli Studi di Modena e Reggio Emilia (Italy).

This study is part of the project 'Ricerche archeoambientali in Metaponto' (2009-onwards; coordinator: A.M.M.); the research is funded by the Institute of Classical Archaeology, University of Texas at Austin (coordinator: Prof. J.C. Carter).

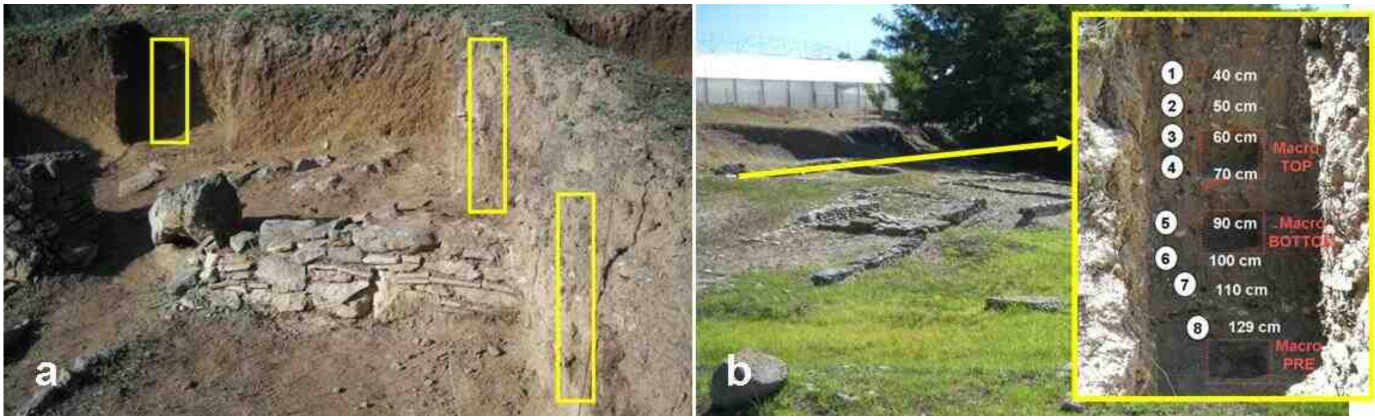

Fig. 2 – Examples of pollen sampling from exposed sections of archaeological sites; a) pollen sequences from an excavation's sector of Sant'Angelo Vecchio - SAV; b) pollen and carpological samples taken from Pantanello - PNT.

sequence in order to obtain more detailed information on past local flora (Fig. 2). Pollen samples were also collected from recent surface soils, a comparative methodology useful to check the composition of modern pollen rain near the sites.

Most of these archaeopalynological samples (61) were treated for the extraction of pollen grains according to the routine method for pollen analyses in use in the laboratory of Modena (FLORENZANO *et alii*, 2012a). The treatment of about 8 g of dry sediment per sample included heavy liquid separation with sodium metatungstate hydrate.

Pollen and NPPs were identified in the same samples. Identification was made at 1000x magnification with the help of keys, atlases and the reference pollen collection of Modena.

The macroremain samples were floated and sieved using a set of three sieves of 10, 0.5 and 0.2 mm meshes. The total residues were sorted under a stereomicroscope and the identification was made at 6x to 80x magnification with the help of keys, atlases and the reference carpological collection.

Results and discussion

Pollen was found in all samples. Pollen concentrations were variable depending on the richness of organic matter and the preservation conditions. Most of the archaeological samples (from FF, SAV and PNT) shows quite high pollen concentration, up to 35 x 10^3 p/g (FF; p/g = pollen grains per gram), and are sometimes even richer than the modern surface samples (FF, SAV).

All pollen types were recorded with different degree of preservation, from good to bad, in the same archaeological sample. Deterioration mainly consisted in folding of the grains and degradation causing thinning of exine (pollen wall). The number of identified taxa in archaeological samples varies from 9 (PZZ) to 69 (FF) taxa per sample, while in the modern surface samples the number of taxa amounts from 53 (PNT) to 66 (SAV) taxa. This suggest that, in general, the past biodiversity was rich and sometimes comparable to the current one.

Pollen spectra describe a territory covered by open areas, with arid grasslands, scanty woodlands and presence of local wet environments. In fact, between the identified taxa, herbs prevail (Asteraceae, Poaceae-wild group, Fabaceae, Brassicaceae and Chenopodiaceae), while forest cover is always low (< 20%) with dominance of Fagaceae (deciduous *Quercus* and *Q. Ilex* type) and Pinaceae. Typical Mediterranean shrubs, such as *Cistus*, *Myrtus*, *Phillyrea* and *Pistacia*, with *Helianthemum*, are present in small amounts. Although hydro-hygrophilous plants (Cyperaceae, Nymphaeaceae, Typhaceae and, among trees, *Alnus*) were found in traces, their presence is highly indicative of wet environments.

Pollen evidence of cultivation and breeding are particularly evident in samples from farmhouses (FF; LANZA CATTI & SWIFT, in press). Cereals are generally few (< 2%; the large pollen grains of cereals are commonly under-represented; BOTTEMA, 1975), and include oat/wheat - *Avena/Triticum*, and barley - *Hordeum* group. *Olea* pollen is fairly well represented in all samples (mean: 2,8%; max.: 13% - SAV) suggesting the this tree was an important element of the agricultural economy of the region. Moreover, plants from grazing environments, mainly Asteroideae and Cichorieae (FLORENZANO *et alii*, 2012b), are very important in the majority of samples suggesting that animal breeding should have had a central role in the economy of the *chora*. The presence of dung of grazing animals is evident from coprophilous fungi (*Sordaria* type and *Sporormiella* type; VAN GEEL *et alii*, 2003) which were observed in all samples.

Plant macroremains from food plants have not been found so far, while some indicators of presence of fodder and pastures were recognised in the analyzed record (*Euphorbia helioscopia*, *Lotus*, *Onopordum* sp., *Reseda luteola*; FF).

Conclusive remarks

The archaeobotanical record from the archaeological sites of the Metaponto area has showed that the economy of the *chora* was mainly based on the grazing and breeding activity, while it was only partly dedicated to the cultivation of trees (olives) and cereal fields.

Pollen results indicate that the natural environment surrounding the sites has had a strong 'imprint' by human presence during the Hellenistic period.

Grazing / breeding and agricultural activities practised around the farmhouses of the Greek colonial system shaped the landscape. Open grasslands were surrounded by shrubby grasslands and a maquis, probably more extended than today, characterised this territory in the past.

South-western area of the Forum of Cumae. Analysis of fabrics and pottery productions

GIOVANNA GRECO (**), BIANCA FERRARA (**), ANTONELLA TOMEO (**)

Fabrics, Cumae, Facem, ceramics, productions.

INTRODUCTION

The analysis of the ceramics excavated in the S/W area of the Forum of Cumae is aimed at drawing a general picture of the production, through an archaeometric study, which can help to identify the characteristics of the composition of each *fabric.*

The research, specifically focused on the fabrics, is included in the project FACEM[1] (www.facem.at). The main objective of this project is to develop an online database of ceramic *fabrics* from the Central Mediterranean, included the site of Cumae, to be achieved through preliminary autoptical examinations, followed by the selection of samples, and the observation with a microscope, to identify the texture of the fabric, as well as the presence and nature of all impurities. The photographic documentation of the analysis is performed with a microscope using different magnifying lenses (8x, 16x, 25x), and added to a database, which already contains fabric samples from several sites of Magna Grecia.

It is a first attempt, using a systematic approach, to collect in relational online database all information concerning the fabrics defining the different Magna Grecia productions. The main objective is to obtain a general picture, which will enable a direct comparison among the fabrics, supported by the images available online. This kind of investigation, through a rather innovative method, also based on mineral-petrographic analysis, can contribute to clarify the dynamics of trade and the circulation of ceramic materials.

The analysis of the *fabrics* carried out on several samples of decorated archaic pottery, Ionian cups and black glazed ceramics can provide an interesting contribution to the debate concerning the areas the clay was collected from in the Phlegrean Fields (LIRER, PETROSINO, ALBERICO 2001, 55-75).

ARCHAIC CERAMICS

Ordinary household earthenware, characterized by red - brown, banded decorations has been examined (MUNZI 2007, 109-110, CUOZZO 2006, 88-91). This kind of production, generally a local one, shows a standardized repertoire, which can provide, in association with Ionian cups, an interesting contribution to the defining of the distinguishing features of specific workshops. All the materials included in the study come from the archaeological contexts circumscribed in the south-western area of the Forum of Cumae and inside the Temple with portico. The exploration undertaken in this area has enabled the reconstruction of a complex stratigraphic reality, which testifies a continuous occupation of the area from the VIII century BC (GRECO 2009, 33-37); nevertheless, since archaic levels have been reached only in few cases, much of the materials belonging to this phase were not directly excavated, but found after the removal from their original place. In the south-western corner of the forum, an area which was involved in an important urban planning project over the VI century BC, a pit has been investigated, with the consequent recovery of various items, possibly belonging to a religious complex. This is indicated by the high number of miniatures, as well as Late – Corinthian Kotylai and small dishes with linear decorations found. The deposit is likely to be referred to a religious area located nearby, which might have functioned all through the VI century BC, up to the V (TOMEO 2009, 67-68). The archaic materials under exam are to be referred to this sanctuary.

Ordinary decorated pottery document the whole formal repertoire typical of this class, with a high number of open shapes, mainly cups, alongside some closed shapes, such as little amphorae and olpai. The analysis of fabrics has made it possible to draw a comprehensive picture of the production, featuring three groups of fabrics. The first group, including a sample of 97 items, comprises three fabrics (CU-CC-7, CU-CC-8, CU-CC-9), characterized by a rather fine matrix and impurities to be ascribed to a clay collected from the Phlegrean area. Microscopical analysis has allowed the identification of slight differences, depending on production techniques and, above all, different firing temperatures.

Fig. 1 – Decorated pottery - Fabrics – First group.

*The project has been carried out bt the University of Wien, in cooperation with the University Federico II of Naples, under the scientific supervision of Professor V. Gassner and Professor Giovanna Greco.

Big and sincere thanks go to Professor V. Gassner, in charge of the projectr FACEM, and to Mrs Traplicher, who has contributed to the definition of each fabric.

(*) Università degli Studi di Napoli Federico II. Dipartimento di Discipline Storiche Ettore Lepore.

The data obtained so far support the hypothesis of a homogeneous production, probably to be referred to different workshops, using the same raw materials. It is important to point out that the use of these fabrics was exclusive over more than a century, from the end of the VII to the beginning of the VI century BC, providing the evidence for a standardization of technological processes, able to preserve constant features over time.

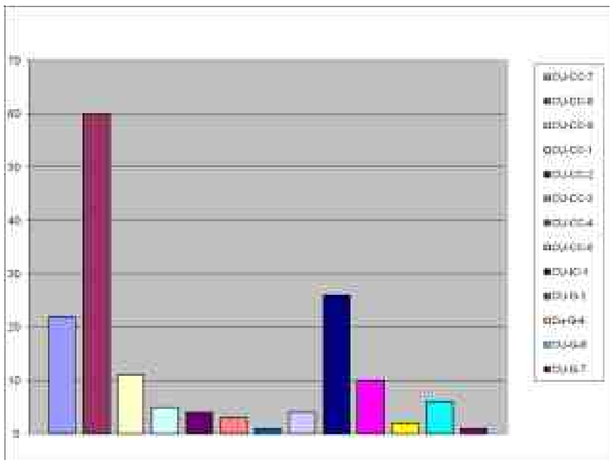

Fig. 2 - Decorated pottery –Fabrics graph.

The second group (CU-CC-1, CU-CC-2, CU-CC-3, CU-CC6), which includes fabrics typical of a local production of non decorated ordinary earthenware, is characterized by higher concentrations of impurities and it was used for the making of objects to be destined to specific purposes, such as bowls for food preparation. The third group (CU-G-4, CU-G-6, CU-G-7, CU-IC-1) includes those fabrics generally employed in the production of black glazed Ionian cups; in this case, the repertoire of available shapes is limited and almost exclusively made of cups.Ionian cups, recovered in the examined contexts together with ordinary decorated pottery, feature morphological characteristics which make it possible for them to be included in the type B of Vallet Villard classification, occupying a span of time which goes from 580 to the late VI century BC (VAN COMPERNOLLE 2000, 89-100).

a b

Fig. 3 - Ionian cups – a) Local fabric – b) Paestan fabric

The study of the fabrics can play a fundamental role in the debate regarding the production areas of this class. As far as the examined sample of Ionian cups is concerned, the use of aprovenance from Cuman based workshops. In order to better fabric (CU-CI-1), so well documented in the locally produced ordinary decorated ceramics, support the hypothesis of theirdefine exchange relations, it is very interesting to point out the presence of a fabric (PAE-G-5), featuring all the characteristics of pottery from Paestum, close to cups B2, with flared lip and round shoulder; a comparison can be drawn with various materials retrieved inside the Sanctuary of Hera at the mouth of the river Sele, therefore strengthening the hypothesis of Ionian cups imported from Paestum (FRANCO 2010, 424-425).

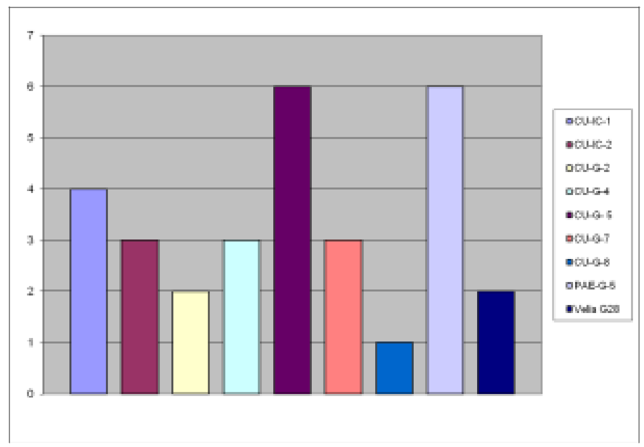

Fig. 4 - Ionian cups – Fabrics graph.

BLACK GLAZED POTTERY FROM THE TEMPLE WITH PORTICO IN THE FORUM OF CUMAE.

The analysis undertaken on the large amounts of ceramics excavated in the temple with portico in the forum of Cumae has also involved the black glazed items, one of the best represented classes from a numerical point of view.
The examined materials, unearthed in a rather heterogeneous context, where sealed stratigraphic unities are mixed with redepositions and big pits with residual objects, have cast a light on the late archaic and Hellenistic phases of the area, allowing a more precise chronological and typological definition of this ceramic class production.
In particular, the objects belonging to the phase of the life of a sacred area, stretching from the interior of the temple's portico to the outside western part of it, have proved to be the most informative ones; in the majority of the cases they can be dated to the first quarter of the IV century BC, skypoi, bowls, cups, little cups, miniatures and household earthenware. The area was gradually abandoned between the end of the IV and the beginning of the III century BC, as documented by the partial demolition of the structures, whereas the relative materials, belonging to this new phase, allow a better definition of the span of time in which each object remained in use.
The analysis of the fabrics has contributed on the one hand to identify the amount and the duration of imports from Greece, and on the other to try to circumscribe the local production of

black glazed pottery alongside probable imports from Paestum or Naples (Campana A) Fig. 5.

As far as imported wares are concerned, on the total analyzed samples, amounting to 294 items, 55 come from Greece; the relative fabrics belong to three groups (ATH-G-1, ATH-G-2, ATH-G-3), characterized by a rather fine matrix, almost free from impurities, or containing almost invisible ones. Attested shapes, in a span of time reaching up to the late V century BC, are mainly open shapes, Kylikes Bloesch C e skyphoi, whereas the closed shapes few are, virtually only lekythoi.

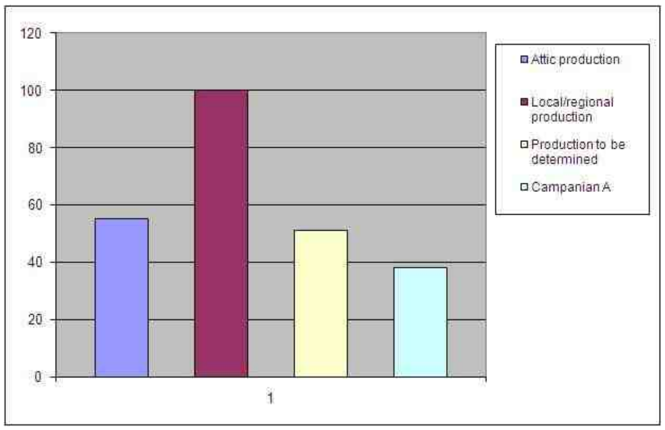

Fig. 5 – Productions graph.

The surface is covered by a layer of black glaze, applied with a brush, which results homogneous on the whole object and which rarely turns to greyish shades; this kind of coating, appearing closegrained and perfectly glued to the vase exterior does not present micro-cracks and appears to be polished, only in a few cases it shows metal reflections. Local production is characterized by the most numerous group of samples, belonging to 7 fabrics (CU-G-1, CU-G-2, CU-G-7, CU-G-11, CU-G-12, CU-G-13, CU-G-14), featuring matrixes which are similar in terms of composition, texture and the nature of impurities (Fig. 6).

There are several shapes belonging to these fabrics, such as kylikes, skyphoi, cups, dishes, lekytoi, olpai and jugs, which are to be referred to a rather long period up to the II century BC.

Fig. 6 – Probably local fabrics.

The surface is covered by a coating applied using a brush, of black colour, which has resulted homogeneous, but not always closegrained and perfectly glued to vase exterior; moreover, it appears opaque with metal like reflections.

Two more groups of items, associated with 2 fabrics (CU-G-10 e NA-REG-G-1), might contribute to define a production of Campana A ceramics, probably made in Naples; they are made of a very fine clay with several impurities of volcanic origin; the shapes which have been studied (patera, dishes, little cups) are typical of this production, the same holds true for decorations and chronological references of comparisons.

Not less important are the groups of fabrics (PAE-G-3, PAE-G-5, PAE-G-8) which are characteristic of the clay used in Paestum, supporting once again the hypothesis of a trade from Paestum to Cumae also for black glazed pottery; this kind of imports is already documented for Velia, from the archaic to the classical period and the examined materials, kylix Bloesch C, Cup-skyphos, skyphos type A, dated to the V sec. BC respect this chronology.

The Sanctuary of Hera at the mouth of the river Sele: non destructive analysis of archaeological finds

GIOVANNA GRECO (*), GIOVANNI PATERNOSTER (**), BIANCA FERRARA (*), MARIANNA FRANCO & MARIALUCIA GIACCO (*)

Key words: *Non destructive analysis, bronzes, Corinthian pottery, Energy Dispersive X-Ray Fluorescence.*

INTRODUCTION

In recent years, the analysis of archaeological materials coming from the sanctuary of Hera located at the mouth of the river Sele, only 9 km away from Paestum, in the province of Salerno, is being supported by a series of non destructive analysis on a sample of objects, aimed at better defining their composition, in order to isolate locally produced wares by imported ones.

The preliminary results of the research were presented during the IX International Conference ART2008 (GRECO *et alii*, 2008, 1-10) of Jerusalem and have been included in a recent publication on the excavations, which are being carried out at the sanctuary since 1987 (DE LA GENIÈRE - GRECO 2010). The research has been focused on those classes of materials considered the most significant for the life of the sanctuary: Corinthian pottery for the archaic period and bronzes.

XRF: THE APPLICATION OF TECHNOLOGY TO ARCHAEOLOGICAL RESEARCH

The decision of using *Energy Dispersive X-Ray Fluorescence* (EDXRF) technology lies in the possibility it provides to carry out measurements in a non destructive way, without the use of samples' fragments.

Measurements have been taken in the laboratory of Archaeometry, inside the Department of Physical Sciences of the University of Napoli Federico II.

The equipment used for this purpose is made up of an X-Ray tube (source), an X-Ray detector (the interaction of X-rays with an object causes secondary (fluorescent) X-rays to be generated. Each element present in the object produces X-rays with different energies to be detected) and a Multichannel connected to a PC, through a dedicated software. A helium flow system, working through the collimator of the X-Ray detector, has been employed in order to achieve a higher sensitivity in the investigation of a wide range of elements in the ceramic items to be examined.

As far as the bronzes are concerned (20 artifacts), single linkage *cluster analysis*, calculating Euclidean distances on three standardized variables (Cu, Pb, Sn), has been carried out.

As for the ceramics (16 artifacts), complete linkage *cluster analysis*, calculating Euclidean distances on six standardized variables (Ca, K, Mn, Fe, Sr, Zr), has been performed.

The analysis of the principal components (PCA) has provided the following distributions of the cases in the levels Fatt1-Fatt2 and Fatt1-Fatt3.

The analysis has made it possible, both for the bronzes and the ceramics, to put the artifacts into different groups, isolating, at the same time, some single objects.

BRONZES

The samples included in the research have been selected among more than 400 objects found in the area of the sanctuary, since they have been judged more representative and significant from a typological and chronological point of view. These materials, which are characterized by reliable chronological references, either based on the provenance or on the comparison with other typologies of similar objects well known in literature, cast a light on the different phases of life of the sanctuary. Eight of the artifacts included in the research date back to the archaic and late archaic phase; the following two date back to the V century BC; two more to the VI century BC and four belong to the Hellenistic-Roman phase.

The objective of this study, based on the accurate examination of the alloys' composition, is on the one hand a deeper understanding of the ways in which production can change over time, and on the other hand the a more precise chronological definition in the absence of reliable stratigraphic data.

The research suggests that the samples are mainly composed of tinned bronze and can be classified into two macro-groups, rather heterogeneous and differentiated inside themselves (Fig. 1).

The first group includes findings with a copper content ranging between 85 and 87,20%, whereas the percentage of tin goes from 6,92 to 13,20%, and the lead from 0,33 to 5,59%. This group includes seven elements; it has, therefore, to be considered a rather dishomogeneous group, showing samples, which are diversified from a typological and a chronological point of view.

(*) Università degli Studi di Napoli Federico II. Dipartimento di Discipline Storiche Ettore Lepore.

(**) Università degli Studi di Napoli Federico II. Dipartimento di Scienze Fisiche.

The second group comprises materials with copper contents varying from 61,00 to 73,10%, lower than the ones of the first group; lead contents are instead undoubtedly higher, ranging between 13,40% and 29,40%; tin is reported to go from 4,40 to 13,10%. This second group appears to be more homogeneous if compared with the former, especially because of the smaller chronological difference which characterize the samples, mainly classified as tableware; moreover, it is important to point out that three of them come from the same context, the second *bothros*, where they were probably laid down at the same time (FERRARA 2009). So far, analysis has reported a clear heterogeneous aspect in the values of alloy components, with variations of copper, tin and lead even up to 20-30 %. In general terms, ancient samples, dated back to the archaic period, between the VI and early V centuries BC, are characterized by high contents of copper and tin, with no lead traces, typical of a "pure" and precious alloy, to be used in the

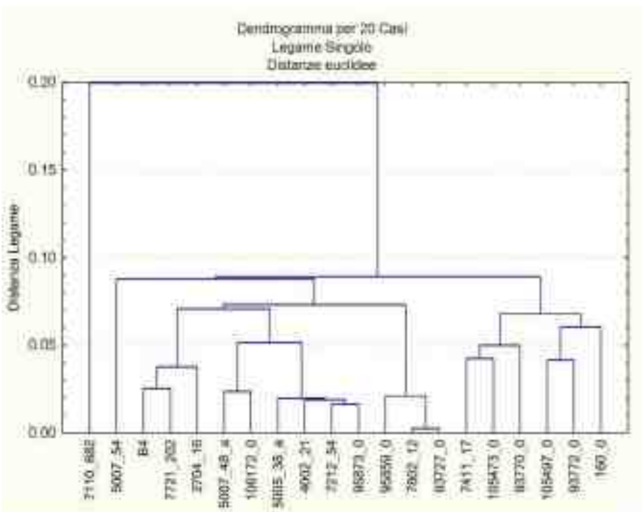

Fig. 1 - Complete linkage *cluster analysis* of bronzes.

production of luxury items.

The materials belonging to the period of occupation by local Lucania peoples, dated back to late V and III century BC, are characterized by lower percentages of copper and tin, compensated by higher lead presence, widely used for its cheap market price (GIARDINO 2010, 177; GIARDINO 2011).

In the light of these results, a different scenario can be imagined for the abovementioned period, in which a change must have occurred either in the religious practices or in the aristocratic classes ordering the artifacts. This change is reflected in the use of an impoverished and less precious alloy, although the differences in the composition of bronze can also be ascribed to a different area of raw materials supply or to widespread processes of bronze melting and reuse.

Further investigations are necessary in order to better define the composition of the alloys, to ascertain whether the differences in values depend on the nature, the function and the destination of the objects, as well as to production techniques or the chronological gap.

CORINTHIAN CERAMICS

Technological research on Corinthian pottery has been spurred by the recognition of a local production made in imitation of Corinthian pottery, already studied in the 30s (ZANCANI - ZANOTTI BIANCO 1937) and confirmed over time in literature (DUNBABIN 1968, 263; HOPPER 1949, 240; GRECO 1981, 59; CIPRIANI *et alii*, 2003).

The main objective of the analysis is to countercheck with scientific methods the hypothesis which has been formulated using traditional methods and, at the same time, to define the chemical, physical and mineral characteristics of the pottery imported from Corinth to Poseidonia.

As a first step, Corinthian pottery has been classified into five types of ceramic objects (DE LA GENIÈRE - GRECO 2010), respectively CC3, CC4, CC6, CC7, CC8, through an autoptical exam, which has outlined the variations in colour and texture, depending on how much purified, homogeneous and hard the clay was.

The samples selected for the research belong either to the group for which the hypothesis of a Corinthian provenance is not questioned (CC3, CC8), or it is very likely (CC4), but also more problematic ones have been included (nn. 1, 2, 3, 8, 9, 10, 12, 16); the clay they are made of is similar to local productions from an aesthetic point of view, showing, nevertheless, some formal and decorative feature which might point to imitation phenomena (Fig. 2).

The complete linkage *cluster analysis* undertaken, calculating Euclidean distances on six standardized variables (Ca, K, Mn, Fe, Sr, Zr), allowed a first consideration on similarity groups.

The dendrogram constructed with the obtained spectra (Fig. 3) shows alongside a numerically high and little differentiated group, which include the majority of the samples of the type CC3, CC4, CC8, an autonomous non homogeneous group (CC6, CC7), characterized by lower concentrations of Ca and higher contents of Fe.

This first result seems to confirm the hypothesis of an identical provenance of the three groups, proving with a high probability that the majority of the Corinthian ceramics found on site (from the three groups) is imported.

The analysis of the principal components (PCA) has provided the opportunity to describe the distribution of the samples, taking into account the probability that a point is closer to a group than to another. The distribution of the cases, both in the levels Fatt1-Fatt2 and Fatt1-Fatt3, shows a cloud of

points very close to each other, whereas samples corresponding to problematic cases (imitations?) are located on the edges, as single non homogeneous elements.

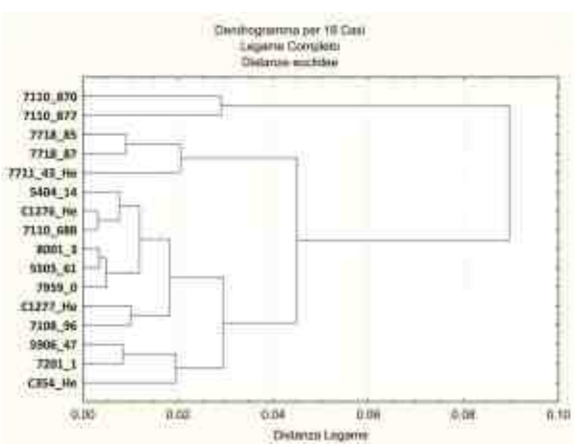

Fig. 3 – Dendrogram of Corinthian pottery samples.

In conclusion, analysis carried out so far enables, on the basis of the chemical composition, to circumscribe in the first phase of the research an extremely homogeneous group, numerically important, which can include a small group of samples on the border of similarity, to refer to the same production area. The analogies reported through the autoptical examination and the stylistic-typological analysis allow to identify this production with the Corinthian one. A comparison with the analysis performed on other classes of local production, such as coarse wares or black figured ones, might help to include these samples, now isolated, inside a wider and more articulated scenario of local or colonial groups and productions. The mineral-petrographic analyses undertaken on the same samples, still on-going, will allow to achieve a deeper understanding of the wares' composition, adding new value to the research.

Methodological approach for the evaluation of the sustainability of man made environments

IETTO F. (*) & SALVO F. (**)

Key words: *environmental sustainability, estimative analysis, quality of life;*

The present study is originated from the awareness that the Development, apparent through the production of Goods and Services, it necessarily has to create an increase of the Quality of Life, intending for Quality of Life not only the "comforts" but above all "environmental health" of the places. To such intention the rapid transformation and innovation of the territory of the last years, in which the conclusive element has been the application more and more increasing of grounds to exploit, has determined a notable advancement in the production of Goods and Services referred as "Quantity of Life" (Q_NL) in this work. This increase has been pursued with the purpose of improving the conditions of life, defined as "Quality of Life" (Q_LL). Therefore the Development of a territory should be understood as an effective summation of the Quantity of Life and Quality of Life (Q_NL+Q_LL). The uncontrolled and wicked recent exploitation of the territory has often determined the overcoming of its limits of sustainability, producing negative feedbacks. These conditions are identified in risks which will certainly reduce the Quality of Life,, with repercussions on natural Goods (landscape and resources), built (building patrimony), and finally on the resident society. An application of the illustrated concepts has been formulated for the inhabited area of Cetraro, situated on the Tyrrhenian coast of Cosenza. Here the increasing application of services (Q_NL), from the after war to today it is reflected in:

- expansion of the residences to the limit of the beaches with consequent destruction of the dune belt;
- cementation of the courses of water and edification of alluvial areas;
- realization of a seaport;
- realization of a railway line situated along the coast and by now to the limit of beach;
- construction of roads and highways (SS18) along the coastal strip.

All services led by the hectic "development" and performed in the absence of adequate planning tools or often modified to the necessity. The high production of goods and services (Q_NL) which would have had to produce the same quality of life (Q_LL), contrary to expectations, has responded negatively to reckless production of material goods, triggering irreversible negative feedbacks with repercussions on the existing goods (landscape, building patrimony, society). The greatest negative response of the territory is here represented by irreversible loss of the beaches due to: a) missed natural nourishment for stiffening, narrowings and reductions of the riverbed; b) high urbanization of coastal strip up to or beyond the natural limit of beach; c) alteration of the regime of the littoral currents following the construction of the seaport.

The estimation of coastal erosion has shown peak values up to -100 m in the time range from 1953 to 2004, which corresponds to an shoreline retreat of around – 2 m/year. The high erosion has made necessary, since 1980, the realization of breackwater, both offshore that onshore, to protection of the residential Goods and the streets of connection. Therefore it has been performed an armor plating, with breakwater, of almost the 90% of the coastline, currently deprived of beaches to advantage of the coastal protections. Direct consequence was an devaluation of landscape obvious and impairment naturalistic of the area. These conditions, representative of a reduction of Quality of Life (Q_LL), have an immediate effect of overflow both in the economic devaluation of immovable property, that of discomfort for the resident society. The economic devaluation has been calculated through the analysis of the historical data of the buying and selling of real estate in the city of Cetraro. The estimative analysis, on the residential buildings, investigates a defined time period, in this case, corresponds to the period 1999-2005. The methodology employed is due to multiple regression models but also to other estimation methodologies such as, for example, the *Market Comparison Approach* (SIMONOTTI, 2006) and others that fall into the estimated methods (APPRAISAL INSTITUTE, 2008) reported by the *International Valuation Standards* (2007). The results show that the economic value of the immovable property, in the reference period, experienced a sharp depreciation estimated in -10%. The quantification of the social discomfort can be displayed instead through the demographic discomfort of the Commune of Cetraro, currently among the Communes of Cosenza with zero- growth, and with demographic variation value of about -2% in the last years (Region Calabria 2011). Therefore the estimates developed on the value of the immovable properties and on the demographic data show that the reduction in Quality of Life can be operationally quantified through appropriate indicators.

This study aims demonstrate how the indiscriminate increase

(**) *Dipartimento di Pianificazione Territoriale, Università della Calabria (CS)*

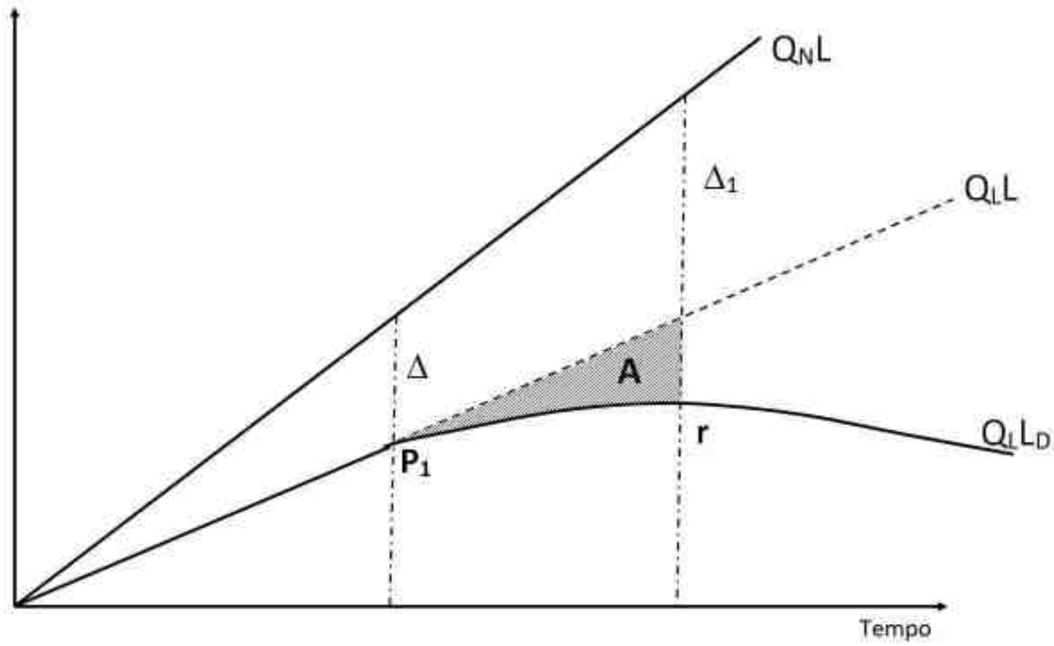

Fig. 1 – Graphical representation the theoretical prospects of variation the Quality of Life (Q_LL) on the basis of to an increase in Goods and services (Q_NL).

in Quantity of Life (Q_NL) can affect the environmental health of the place causing negative feedbacks, that we can quantify also in terms of the market. The concepts expressed can be represented graphically in the diagram of Fig. 1, which highlights a Δ growing over time between Q_NL and Q_LL up to become inversely proportional in a perspective of prevailing Q_NL increase (Δ_1). The point r and the line of parable that it follows, measurable by a single factor or for a summation of factors we can estimate in terms of market , begins when the limits of environmental compatibility are overcome and so adverse feedbacks can no longer withdraw spontaneously. This condition causes increasing loss of Quality of Life (Q_LL_D). For the specific case of the Commune of Cetraro how much affirmed it is expressed in the by now irreversible erosional coast (negative feedback) with consequent loss of the economic value of the immovable Goods.

In the diagram proposed the dashed line (Q_LL) represents the theoretical prospects for increasing the quality of life on the basis of to an increase in Goods and services (Q_NL). While point r represents the end of the environmental flexibility (or environmental resilience) within which, stopped the human action, the environment or the resource concerned is still to be able to replenish itself.

It follows that the hypothetical area A, bounded by the point P_1 (beginning of negative feedback) and r, represents the cumulative risk for a single factor or the summation of factors, beyond which the natural system is no longer able to replenish itself autonomously. The diagram proposed is purely indicative, the necessary checks will quantify the functionally identified curves.

Geo-archaeological research in Hierapolis of Phrygia (Turkey): preliminary results

S. MARABINI (*), G. SCARDOZZI (**)

Key words: *earthquakes, geo-archaeology, fault sanctuary, Plutonion, Hierapolis, travertine, thermal springs.*

INTRODUCTION

The archaeological remains of Hierapolis in Phrygia lie on the famous Pamukkale travertine terrace, which to the south-west overlooks the fertile valley of the river Çürüksu, the ancient *Lykos*, a tributary of the Meander, in south-western Turkey (Denizli Region).

The foundation of Hierapolis in the 3rd cent. BC, its development and decay over centuries, and its abandonment in the 14th cent. AD, as well as the preservation of its monumental ruins, are closely related to the peculiar geological context of the site, characterized by frequent destructive earthquakes; in fact the site is located on the north-eastern and seismically active side of the Denizli Basin, a graben WNW/ESE oriented and approximately 70 km long (ALÇIÇEK *et alii* 2007).

The north-western master fault of the graben is the so-called Pamukkale fault. It delimits the *Lykos* valley at the top of the slope that descends from the plateau of Uzunpınar; metamorphic schists and marbles of the basement emerges in the plateau and in the slope, below a thin sedimentary Mesozoic/Neogene covering. The Pamukkale fault surmounts a steep slope with steps identified by parallel faults which draw on deep partial karstic aquifers. One of these faults corresponds to the surface with the band of gaping fissures that crosses longitudinally Hierapolis for an average width of about 100 m; it is the so-called Hierapolis fault zone (HANCOCK, ALTUNEL 1997), from which emerge in abundance the thermal waters that have encrusted in white travertine, for thicknesses up to 3-4 m, the entire western sector of the ancient city and the steep slope that descends to the *Lykos* valley (the so-called "cotton falls" of Pamukkale).

The Italian Archaeological Mission, which operates at Hierapolis since 1957, started in 2003 a systematic study of the ancient topography of the site, aimed at the reconstruction of the urban layout and its transformations from the Hellenistic age to the Mid-Byzantine and Seljuk periods; during this research, adequate consideration is given to the geological and seismic phenomena that at various levels have interfered with the ancient city. In particular, in this paper some results of the 2010-2011 geo-archaeological research activities are preliminarily summarized; the results further highlight the importance of the geological characteristics of the site for the founding of the city, for the conditioning of its plant in several places and, above all, their centrality in particular religious practices that took place in Hierapolis in Hellenistic and Roman times, when the two main sacred areas (the Sanctuary of Apollo and the so-called Sanctuary of the Springs) were built along the fault. [S.M.]

This work was performed under the research activities of the Italian Archaeological Mission in Hierapolis (director prof. F. D'Andria), using financial contributions of the Calabria University and CNR-IBAM.

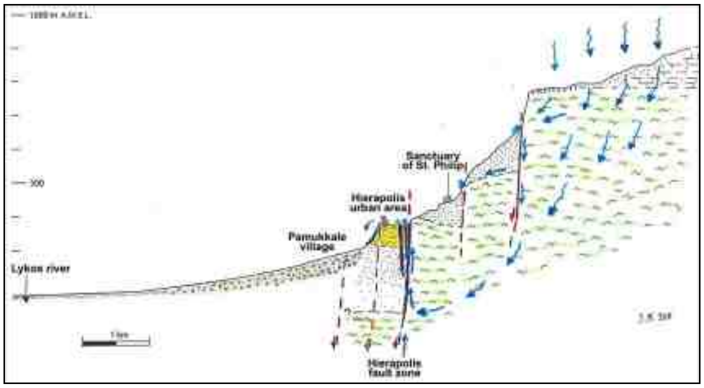

Fig. 2 – Section of the north-eastern side of the *Lykos* valley. [S.M.]

THE TECTONIC AND HYDROGEOLOGIC INFLUENCE IN THE FOUNDATION OF THE CITY AND IN THE LOCATION OF THE MAIN SANTUARIES

Before the founding of Hierapolis by the Seleucids (who significantly not assigned a dynastic name but that of "Holy City"), the site was probably occupied by a small village linked to a place of worship sacred to the Anatolian mother goddess Cybele; it consisted of a cave located in correspondence of a crack in the soil along the fault, from which exhaled gas emissions (mostly CO_2 and H_2S) and thermal waters. Upon their colonization, in the 3rd cent. BC, Greeks identified the cave with the *Plutonion*, i.e. the access to Hades, and dedicated to Pluto and Persephone-Kore this place of communication with the underworld. Around the *Plutonion* was built a sacred area, today called Sanctuary of Springs by archaeologist that recently have discovered the cave (D'ANDRIA 2012 and in press). It was described by several ancient writers (in particular Strabo, Apuleius, Cassius Dio and Damascius) who visited the site between the end of the 1st cent. BC and the first half of the 6th cent. AD; they marveled greatly for the awesome power of vapors that emanated from the subsoil and with whom were killed the sacrificing bulls, which were not slaughtered, but they were suffocated by the gas.

In the new city, the Pythian Apollo of Delphi (the mythical founder of the Seleucid dynasty) was established as patron divinity and he was worshiped at Hierapolis as Archegete, i.e. leader of the colonists; so, its oracular sanctuary was built in the middle of the city, immediately to the north of the place sacred to Cybele, along the same tectonic fissure. Inside the Sanctuary of Apollo, which ceremonial route linking to the neighbouring Sanctuary of the Springs and the cave of *Plutonion*, divination activities (cleromancy) were performed in direct connection with the fault; in fact, the so-called Building A and the nearby *manteion* were built immediately above the fissure (accessible through a narrow opening lined with marble slabs), as well as the so-called Building C, which had a chamber built in contact with the crack in the subsoil.

So, the peculiar geological characteristics of the site played a key role in his choice for the foundation of Hierapolis, where the sacred areas were set up like fault sanctuaries.

Fig. 3 – Aerial view of the central area of Hierapolis where are visible the ancient tectonic fissure (A) included in the Sanctuary of the Springs/*Plutonion* (1), with the thermal springs (S), and in the Sanctuary of Apollo (2, *manteion*; 3, Building A; 4, Building C); further downstream, westward, are visible other two fissures (B-C) produced by recent earthquakes (after the mid-seventh cent. AD). [G.S.]

It therefore follows that before the foundation of the city and in the Hellenistic and Roman period was already clearly visible, with all its manifestations (leakage of hot gas and thermal water from the subsoil), the long tectonic fissure corresponding to a small morphological step that separates the eastern sector of the city (sloping towards the west and with a subsoil characterized by ancient travertines overlapping metamorphic schists) from the central-western flat sector (where recent travertines overlapping the ancient ones). This morphological and tectonic lineament, along which aggregated the main sacred areas of the city, is pre-existing the several fissures of the Hierapolis fault zone; these cracks are located further downstream and were caused by recent earthquakes, as they cut monuments and structures built in Byzantine times (particularly after the mid-seventh cent. AD).

At the beginning of the 5th cent. AD, when the Christianity became established and Hierapolis became an important center of pilgrimage for the presence of the tomb of the Apostle Philip, the two pagan sanctuaries are dismantled and the cave of *Plutonion*, together with the tectonic fissure, are filled with soil and building materials. The religious center of the city was moved to a hill just north-east of the urban area, far from the Hierapolis fault zone, in the place of martyrdom and tomb of St. Philip, where was built a large sanctuary (D'ANDRIA 2011 and in press). An echo, so to speak also "geological", of these events and changes in the topography of the city has in the *Acta Philippi* (PICCARDI 2007). This hagiography says that the arrival of Philip in Hierapolis was highlighted by two extraordinary phenomena: first the apparition of a dragon associated with a strong earthquake and lighting; and second the opening of a deep "abyss" in the earth (maybe an echo of a tectonic fissure) which swallowed up the Viper (a clear echo of Cybele), the temple and the priests of the Viper and 7,000 men (later rescued) that worshipped this infernal snake-goddess which dominated the town at that time. Moreover, it is important to highlight that within the Sanctuary of St. Philip purification rites were held which included extensive use of water that fed the baths, fountains and basins that characterized the buildings of the monumental complex. The water came through a branch of an aqueduct that supplied the city, but the geological survey has discovered "dry" springs in the area to the east of the sanctuary; these were related to shallow aquifers directly fed from the nearby plateau of Uzunpınar, and they provided no thermal water. So, in the cult of St. Philip in Hierapolis appears a very important role of fresh water, drinking, clear, purifying, as bearer of life, coming from heaven, with a value that can be read also in contrast with the hot water, not drinking, impure, as bearer of death, coming from the underworld and the hell, which flowed in the middle of the city, inside the two pagan sacred areas along the Hierapolis fault zone. [G.S.]

THE TECTONIC AND HYDROGEOLOGIC INFLUENCE IN THE URBAN LAYOUT

Hierapolis was characterized by an orthogonal road network based on a wide and long *plateia*, NW/SE orientated, and on at least 9 parallel narrow *stenopoi*; these roads were crossed at right angles by another 35 *stenopoi* NE/SW oriented, which outlined rectangular blocks. In the middle of the city lie the main sacred areas, the Sanctuary of Apollo, with a *temenos* fully inserted in the orthogonal urban layout, and the Sanctuary of the Springs, whose limits have not yet been defined; their internal structures, however, differ from the overall system, since they are conditioned by the tectonic lineament on which they are built.

The urban layout of Hierapolis is clearly the result of a careful planning, characterized by the provision of roads that adapts to the geomorphology of the site; indeed, since the western sector of the city lies on flat land, while the east one lies along a slight slope, the *plateia* and other parallel roads have an orientation that mirrors that of the contour lines, while the orthogonal *stenopoi* follow the slope. Moreover, the orientation of the road network had a close relationship with the sewerage system, with the disposal of storm water and the distribution of drinking water, all planned in relation with the morphology of the site. This attention to the geomorphology is further proved by another characteristic of the urban layout: in fact, the urbanization seems to exclude two peripheral northern and southern areas that in ancient times were probably affected by sinkhole phenomena, maybe karst as well as tectonic, along the Hierapolis fault zone. In this regard it is interesting to recall how the existence of karst phenomena in the *Lykos* valley was already known to ancient authors, since Herodotus (5^{th} cent. BC) and later Strabo and Ovid (late 1^{st} cent. BC - beginning of the 1^{st} cent. AD) tell the underground section of the river (about 800-900 m long) in Colossae, located about 15 km SE of Hierapolis.

Furthermore, the plan of some large buildings of Hierapolis depart from the overall orientation of the urban layout for the need to adapt to the morphology of the site. This is the case of the Gymnasium, built in the 1^{st} cent. AD in the southern periphery and turned through 11 degrees to the SW to adjust the layout of the large monument to the original shape of this marginal sector of the travertine terrace, now partly covered by recent calcareous deposits. Another case is that of the Theatre built in the 1^{st} cent. AD in the middle of the city: it is always rotated 19 degrees in NE direction with respect to the urban layout, so that the *cavea* was adapted to the slope and the foundations were fully rested on a very compact travertine bed as well as on the underlying schists of the metamorphic basement. Despite its rotated orientation, the building is perfectly placed in the orthogonal road network, because its accesses coincide exactly with the *stenopoi* reaching it.

Instead, a different building solution was adopted for the second Theatre of Hierapolis, built in the late 1^{st} or early mid 2^{nd} cent. AD in the northern periphery, at the same time of the underlying North Agora, to which its plan is strictly parallel. For the location of the *cavea* a concave portion of a slope was chosen, probably previously used as quarry of clay; in fact, schists (i.e. a compact and stable basement) emerge only marginally in this site, while clays and sands of the Neogene cover (i.e. soils greatly predisposed to erosion by weathering) emerge more widely. So, the different "geological" choices of the sites where building the two theatres have greatly influenced their survival in a highly seismic context such as Hierapolis: in the case of the oldest Theatre, the optimal natural basement and the choice to turn the building allowed him to quietly withstand several earthquakes and reach today in good condition of preservation; otherwise the North Theatre was restored several times in his short life (about two and a half centuries), collapsed in an earthquake shortly after the mid 4^{th} cent. AD, and it was largely demolished to provide building materials reused in the nearby Early-Byzantine city walls. So, this building reveal the negligence of the project compared to the geomorphology and geotechnical characteristics of the slope where was placed. [S.M.]

Ancient Landscape in Sicily: a net of experiences for ecological restoration in archaeological sites

GIANLUIGI PIRRERA (*) & VERA GRECO (**)

Key words: *ABE "Ancient BioEngineering", Archaeological sites, Consolidation and Drainage, Ecological Restoration, Flora & Ancient Landscape, Kore Net, Sicily.*

INTRODUCTION

Bio Engineering compatibility depends on technical, biotechnical, ecological, correct landscape and correct social development feature. However, when we are in an archeological site, historical feature are much more important. The first proposal in Sicily was in the Casale Roman Villa, Unesco Site in Piazza Armerina (EN) with latin *oppidum* for a slope consolidation with flora species deriving from Mosaics source. But sometimes, on the contrary, archaeological landscape is not the correct one. For example, in Selinunte (*Selinus*) where there was once a harbour and two rivers there are now pollution and an invasive and exotic vegetation and, among the dunes, *Eucalyptus*, *Acacia horrida*, and even mushrooms. There are a few examples in Italy of rigorous use of ancient species, except Pompei, thanks to Prof. Anna Maria Ciarallo.

There is a MCA (Multi Criteria Analysis Method) to choice compatible ancient flora born by the consolidation of the Kamarina slope. The MCA is based on: historical & archaeological compatibility; ecological & biotechnical compatibility and ancient landscape compatibility in two steps. 1^{th} Step is a Matrix SPECIES (*n*°) X COMPATIBILITY (3). But we have 11 lists (1 fossil, 4 historical, 5 ecological e biotechnical, 2 for the landascape compatibility) species. So, 2^{th} step, we use a Matrix SPECIES (*n*° species) X LISTS (11 lists) (GRECO & PIRRERA, 2010). Currently the data base, among the 260 species of potential use in the 37 archaeological sites in Sicily, includes 148 ancient landscape species discovered by historical, latin and greek (Pindaro, Plinio, etc.), paleo-botanical (Gorghi Tondi, Biviere di Gela, Pergusa), and other archaeological Sicilian sources. (PIRRERA, 2012).

(**) Soprintendente ai Beni Culturali e Ambientali della Provincia di Catania.

Voluntary work performed without the contributions that summarizes the results of executions in different ways

The conviction of a more appropriate quality of the landscape in Sicily, in view of the immense archaeological heritage, in addition to historical bioengineering techniques, needs a diffusion of knowledge of the floristic history. Condition and dissemination required for an archaeological & ecological restoration, at any scale you want to think, takes advantage of research and applications of the last three years. It was necessary to act directly at the moment of the return of the Morgantina Goddess to Sicily, the land devoted to Demeter and Kore, represented almost everywhere worshipped with offerings of wheat and pomegranate. The myth of Demeter and Kore are related over 11 species. Kore has been chosen as a symbol, because kidnapped from her mother Demeter, goddess of vegetation, and taken to the underworld by Pluto. Kore, according to myth, spends only spring and early summer time in the land, but it's the period in which the fertility of the earth bears fruit, scents and flowers. A symbolic rebirth for a campaign aimed at the revival of the archaeological territory in the ecologic sense.

"The Gardens of Kore", a net of experiences with correct wood and stone ancient tecniques and correct species, means a net of places and people with the intent to act in favor of the the ancient landscape flora: voluntary actions to counteract the not native vegetation, especially the invasive one, because extreme symbolic actions can be more effective. All that, exspecially to counteract the lack of attention paid to the green in archaeological areas that led to the abuse of alien and invasive species as *Ailanthus*, the risk of contamination of plants such as *Vetiver* and seed mixtures, "patented" but without a declaration of origin and composition of the seed. Actions in defense of Bacchus, Demeter, Zeus and dozens of other gods, demigods, heroes and nymphs, through their species: Vine, Corn, Pomegranate and Walnut and dozens of other species to choose from with coherences archaeological, landscape and naturalistic. The work, sponsored by AIPIN Sicily (the Sicilian bio engineering association), transfers floristic ethical obligations and technical/scientific cooperation to companies and people, subject to rigorous assessment of the moral character. In the areas have been planted or cultivated species of the ancient landscape with strict criteria and attention also for the reuse of rainwater, using natural fertilizers such as dung and soil from worm farming and/or composting of green branches, lopping and organic products.

CASE STUDIES

At now there are 5 case studies:

The 1st place is a little lab in Palermo adapting a small yard of 28.5 sq.m. This has been renewed with ancient construction techniques ("coccio pesto", painting wall with Pompeian red colour), with flower beds and pots for plantations perimeter. The lab includes: collection and storage of rainwater in barrels of 100 liters gravity irrigating plants, self-production of green compost after shredding of waste wood. The lab enables research, database, teaching, dissemination, promotion of economic activities (cultivation, etc..), dissemination, biotech and morphometry of individual radical species of ancient flora and the methodology of choice of species. There are 7 models in 1:10 scale of ABE “Ancient BioEngineering”: techniques as consolidations (oppidum, stone walls, etc.) and bundles of drainage. There were seeded or repotted, planted or transplanted in the ground 75 species of the ancient landscape of Sicily a database continuously updated. The walls were decorated with badges of botanical species, copies of Sicilian evidences (Ex: medallions with the Spring with rose and Ambrosia for the Vite, both reproductions of the mosaics of the Villa Romana del Casale), and copies of pottery from mythology (Ex: Zeus, Volcano, Pluto, Gorgons, Aeolus, etc..). The lab is also an indirect fauna actions, because it is home to blackbirds nests among the branches, dens of geckos in the walls with stones of great size, and also promotes the direct appeal of destructive insect fauna and birds. In addition a small bank of germoplasm and a micropropagation lab will be available to nurserymen who share the objectives of the network.

The 2nd place is the "'Garden of Zeus", so named for the spread of walnut that binds to the mythology of Zeus, the father of the gods in the Archaeological Park of Cava d'Ispica (Modica). Here, in a troglodyte area, 16 species of the ancient landscape of the Cava were planted during consolidation work on a clifftop for the maintenance of an access road and to ensure the fruition of the caves. Particularly for the *Gymnasium*, dated back to Hellenic – Roman times, recently brought to light. Here tradicional bioengineering techniques (stone walls and wood net) and new ones (green stone walls and "Ispica" wood net) were experienced to get better results with plants for walls with great heights. Some of these 16 species were planted at the entrance of the park with a didactic function.

The 3rd place is the farm Bannata (Enna) where, among oaks, cereals (wheat, barley) and fruit (pomegranate), dedicated to the worship of Demeter and other products of archeoagricolture are produced. Here the works included an ecological river restoration with the consolidation of the slopes and the cut of alien and invasive species as *Ailanthus.*, *Eucalyptus* and *Acacia sp*. The location of the farm, with very old sheep folds restored, is especially important because it is inside a triangle key to the cult of Demeter and Kore. The farm is a few kilometers far from Lake Pergusa, just the place of the myth of Persephone Rape (Kore), and is in the area between the Archaeological Park of Morgantina (the largest producer of wheat in ancient time and it is home to Acroliti and the Goddess, both the figures attributed to Demeter) and "Philosophiana" (a large agricultural area of the Villa Romana del Casale in Piazza Armerina), now an Archaeological Park too.

The 4th place is an old naturalistic reserve of coastal wetlands (Gorghi Tondi) where were tested nurseries of *Quercus calliprinos.* Palynological analyzes showed holocene environmental and climatic changes. The site, in fact, along with other wetlands (Pergusa, Gela and Urgo di Pietra Giordano) holds, between silts, the most important ancient Sicilian pollen and charcoal data. The database now includes 146 species in Sicily from palynological investigations with a significant proportion of endemic species (e.g. trees and shrubs such as *Abies nebrodensis*, *Adenocarpus bivonii*, *Betula aetnensis*, *Celtis aetnensis*, *Erica sicula*, and *Zelkova sicula* or reptiles such as *Emys trinacris* and *Podarcis wagleriana*).

The 5th place is the Urgo di Pietra Giordano, in the higher Madonie mountains, where the work is under way to stabilize the southernmost bog of Europe. The works include small drainage for the restoration of the conditions of stability of the water and the ecological restoration of the wetlands. The site is particularly important because it falls in the *Abies nebrodensis*

Fig. 1 – Consolidations *Gymnasium* stone walls in Cava d'Ispica and the result of the ecological restoration in 9 months.

(relict evergreen coniferous) areal, the most important Sicilian fossil specie, with endemic thorny–cushion vegetation (e.g. *Astragalus nebrodensis, Astragalus siculus*) above treeline.

CONCLUSIONS

In addition to historical techniques of bioengineering the ecological restoration in archaeological sites needs a diffusion of floristic historical knowledge. It's necessary "Re-estabilisching a link between nature and culture" (SER, Society for Ecological Restoration, 2012), that means a link: between nature and archeology, between the existing and the ancient landscape, between technology and ABE "Ancient BioEngineering". The net includes five place, included a little lab, and works in which the ancient flora is important to get results of consolidation and drainage.

Did powerful land uplift and offshore subsidence events displace ancient Hipponion's port facilities on Calabria's Trainiti coastal margin?

JEAN-DANIEL STANLEY (*) & MARIA PIA BERNASCONI (**)

Key words: *archaeology, breakwaters, Calabria, Hipponion, neotectonics, port facilities, slumps, submergence, subsidence, terraces, uplift.*

THE PROBLEM

Ports and coastal facilities were essential for the trade and nautical activities at ancient Greek and Roman settlements along the shores of the Mediterranean (CUNLIFFE, 2008). The scholar most involved in the early years of coastal archaeology in southern Italy was Paolo Orsi who, from the late 19th to early 20th century, left a valuable and extensive published record. Numerous specialists have continued to study offshore Calabria, especially since the 1950's, by using newer technologies, particularly those involving underwater excavation, coring and data gathering by diving archeologists. Geophysical surveys supplement these technologies by using high-resolution shallow penetration systems for sub-seafloor reconnaissance and multibeam sonar for detailed seafloor surface observation. Together, these help clarify the evolution of the seafloor and now-submerged archaeological sites off Calabria.

The Cities Under the Sea Project (CUSP), initiated in 2000 and co-directed by this contribution's authors, seeks to update observations of Mediterranean coastal port facilities, principally those presently submerged offshore southern Italy, by using diverse geoarchaeological techniques. Such construction features have been examined on those Calabrian margins previously occupied by the Greeks in Magna Graecia 28 or more centuries ago and, in some cases, subsequently utilized by Roman and later populations. The project is multi-disciplinary, multi-organizational and multi-national and focuses primarily on *why*, *how* and *when* such anthropogenic features became submerged. The practical objective, beyond gathering databases and conducting basic research on marine archaeological sites, is to provide marine archaeologists and coastal engineers with information for the potential implementation of protective measures for ancient submerged sites and for modern, vulnerable, low-lying populated coastal centers in nearby areas.

Herein, the focus is on one of ancient Greek Hipponion's ports located northwest of the modern town of Vibo Valentia on the SW Calabrian margin (Fig. 1). Hipponion, about 500 m above present mean sea level (msl) and ~4 km from the coast, was positioned in the northern part of the Capo Vaticano peninsula bordered by the Tyrrhenian Sea. This colony was established by a population that had migrated from Locri Epizefiri, a site on Calabria's SE coast along the Ionian Sea (JANNELLI *et alii*, 1992). The Locrians crossed the southern Calabrian mainland and settled the steeply scarped highland well above the coastal plain at the end of the 7th century B.C. Several localities along the present coast have been suggested as possible sites of Hipponion port areas, but most remain modestly to poorly defined as they are buried by sediment on the narrow, low-lying coastal plain formed below Hipponion and west of the modern port of Vibo Marina (LENA, 1989; LOMBARDO, 1989;

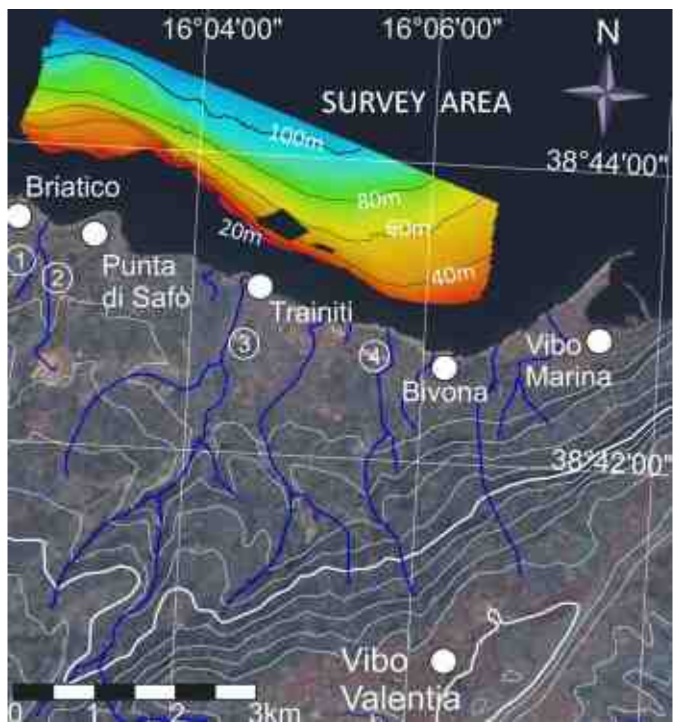

Fig. 1 – Map showing multibeam sonar study area west of Vibo Marina, between Bivona and Briatico, on the northern margin of the Capo Vaticano peninsula in southwestern Calabria. Shown are major fluvial systems (1 - 4) that flow northward across steep highland slopes, uplifted terraces, and the narrow coastal plain to the shore.

CUCARZI *et alii*, 1995). Among the largest and most readily visible structures explored offshore are two completely submerged Greek and Roman breakwaters (IANNELLI, 1989) at the Trainiti river mouth and delta (Fig. 2a,b). The depths and positions of these features and attributes of the proximal shelf seafloor are of prime consideration here. A multibeam sonar survey carried out in June 2011 along a ~6 km coast-parallel stretch serves to better interpret how and why the upper surfaces of these large features have been lowered to a considerable depth below present mean sea level (msl) during a short period of less than ~2.5 millenia. We use the past as a 'key' to better interpret conditions in present nearshore settings and to help predict their future evolution.

AN ACTIVELY MOBILE GEOLOGICAL SETTING

The port's post-construction evolution on northern Capo Vaticano's coast-to-shelf margin requires consideration of salient aspects of the regional geological framework. This sector of the Calabrian Arc is one subject to powerful and complex levels of neotectonic activity and seismicity, and is one of Italy's most active areas. More than one hundred scientific geological and geophysical articles and monographs have been written to date on this region, many during the past decade (see references listed in TORTORICI *et alii*, 2003; CUCCI & TERTULLIANI, 2006; BIANCA *et alii*, 2011). Most studies allude to a remarkable level of recent tectonic mobility as recorded by varied field observations and applied modeling. These highlighted a series of tectonically displaced markers in the Arc formed by the contact between the Southern European and North African plates (MONACO & TORTORICI, 2000; and many others). Geological, seismological and geographical patterns indicate the overall importance of rapid uplift of terrestrial terrains backing the coastline. Recent uplift patterns are recognized in the field by mapping of age-dated stratigraphic sequences, styles and patterns of recent fault motion, and elevation of step-like Pleistocene terraces that once formed at or near coastlines, with some now positioned at elevations up to hundreds of meters above present msl. Of particular note are (1) the regional northeast tilt of strata in the Capo Vaticano peninsula toward the study area and (2) calculations of terrain and terrace uplift rates that reach nearly 1 mm/yr and, locally up to ~2 mm/yr (TORTORICI,*et alii*, 2003; CUCCI & TERTULLIANI, 2006, 2010).

Active mobility affecting the land mass landward of, yet in proximity to, the coast has continued from early historic time to the present, resulting in marked lateral shifts of the coastline and changes in relative sea level during the Holocene (STANLEY & BERNASCONI, 2012). For example, cores collected on the coast near Bivona (Fig. 1) record a seaward prograding shoreline in the late Holocene (CUCARZI *et alii*, 1995). Moreover, recent seafloor surveys at the Capo Vaticano study area and other sectors off southern Calabria reveal generally narrow shelf platforms of laterally variable depths that are unevenly covered by recent sediment transported by bottom currents. These surveys also provide evidence of recent seafloor substrate displacement that commonly involves normal faults of various amplitudes; faults have led to the formation of variable surface relief features and irregular shelf platform depths by uplift as well as subsidence. In a method similar to those used to measure Quaternary terrace elevations on land, examination of closely-spaced multibeam sonar (MBS) profiles record sharp structural breaks and terrace-like relief features offshore (STANLEY *et alii*, 2011). These provide a means to identify and evaluate recent neotectonic motion seaward of the coast. Sediment facies in cores at the Trainiti coast (study in progress), coupled with examination of dated archaeological structures offshore, also provide the geologist and archaeologist with data to interpret the nature and timing of stratal motion beneath the sea.

Mariottini).

OBSERVATIONS OFFSHORE

Two distinct linear and fully submerged wharf-like structures are positioned immediately off the coast between the modern towns of Bivona and Briatico (Fig. 2b). A very long structure (to ~350 m) trending northwest (N330°W) is positioned to the east, just off the Trainiti river mouth. A much shorter one

(~100 m) extends northeastward from a small coastal promontory about 400 m west of the Trainiti river. Their widths range from 30 to 70 m. Mapping of these features was achieved by diving (Dr. Stefano Marriottini of Kodras Association, Mentana; *in* LENA, 1989 & JANNELLI *et alii*, 1992). The structures, visible in both aerial and satellite images (Fig. 2b), are interpreted as breakwaters partially enclosing a harbor area that covers >0.1 km^2.

Of interest is the increasing depth seaward of the longer structure positioned to the east of the former harbor. The base of the breakwater along much of its length is buried by sandy silt and silty sand. Depth of the sediment along its proximal base at the Trainiti coast is -4 m, while the structure's upper surface is at -3 m (Fig. 2c). At its NW distal terminus, the structure's upper surface merges with and is buried by sediment at a seafloor depth of about -9 m (Fig. 2c).

Measurement of the structure's total submergence and average rate of subsidence since construction depends on its "functional height." This term refers to the original elevation to which an archaeological feature was constructed so as to function with respect to msl estimated for the period of time when it was built. In the case of the submerged breakwaters considered here, their functional height denotes their original upper surface elevation as most likely positioned during Greek and Roman time since ~2500 yrs ago. Using the method to measure subsidence outlined by STANLEY & BERNASCONI (2012), this breakwater surface elevation takes into account a rise in msl of 2 m from construction to present (applying, for example, the sea level curve constructed by LAMBECK *et alii*, 2004), plus addition of 1 m above that msl to allow the structure, emergent at the time, to function properly. Thus, in addition to msl rise, the breakwater's surface near the present Trainiti coast has lowered 2 m (2000 mm) in ~2500 yrs, a long-term average substrate subsidence rate of 0.8 mm/yr. It is also assumed that at the time of breakwater construction, (1) its upper surface was a horizontal one between its coastal and offshore ends, and (2) was emergent by +1 m above msl along its extension during that period. The surface of the distal end of the structure during, and shortly after, colonization of Hipponion by the Locrians was thus also about 1 m lower than present msl. The structure's seaward terminus and substrate have subsided an additional 8 m since construction, not 2 m as at the coast, implying a much higher rate of lowering 350 m offshore during the ~2500 yrs. Calculation indicates a significant subsidence rate of 3.2 mm/yr at a distance of only about 350 m from the present shore, a rate four times greater than at the present coast.

Some progressive lowering seaward of the breakwater surface due to weighting from the structure itself and sediment substrate compression beneath it cannot be excluded. However, a four-fold increase of subsidence rate along such a short distance is more strongly indicative of a response due to some mechanism other than simple artificially induced compaction. In this respect, we believe the recent seafloor survey of the nearby shelf platform by MBS at a distance of 400-1000 m from the coast, at depths between 15 and 100 m, can shed some light on the matter. Of particular interest, the MBS data reveal the presence of a distinct, sharply-defined, nearly coast-parallel step-like break at a depth of about -20 m around 500-1000 m seaward of the shore. A cross-shelf transect perpendicular to the coast indicates a change from a gentle (1:20 to 1:50) inner shelf inclination to the distinct, much steeper (1:2 to 1:5) step-like break at -20 m; below this, an average inclination of 1:9 to 1:20 extends downslope to a depth of about -100 m near the shelf-slope break.

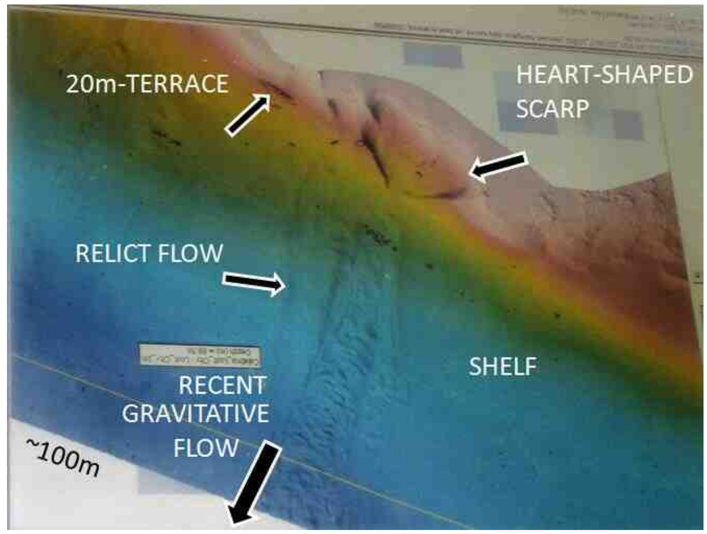

Fig. 3 – Multibeam sonar survey image, ~500 m offshore, showing heart-shaped scarp incised at the well-defined -20 m terrace, and an associated recent sediment gravity flow train below the scarp that extends across the shelf to a depth of >100 m. An older, more muted flow deposit is observed to the left.

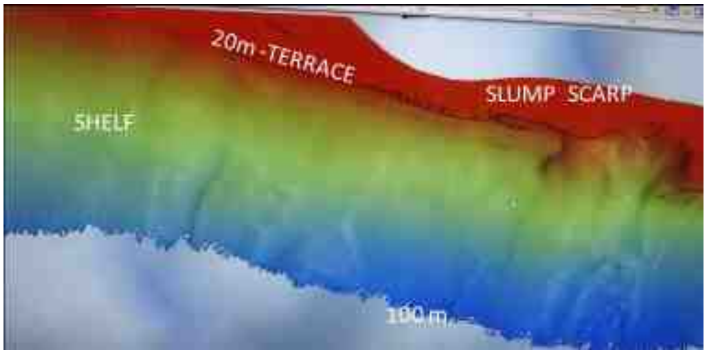
The submarine step-like break at -20 m displays some attributes similar to subaerial terraces exposed on land behind the offshore study area, including a much steepened relief over a short horizontal distance (100-200 m) with a series of scalloped depressions along it. These are interpreted as slump scars as evident from the elongate trains of blocky material that can be traced from below the scars and downslope across the shelf surface to the seaward limit of the MBS survey that reached depths of just over 100 m. This material comprises large blocks (diameter to >15 m) of consolidated material mixed with less coarse grained sediment. One particularly fresh scarp (about 200 m wide and named 'heart-shaped' because of its distinctive shape; Fig. 3) is directly associated with a gravity flow train that has not been masked by recent sediment cover; it is probably of very young age (yet to be determined). Numerous other scarps observed along the -20 m submerged terrace are also accompanied by linear, cross-shelf gravity flow deposits that extend below the incisions; however, most appear to be partially buried by a thin to moderate cover of sediment, indicating that these record somewhat older events (Fig. 4). It is noted that the slump scarps at -20 m and their associated gravity flow deposits show no direct connection with fluvial systems incised landward of the coast (Fig. 1). The absence of a relation with terrestrial river mouth floods implies that sediment transport events at and below the submerged terrace are most likely associated with the active accumulation of sediment on the terrace that is then episodically displaced downslope by tectonic shaking along a probable fault break at about -20 m.



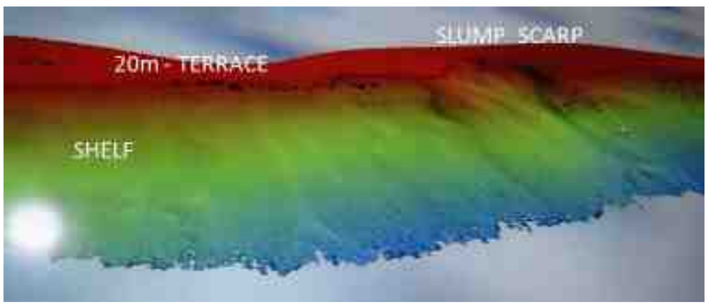


Fig. 4 – Two multibeam sonar images of the same seafloor area (upper, plan view; lower, oblique view) showing a series of scalloped-shaped slump scarps formed along the well-defined -20 m terrace. Note the linear trains of gravity flow deposits, some of recent origin and others, more muted of earlier formation, that are now partially covered by sediment.

SIGNIFICANCE

Is there a relationship between the configuration of Hipponion's harbor vestiges seaward of the Trainiti coast and recent evolution of land and submerged seafloor on the northern Cape Vaticano margin? Seismicity and earthquake epicenter

maps of this sector indicate that both the entire emergent terrain and contiguous marine sector to the north continue to be affected by earthquakes each year. Hundreds documented between 1981 and 2002 A.D. registered an intensity of up to or less than M=4; nine of the more historically important quakes (intensity of M=5.5 or more) occurred from 1659 to 1928 A.D. and are depicted by CUCCI & TERTULLIANI (2006). In addition, four epicenters of some highly destructive events recently affecting the Calabrian study area have also been proposed on the basis of macroseismic analyses. One such event includes the 8 September 1905 temblor that resulted in numerous deaths, serious destruction of towns, and tsunami damage along the Capo Vaticano coastal study area. Postulation of two of the four epicenters places one near Vibo Valentia and another just north of Briatico (CUCCI & TERTULLIANI, 2006, 2010). Displacement along a suite of major active normal faults in the Capo Vaticano peninsula is also indicated: these include the Tropea and Vibo fault systems that trend SW-NE, the former extending northeastward to the coast and seaward of Briatico.

We postulate that high rates of land uplift in the Capo Vaticano peninsula during the Quaternary have been accompanied by a series of coastline shifts and depth changes of the seafloor substrate offshore. This may include submergence by a bowing downward of the inner shelf and dislocation of the seafloor by normal fault processes at and along the -20 m terrace northwest of Hipponion's harbor at the Trainiti coast. Examination of anthropogenic fragments in core horizons buried at a depth of -8 m below msl on land in the Trainiti delta also suggests that some lowering may have occurred just landward of the longer breakwater. The irregular and episodic lowering of the eastern breakwater's upper surface in a seaward direction indicates that the bowing down and structural offset are geologically recent. The absence of an offset along the structure's length, however, probably precludes an active fault break beneath the breakwater and harbor. We propose that the careful measurements of depth, at present and in the future, at several specific points along the breakwaters' upper surface could serve as gauges to detect ongoing geological motion potentially affecting the inner shelf off the Trainiti coast. In turn, such variations in the depth of these points may provide a means to calculate rates of change in relative sea level.

Changes to the route of Appian Way in northern Campania: subsidence and waterlogging of coastal areas

UGO ZANNINI[1,] LUIGI SCARPA[2,] CLELIA CIRILLO[3] & GIOVANNA ACAMPORA[4]

Key words: *ancient toponoymy, Appian way, roman roads*.

In 312 BC the construction of the Appian Way began that starting from Capena, Ad Nonum, Bovillae, Aricia, Sublanuvio, (Ad) Sponsas, Tres Tabernae, Forum Appi, Ad medias, Terracina came to Fundi. Passed, after being wedged in the narrow valley of St. Andrea, towards Itri, it directs to Formia. Beyond Formia, the realization of the way was begun in 307 BC (year of the consulship of Appius Claudius) or in conjunction with the construction in 296 BC of *Sinuessa* and *Minturnae* colonies. Bypassed, after *Minturnae castrum*, the bridge over the river Garigliano, that someone wanted to identify with the *pons Tirenus* which Cicero mentions in the description of his return journey from Aquino, the *Appian Way* was wedged in the narrow strip of land between the sea and the ultimate ramification of Massico chain (Monte Cicoli) where *Sinuessa*, coeval colony of *Minturnae*, is located guarding the forced coastal passage that gave access to the fertile plains of Campania. Unlike the following path of via Domitiana, built in 94 AD, that just after linking up *Sinuessa* with the *Appian Way*, along the coast, reached the important port of Pozzuoli, the *regina viarum* veered sharply towards the inside crossing the *ager Falernus*. From there the road headed towards the *mansio* of *pons Campanus* famous as nearby, in a small tavern, Horace stopped there. Today that location is localizable not far from the farm S. Janni on the river Savone. After having bypassed *pons Campanus*, and after having crossed

Urbana colony in the age of Silla, which is localized in the estate of Francolise Municipality, headed towards *Casilinum* (currently Capua), meeting point of the *Appian Way* and Latina Way and reached Capua (now called Santa Maria Capua Vetere). A few years later, in 268 BC, it was prolonged to Beneventum. At the same time the latter colony was connected with Taranto. Only in 244 BC, the route was finished with its extension to Brindisi. A more ancient path of the *Appian Way* should be discarded which from Minturnae, instead of proceeding to *Sinuessa*, would have licked Sessa Aurunca and then reached *Capua* not before touching Teano. Even if it is established the presence of that connection in Roman times, it cannot be confused with the Appian Way. In fact both the routes and the written sources recognize just one Appian Way which after having crossed the colonies of *Minturnae* and *Sinuessa* through *ager Falernus*, reached *Capua*. Radke is among the first scholars to speculate that the Appian Way passes, at least in the earliest phase, through Sessa Aurunca or more precisely in its vicinity, a theory which will be shared by Wiseman albeit with some distinctions. Convinced that fora always marked half of an entire route, Radke explains the existence of Claudius Forum by putting it into relationship with the *Appian Way*. Road which he said would have been built, in the second section, by Appius Claudius during the consulship of 307 BC starting "from Formia and passing through Minturnae, Forum Claudi, Theano, Cales and Casilinum up to Capua." Without discussing the thesis of the scholar, and in particular on the argument that the for a were always placed in the middle of a road path, it is clear how the supposed route of the *Appian Way* to Sessa Aurunca is based solely on the existence Claudius Forum. But a more careful historical analysis on medieval sources revealed how labile are the assumptions that "prove" the existence of Claudius Forum. That being said it is clear that the theory according to which the *Appian Way* linked Sessa Aurunca to *Capua*, based on the intermediate position of Claudius Forum between Formia and *Capua*, is clearly impossible. In fact, Wiseman dissociates from Radke and even reproposing the way to Sessa Aurunca, he justifies it with the presence of coastal wetlands and the subsequent choice by the Roman engineers of an inner itinerary. We know, however, that in other cases, Roman builders had already dealt with wetlands such as those of *Pomptinae Paludes* obtaining, among other things, good results as well as it was not difficult for engineers to make the *Appian Way* pass, as they actually did, "between marshy Minturnae and Petrino Sinuessano."

The hypothetical path of the ancient Appian Way through Sessa Aurunca is not supported, then, by any real evidence with the exception of the archaeological record that witnesses the existence of a road artery in Roman times, which, however, is not to be confused with the *Appian Way*. The fall-out of use of the original path *Minturnae-Sinuessa-pons Campanus* with respect to the medieval route, which used the Roman roads in this area, *Garigliano-Suessa-pons Campanus* certainly contributed to give rise to such a confusion.

Even in the seventh century AC, many sections of the *regina viarum* continue to be still in use as it can be deduced from *Cosmography* of *Ravenna anonymous cleric*. In the High Middle

Corresponding author: giovanna.acampora@ibaf.cnr.it

Ages, however, the ancient Roman road network is gradually replaced. It is just the *Cosmography* of *Ravenna anonymous cleric* to give evidence, in fact, of a path change in *Falernian area*: after *Forum Appi*, instead of Terracina, it is reported "Feronia" and then "Suesaruntia". From Sessa Aurunca the path is linked to "Pons Campanii" to continue towards "Kapua" through the intermediate steps of "Urbanis" and "Casilinum". Compared to other routes, we realize the absence, therefore, of the steps of *Minturnae* and *Sinuessa*. It is clear that if the path to Sessa Aurunca, being longer and more tortuous, was preferred it should be supposed that the original ancient *Appian Way* had become not feasible in the non-coastal *Minturnae-Sinuessa* section and / or in the innermost section *Bagni Solfurei-Pons Campanus*. But which were the possible causes that forced to bypass part of the *ager Falernus* at least in the seventh century AC. We may say at least as we do not know if already in the sixth century AC the path was already changed even though some signs might suggest that well before the seventh century some phenomena had occurred to force entire populations to leave the old Roman centres of *Sinuessa Minturnae* and *Forum Popilii*. Recently it was strongly suggested the thesis that includes these areas, in the broader context of the Mediterranean basin, affected by climatic variations which changed the geomorphology of the area. We wonder, indeed, the attention that lately has catalyzed this hypothesis since reliable data are acquired over several decades, certainly since 1969 the year in which the geologist Vita Finzi shows unequivocally that a thick layer of *alluvium* was formed in the valleys of Mediterranean countries, between 400 and 900 AC. Of course the whole question about the root causes of this phenomenon to which geologists are still investigating remains open, while for the medievalist archaeologists there is nothing new on the horizon considering that "the recent coverage" (the Younger Fill) is an element ascertained by now. And it is possible, therefore, to relate the abandonment of the section of the *Appian Way* in the *ager Falernus* with microclimatic changes that had also affected our area. The areas at the bottom of the valley have suffered a catastrophical burial thus destroying many centres and covering the roads in several places. In this context it should be explained the alternative path used in the seventh century AC, *Feronia-Suesarunca-Pons Campanii*, being still active in the early twelfth century since the *Geographia* by *Guidone* still attests its existence.

Seismic attenuation tomography and anisotropy beneath the Southern Tyrrhenian Sea subduction system (Italy)

BACCHESCHI P. (*), DE GORI P. (*), MARGHERITI L. (*), STECKLER M.S. (**) & CHIARABBA C. (*)

Key words: *Subduction Zone, Southern Italy, Attenuation tomography, Seismic anisotropy, S-wave splitting.*

The Southern Tyrrhenian subduction system results from several partly synchronous processes that involved the Central Mediterranean region, such as oceanic subduction, continental collision, slab rollback, and back-arc basin formation (Faccenna et al., 2004; Jolivet et al., 2008). It shows a complex interaction among asthenospheric flow, subducting slab and overriding plate. To shed light on the complex structure of the study region we investigate the seismic attenuation and anisotropic structure of the slab and surrounding mantle. Seismic attenuation can be particular useful to understand the mechanical and thermal properties of subduction zones since it is sensible to spatial variations in temperature, volatile and water content, and melting occurring in such a very limited volume.

Here we present new attenuation results obtained using several S-waves from earthquakes located within the descending slab.

The high-resolution *Qp* and *Qs* attenuation models are computed down to 300 km depth and were obtained by the inversion of high quality P- and S-waves *t**. Attenuation results show a much more complex setting, in which the seismic attenuation structure has a marked variability, both vertically and horizontally. The subducting slab is imaged as a low attenuated body down to 350 km depth, but heterogeneous in its *Qs* and *Qp* structure (*Qs* values up to 1100; *Qp* values up to 1200), while the adjacent mantle wedge exhibits a strong attenuation region, as beneath the Aeolian magmatic arc. These two different features may be explained in terms of a cold oceanic, rigid plate descending into a warmer, ductile mantle, whose attenuation is even more enhanced by the long-term and continuous release of fluids from the slab itself. At 100 km depth the high *Qp* and *Qs* body is well reconstructed beneath the Calabrian arc and at 200 km depth it extends offshore the Southern Tyrrhenian Basin beneath the Aeolian Islands. A worth nothing feature is the clear concentration of seismicity in the 120-200 km depth interval, clustered where *Qp* and *Qs* models clearly show the existence of a high-attenuation region with low values of *Qs* and high *Qp/Qs* structure. A reasonable explanation for this anomalous low *Qp* and Q_S region and denser volume of seismicity could be dehydrating minerals associated to the slab metamorphic reactions involving noticeable slab volumes and accompanied by the conspicuous presence of water due to ongoing dehydration of slab serpentinite. The observed low *Qs* anomalies regions between the slab and the Aeolian volcanic arc could be indicative of melting processes in the mantle and also of the large-scale serpentinization of the slab (Baccheschi et al., 2011b; Baccheschi, 2011).

To reconstruct the deformation state of the Southern Italy subduction system we also investigate the anisotropic properties of the region. Due to its relationships with past and present deformation of the medium crossed by shear waves, seismic anisotropy is becoming extensively used in studying dynamic processes in subduction system. Indeed, the observed anisotropy can help to understand the dynamic processes occurring in the upper-mantle wedge above the sinking oceanic slab and the slab deformation. In this study we therefore analyzed several S phases whose ray-paths mostly sample the slab and the wedge above it.

The S φ-δt splitting parameters show a complex pattern of anisotropy with variable fast directions and delay times across the subduction zone. Measurements at single stations are quite variable, thus excluding the overriding plate as main source of anisotropy. The S wave splitting parameters also show frequency-dependent behaviour that could be attributed to the presence of small-scale anisotropic heterogeneities. S splitting reveals a well developed toroidal flow at the SW edge of the slab, while at its NE edge the pattern is not very clear, *suggesting that the anisotropy is mainly controlled by the slab rollback.* Comparison of the S splitting measurements to the P-wave velocity anomaly at 100-200 km depth shows small delay times where the rays primarily sample the slab, while the delay times are quite high where the S rays sample the mantle wedge. This δt pattern depicts the slab as a weakly anisotropic region and suggests that the main source of anisotropy in the subduction zone is the surrounding asthenosphere (Baccheschi et al., 2011a; Baccheschi, 2011).

Seismicity and Focal Mechanisms at the Calabro-Lucanian boundary along the Apennine chain (southern Italy)

SEBASTIANO D'AMICO (*), ANNA GERVASI (**), IGNAZIO GUERRA (°), GIANCARLO NERI (°°), BARBARA ORECCHIO (°°), DEBORA PRESTI (°°) & CRISTINA TOTARO (°°)

Key words: *Calabro-Lucanian region, earthquake location, focal mechanisms.*

The Calabro-Lucanian boundary is a complex geological zone marking the transition between the highly seismogenic tectonic domains of Southern Apennines and the Calabrian Arc. Historical catalogues include earthquakes with macroseismic effects up to VII-VIII MCS (CPTI WORKING GROUP, 2004) and paleoseismological investigations suggested that earthquakes of magnitude between 6.5 and 7 may have occurred in this area, between the 6th and the 15th century (MICHETTI *et alii*, 2000). More recently, on 9 September 1998, an earthquake of moment magnitude M5.6 occurred at the north-western margin of the Pollino massif (GUERRA *et alii*, 2005; ARRIGO *et alii*, 2006) and since the second half of 2010 the same region was interested by a noteworthy seismic activity characterized by several swarms with thousands of events with a maximum magnitude of 3.6.

We have investigated the seismicity occurring in the last decades at the Calabro-Lucanian boundary with the main purpose of improving the accuracy of seismogenic fault detection. Data and recordings relative to earthquakes shallower than 30 km which occurred between January 1981 and December 2011 have been collected from the Italian national catalogs and databases (http://www.ingv.it) and from the databases of University of Calabria, including permanent and temporary seismic networks operating in the region (BARBERI *et alii*, 2004; http://www.ldeo.columbia.edu/res/pi/catscan/). We located the earthquakes using both linearized (SimulPS, EVANS *et alii* 1994) and non-linear (Bayloc, PRESTI *et alii*, 2004 and 2008) earthquake location algorithms and the three-dimensional crustal velocity models developed for this region (BARBERI *et alii*, 2004; ORECCHIO *et alii*, 2011).

We also estimated the focal mechanisms for some dozen of earthquakes with local magnitudes greater than 3.0 which occurred in the study region in the last decade. We applied the Cut And Paste (CAP) method (ZHAO & HELMBERGER, 1994; ZHU & HELMBERGER, 1996), that allows the determination of source depth, moment magnitude and focal mechanism using a grid search technique. Waveform modeling has been used to estimate faulting parameters of small to moderate size earthquakes. The capacity of CAP method to obtain high quality results for the investigated dataset has been accurately verified by comparisons with different methods and by several tests related to seismic network geometry, velocity model and earthquake location uncertainties (D'AMICO *et alii*, 2011).

A joint analysis of the results of the present study with others geophysical and geological information available from the literature has been performed with the purpose of better understanding the dynamic processes leading to the generation of the individual seismic phases and of improving the available seismotectonic knowledge of the study region.

INTRODUCTION

During the last few centuries, Calabria has been one of the Italian regions most affected by catastrophic earthquakes (Mw > 7). The event that occurred on the night of the 8 September 1905 in the western Calabria is one of the strongest hitherto known, according to the estimated M_w 7.5 (MICHELINI *et alii*, 2006; macroseismic $M_{w,}$ derived from intensity data, is ~ 7.0; see GRUPPO DI LAVORO CPTI04, 2004). This earthquake claimed 557 casualties, more than 2000 injured, and about 300,000 people were left homeless. This event severely devastated a wide area and triggered a tsunami wave (see PIATANESI & TINTI, 2002), which was observed both in the open sea and along the coast bordering the Sant'Eufemia Gulf. The epicentral location of this event still remains controversial. RIZZO (1906) and BOSCHI *et alii* (1995) suggest an onshore epicentral location, whereas CAMASSI & STUCCHI (1997) and RIUSCETTI & SCHICK (1975) maintain that it was located offshore.

In the last 20 years, several studies have been performed to analyze the structural setting (ARGNANI & TRINCARDI, 1993; PEPE *et alii*, 2010; MILIA *et alii*, 2009), the gravitational and sedimentary processes (TRINCARDI *et alii*, 1995) characterizing these two slope basins, and to identify processes and potential seismogenic sources responsible for the 1905 earthquake. With respect to the latter, some authors have proposed: 1) a NE-SW oriented normal fault located offshore Tropea and called Capo Vaticano (CV in Fig. 1; MONACO & TORTORICI, 2000); 2) the Vibo Valentia fault, NE-SW oriented, together with the Capo Vaticano Fault (PIATANESI & TINTI, 2002); 3) the NW-SE oriented Nicotera fault (CUCCI & TERTULLIANI, 2006).

To address these issues and to improve the knowledge concerning the seismogenic potential of the region, a well targeted multidisciplinary survey was realized during the summer of 2010 in the Sant'Eufemia Gulf (SE Tyrrhenian Sea). The acquired dataset (Fig. 1) is made up of geophysical data (330 km of MultiChannel Seismic - MCS data, 2223 km of Chirp profiles, 2231 km^2 of high resolution morpho-bathymetry), 12 biological and geological samples (gravity cores), 12 oceanographic data measurements, and 10 geo-chemical samples. Geophysical data were acquired to analyse the tectonic setting of the area and to study the potential seismogenic source of the 1905 earthquake. Moreover, oceanographic measurements, chemical and biological samples were acquired to detect hydro-thermal activity and fluid escape features that could be associated with recent tectonics. Moreover, we also employed shaking scenarios as a powerful tool to assess seismogenic source models, whose outcome will be here analysed and integrated with the first results of geophysical, biological and chemical data.

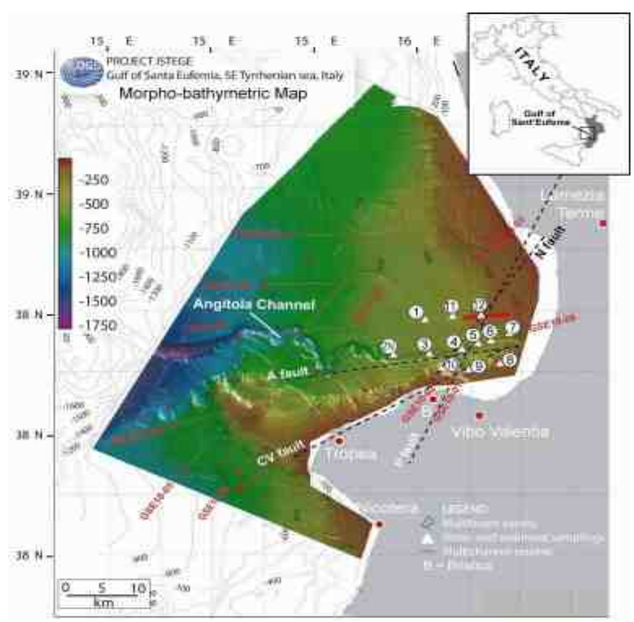

Fig. 1 – The new high resolution morpho-bathymetry. The seismic dataset (red lines), the oceanographic and geo-biological measurements locations (white triangles) are indicated. Part of the seismic profile here analysed is indicated with red thick line. Black dashed lines indicate the four faults modeled.

FIRST RESULTS

Geophysical data. The analysis of the entire seismic dataset allowed us to define the morpho-structural setting of the sedimentary basin within the Sant'Eufemia embayment. Thanks to these data, some key tectonics elements have been identified. In particular, a likely strike-slip fault, ENE-WSW oriented and likely controlling the Angitola channel, was recognised by the gentle deformation of sediments imaged on the seismic profile GSE10-4A (more details in LORETO *et alii*, 2012) and by the straight trend of the inner part of the channel. This fault is here called A fault (Fig. 1).

Analysing the seismic profile GSE10-07 (Fig. 1), we identified a normal fault NE-SW oriented, located close to the shelf margin of the Sant'Eufemia Gulf. This fault plane dips to the SE ca. 48° (Fig. 2). Bottom-up, it cuts the top Miocene, the whole Plio-Pleistocene succession and the sea-floor too. We hypothesise a lateral extension of this normal fault of ca. 30 km (N fault in Fig. 1).

Finally, sediments in the central part of the Gulf of Sant'Eufemia are faulted and locally gently folded. They are organized in a system of reverse faults deforming the upper Plio-Quaternary sediments, and in an older one showing a normal faulting that has affected the deeper Plio-Quaternary succession and the top of the Miocene deposits. This faults system is completely buried below the recent sediments.

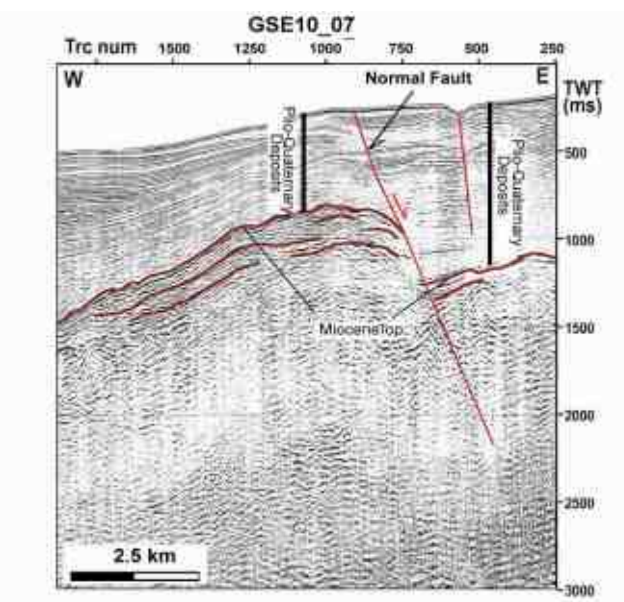

Fig. 2 – Part of the time migrated seismic profile GSE10-07 located close to the continental shelf (see Fig. 1). Vertical exaggeration is about 4:1.

Seismological modelling. Seismic hazard assessment for a given area requires the characterization of the seismogenic sources, the knowledge of ground motion attenuation (or seismic intensity) with respect to epicentral distance, a realistic modelling of seismic wave propagation, and the knowledge of local geology for site-specific analyses.

Such study aims at a description of the intensity of shaking at a given site due to a nearby earthquake, assuming a certain magnitude, or a map showing levels of ground shaking in various parts of the area that have an equal chance of being exceeded.

Input data for the 1905 earthquake ground shaking scenarios are: the Angitola fault (A Fault in Fig. 1); the Sant'Eufemia normal fault (N Fault in Fig. 1); and the CV and the P Faults (see Fig. 1). We opted to model the Capo Vaticano fault (CV) too since several authors have considered it as a likely seismogenic source for the 1905 earthquake and the associated tsunami (PIATANESI & TINTI, 2002). The P fault was obtained applying the KF inversion technique (PETTENATI & SIROVICH, 2007; LORETO *et alii*, 2012). Acceleration fields for the four faults are shown in Figure 3.

The shaking scenarios (Fig. 3), performed using the above described faults, need to be compared with the intensity distribution map (Fig. 4). The profile of the radiation that emerges using the A fault as input shows a prevalent trend in the east-west direction, with maximum accelerations concentrated along the coastal area between Lamezia Terme and Vibo Valentia (Fig. 3A) entirely within a minimum of radiation. The radiation profile slightly changes taking into account the Capo Vaticano (CV) fault (Fig. 3B). For this case, the absolute maximum is detected at the Capo Vaticano Promontory. A radiation pattern with NNE-SSW direction results from the fault model P (Fig. 3C). This model shows two maxima: 1) one southwest close to the town of Nicotera; 2) the other one to the northeast, just south of Cosenza. Notice that, even if both acceleration (Fig. 3C) and intensity (Fig. 4, right) distributions appear to be similar, the estimated acceleration values are too low if compared with intensities. Values much more in accordance with the macroseismic field are obtained with the fault model N, since this shows a first maximum at Briatico, the second in the area southwest of Lamezia Terme, and a general trend NNE-SSW oriented (Fig 3D). The trend of the fault model N follows quite closely the intensity distribution including the majority of the points with Is $\geq$ VII MCS. The secondary extensions in the E-W direction of the high accelerations are reported north of Catanzaro and south of Vibo Valentia.

Chemical and biological results. The 12 stations sampled (see white triangles in Fig. 1) for chemical and biological parameters in the sediment are grouped into three transects, with inshore-offshore direction: the "south" transect includes the Stations (St.) 8, 9 and 10; the "Angitola channel" transect includes stations from the 2N to the 7; and the "north" transect includes the St. 1, 11 and 12.

Total Nitrogen (TN), Total Carbon (TC) and Total Organic Carbon (TOC) values do not show any evident differences among stations, except for the southern transect along which a small decreasing gradient can be sea-ward observed. Moreover, the highest values of TN, TC and TOC were measured at St. 8. In general, the TN content ranged from 0.66 ± 0.01 mg N g^{-1} (St. 10) to 0.89 ± 0.04 mg N g^{-1} (St. 8). TC varied from 18.21 ± 0.04 mg C g^{-1} (St. 5) to 21.16 ± 0.08 mg C g^{-1} (St. 8) while the organic fraction of carbon (TOC) from 6.19 ± 0.12 mg C g^{-1} (St. 12) to 8.20 ± 0.09 mg C g^{-1} (St. 8).

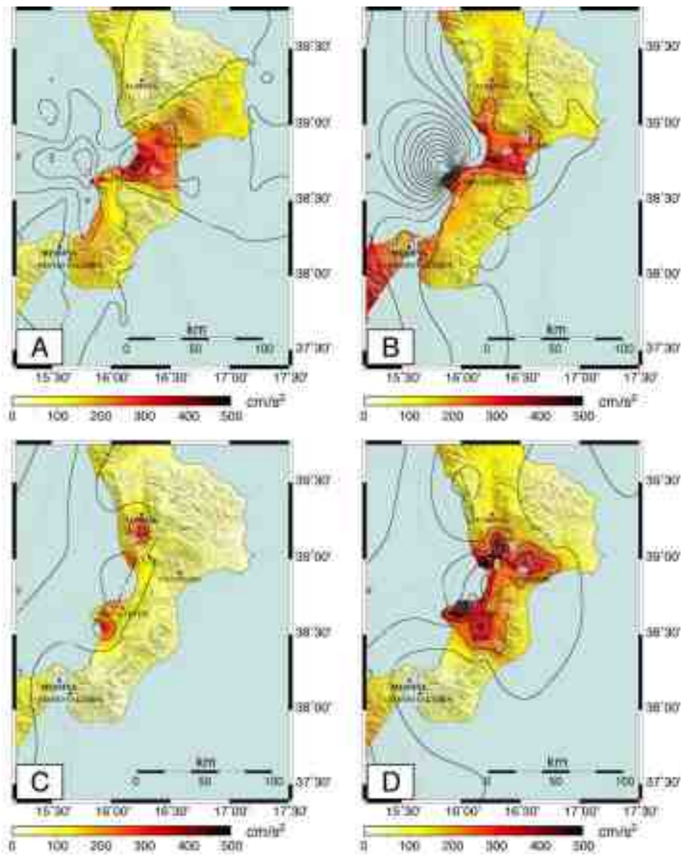

Fig. 3 – Maximum ground accelerations (1 Hz cutoff frequency) calculated for a uniform distribution of seismic moment on the fault surface and a bilateral rupture that propagates from its center. The geometric models are those reported in Table 1 and here corresponding to (A) A fault, (B) CV fault, (C) P fault, and (D) N fault.

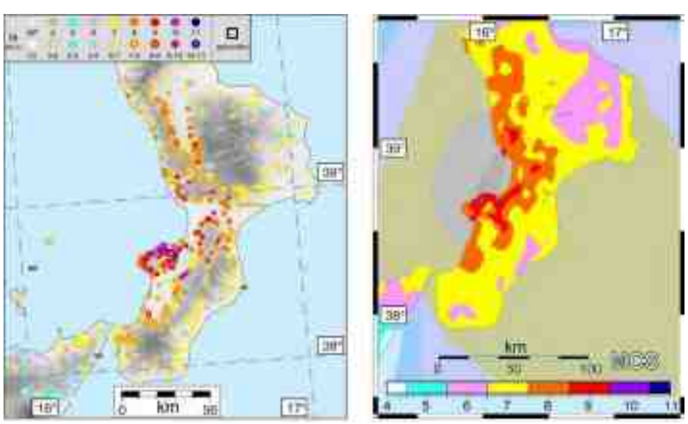

Fig. 4 - Left: macroseismic intensities map of the earthquake of 1905 (data from the database of macroseismic observations of Italian earthquake. Right: contour map of intensity values (only integer degrees) prepared using the natural neighbours technique.

According to the biological analysis, proteins were the main constituent of the BPC (Biopolymeric Carbon), followed by lipids and carbohydrates. Protein content did not change remarkably among stations since it ranged from 888 ± 18 µg C g_{dry}^{-1} (St. 12) to 1113 ± 28 µg C g_{dry}^{-1}. An exception is represented by St. 7 characterized by the highest value (1623 ± 25 µg C g_{dry}^{-1}). Lipids showed a slightly higher variability, particularly along the Angitola channel. Along the southern transect, we measured a decreas of lipids, from 626 ± 78 µg C g_{dry}^{-1} (St.8) to 229 ± 24 µg C g_{dry}^{-1} (St. 10), along with an increasing depth. Colloidal carbohydrates (CHO-H2O) were characterised by a high variability and no evident pattern is detected. The lowest contents were measured along the Angitola channel (14 ± 1 µg C g_{dry}^{-1} at St. 4 and St. 5), whereas the maximum was found at St. 8 (55 ± 2 µg C g_{dry}^{-1}). Carbohydrates extracted in EDTA varied from a minimum of 61 ± 6 µg C g_{dry}^{-1} (St. 10) to a maximum of 218 ± 12 µg C g_{dry}^{-1} (St. 2), with higher values along the "Angitola channel" transect.

Prokaryotic abundance in the sediment showed a great variability among stations, particularly along the Angitola channel (Fig. 1). The lowest prokaryotic number was measured at St. 11 (0.70 ± 0.05 10^8 cells g_{dry}^{-1}) whereas the maximum at St. 7 (2.94 ± 0.38 10^8 cells g_{dry}^{-1}). A strong variability was also observed along the northern transect, where an increase of the prokaryotic abundance was detectable at the St. 12, and along the southern transect with high values at the St. 8.

The integrated analysis of data and modelling here described allowed us to verify the validity of methods (seismological, geophysical and biological) applied to the study of a historical earthquake as the 1905 event. In particular, the high prokaryote abundance identified at the St. 12 supports the hypothesis of an active normal fault, already detected via seismic data. Shaking scenarios allowed to identify the most probable seismogenic sources that are represented by the normal (N) fault and by the Capo Vaticano (CV) fault, and allow also to rule out other structures such as the Angitola (A) fault. Moreover, the good result of the P fault modelling, in turn derived from the FK inversion method, positively bech-marked the numerical technique as robust.

FUTURE PERSPECTIVES

The first results of this multidisciplinary study, whose purpose is to identify a potential seismogenic source for the 8 September 1905 earthquake, strongly support the validity of the applied methods and, although not conclusive, it allowed to identify some credible solutions. Moreover, variation of chemical and biological parameters partially reflect the recent tectonics activity of a normal fault, first identified on the new MCS data acquired.

The detailed analysis of the Chirp profiles, spanning the entire Gulf, will help to identify most of the active structures affecting recent sediments. The resulting deformation pattern is a likely key tool to discriminate among the proposed seismogenic sources and to analyse the recent processes that could be associated with climate changes, with recent tectonics and with sedimentary processes. Such further studies will be augmented by the analysis of sediments sampled by gravity cores.

Moreover, these dataset open new issues about geo-hazards to be analysed, as: detection and characterization of active faults bearing tsunamogenic potential, tectonics control on and activity of submarine volcanoes, and submarine landslide processes. The analysis of these elements if supported by geo-chemical information could be integrated with the on land data (Italiano et al., 2010).

Further new data, such as on-land field survey of geological and geomorphological features spanning the whole area that includes the Gulf of Sant'Eufemia, and tsunami modelling, are needed to best constrain the long- and short-term tectonic activity that affects the whole area, and to fully characterize the potential seismogenic source of the 1905 earthquake.

Finally, the methods tested in the frame of the ISTEGE project may allow to define a viable procedure to study historical earthquakes whose potential seismogenic source is located offshore, and that may still be unknown or doubtful – a fairly frequent circumstance, especially when instrumental data may inevitably lack. The ultimate goal, of course, is to increase the knowledge of seismic hazard in sensible regions such as coastal areas are bound to be.

A multiscale/multiparameter study of the seismogenic North-Anatolian Fault system in Sea of Marmara (Turkey)

ALINA POLONIA (*), LUCA GASPERINI (*), FABRIZIO DEL BIANCO (*)

Key words: *North-Anatolian Fault, Sea of Marmara*

INTRODUCTION

The Sea of Marmara has been widely recognized as a seismic gap that will be probably filled in the next decades by a strong (M >=7) earthquake along the North-Anatolian Fault (NAF) system. This occurrence, together with the high density of population, makes this area as one of the most hazardous of the Planet.

Several research groups from many countries are carrying out geological, seismological and paleo-seismological studies of the submerged part of the NAF, in order to understand how this gap will be filled.

We attempted a multiscale/multiparameter approach to gather information on: 1) long-term evolution of sedimentary basin associated to the NAF system in the Sea of Marmara; 2) nature and degree of activity during the Holocene of seismogenic faults; 3) effects of the last earthquake at the seafloor in term of surface rupture and mass wasting; 4) effects of historical and pre-historical large earthquakes in the sedimentary record; 4) effect of fault-related deformation in term of fluid and gas emission from the seafloor.

THE NORTH-ANATOLIAN FAULT IN THE GULF OF IZMIT

After several years of geo-marine studies (POLONIA *et alii*, 2002; POLONIA *et alii*, 2004; CORMIER *et alii*, 2006; CAGATAY *et alii*, 2009; GASPERINI *et alii*, 2011a,b), which include collection and interpretation of high-resolution morhobathymetric maps, chirp-sonar profiles, side-scan sonar images, multichannel seismic profiles and several well-targeted gravity and piston cores, we can conclude that the Gulf of Izmit is characterized by the presence of a wide (>10 km) deformation zone across the trace of the North-Anatolian Fault (NAF) system (Figure 1), similarly to what observed in the Sea of Marmara, where the NAF trace is displaced by three major oversteps in correspondence with depocenters that reach over 1200 m of water depth. Figure 2 shows a detailed morphobathymetric map of the western end of the Izmit Gulf, the so called Darcia Basin, where the NAF trace shows a small scale complexity that reflects its behaviour at a larger scale.

We were able to precisely reconstruct the Principal Displacement Zone (PDF) in key areas where it is extremely narrow and shows an almost pure strike-slip deformation pattern. Due to the presence of displaced geomorphic features, such as abandoned canyons and river streams, we carried out estimates of horizontal and vertical deformation rates along these fault strands during the Holocene. Our estimated rate of about 10 mm/y, on both sides of the Marmara basin is low relative to models based on geodetic data, and suggest that either deformation is more diffused relative to the observed active faults, or geodetic data, at the scale of few decades, are not representative of the long term fault behaviour.

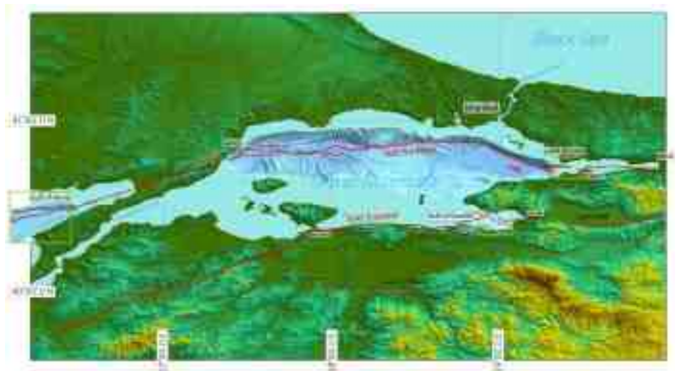

Fig. 1 – The North Anatolian Fault in the Sea of Marmara. Yellow box indicates the location of the W end of the Izmit Gulf were most of the work has been carried out..

Our data indicate that the surface rupture associated to the last Mw 7.2 Izmit earthquake reached the end of the Izmit Gulf, probably causing a tectonic load to the next segment towards Istanbul.

Moreover, we were able to determine association between active seismogenic features and the presence of "cold seeps" along the PDF of the NAF system in the Sea of Marmara. Round shaped features, probably created by the expulsion of fuids at the tip of transtensional faults are observed in the Gulf of Izmit (Figure 2), as well as the so called "black-patches". Such features are typical indicators of relatively continuous emission of methane at the seafloor. The anaerobic oxidation of methane

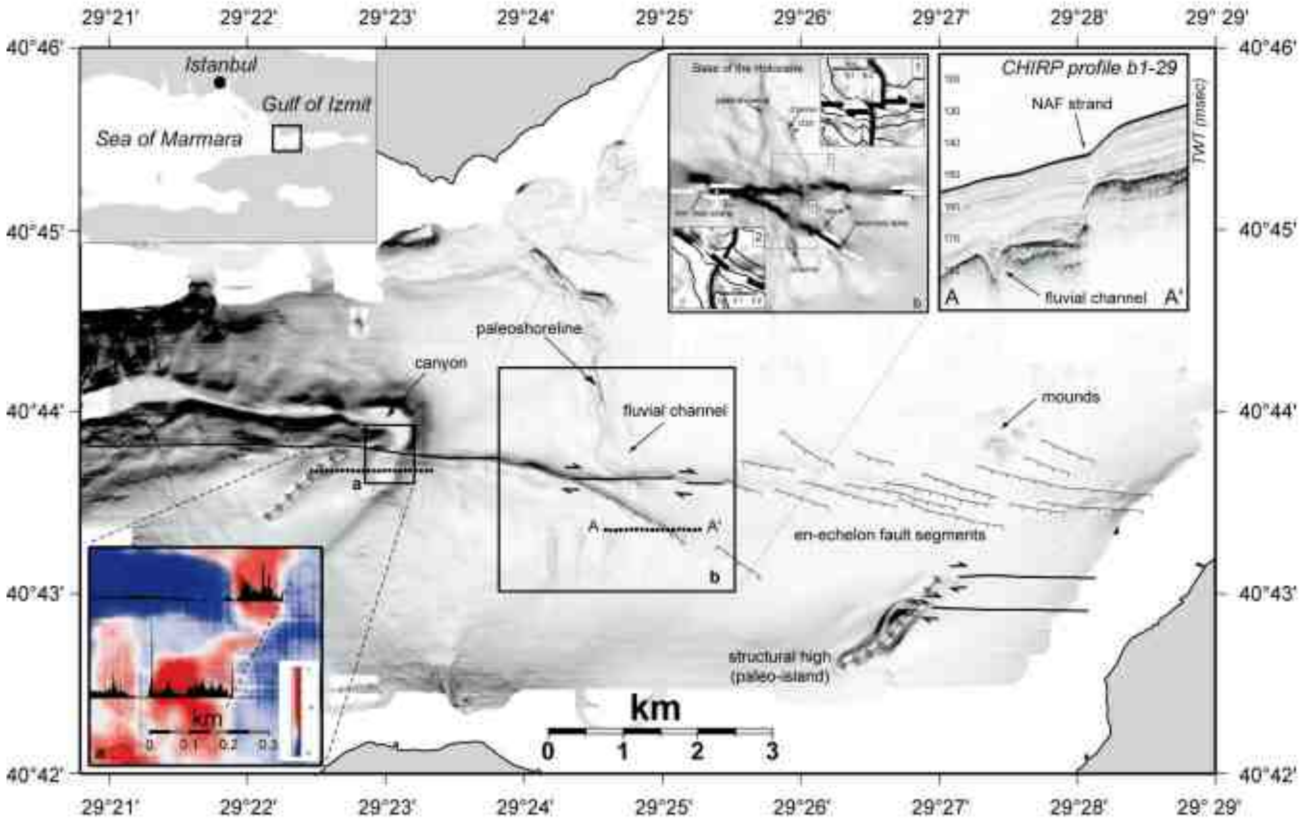

Fig. 2 – The Darica Basin at the W end of the Gulf of Izmit. We note that the NAF trace changes from wide transtensional deformation patterns (E), to more focued, almost pure strike-slip segments to the W. Several geomorphic features buried below 10-20 m of marine mud, including a displaced canyon and a river incision were used to estimate slip-rates at the scale of 10 ka.

triggers a suite of biogeochemical reactions that ultimately result in production of black Fe and Mn sulfide mineral assemblages.

We used these information to start a long-term monitoring of seismicity and gas and fluid emission through the combined use of seismometers and gas sensors deployed at the seafloor, to study the fault behaviour through time (MARINARO *et alii*, 2008).

Summary of results of RETREAT project

PONDRELLI, S. (*), MARGHERITI L. (**), SALIMBENI, S. (*), PIANA AGOSTINETTI N. (**), PICCININI D. (**), LUCENTE F. P. (**), LEVIN V. (***), PARK J. (°) & PLOMEROVA J. (°°)

Key words: *Seismic anisotropy, Subduction geometry, Temporary seismological network, Upper mantle fabric.*

The RETREAT project, is a multidisciplinary study of the Northern Apennines (earth.geology.yale.edu/RETREAT/), funded by the United States National Science Foundation (NSF) in collaboration with the Italian Istituto Nazionale di Geofisica e Vulcanologia (INGV) and the Grant Agency of the Czech Academy of Sciences (GAAV). The main goal of RETREAT was to develop a self-consistent dynamic model of syn-convergent extension, using the Northern Apennines as a natural laboratory. In the context of the project a passive seismological experiment was deployed in the fall of 2003 for a period of three years. RETREAT seismologists aimed to develop a comprehensive understanding of the deep structure beneath the Northern Apennines, with particular attention to the patterns of mantle flow. Specific objectives of the project have been the crustal and lithospheric thicknesses, determined trough Receiver Function (RF) analyses; the location and geometry of the Adriatic slab, and the distribution of seismic anisotropy laterally and vertically in the lithosphere and asthenosphere, obtained studying SKS splitting, QLove analysis and again RF techniques. The project collected teleseismic and regional earthquake data for 3 years to reach these goals. Attenuation map or tomographic models have been added to the results given by RETREAT seismological data.

Here we present a summary of mainly seismological, but also geological, results obtained within the project. From the seismological point of view, the data analysed bring to the conclusion that the rollback of the Adriatic slab didn't occur completely along the whole front. We suggest that slab-rollback, which created the Apennines and opened the Tyrrhenian Sea, evolved in the north boundary of Northern Apennines in a different manner from its southern part. In particular, the trench-retreat developed primarily south of our study region, with an eastward rollback. In the northernmost part of the mountain chain, after a first stage of retreat perpendicular to the trench, it became oblique with respect to the structure. The process continued as a secondary effect of the energetic slab-rollback going on in the southern edge of Northern Apennines. A slowdown of slab retreat produced the characteristics evidenced here: the orogen is narrower compared to its southern portion and the deformation of the mantle due to the slab retreat is located beneath the inner part of the chain rather than beneath the crest, as occurs south of RETREAT field area.

Earthquake focal mechanisms, seismogenic stress, and seismotectonics of the Calabrian Arc, Italy

DEBORA PRESTI (*,**), ANDREA BILLI (°), BARBARA ORECCHIO (*), CRISTINA TOTARO (*), CLAUDIO FACCENNA (**) & GIANCARLO NERI (*)

Key words: *Calabrian Arc, earthquake focal mechanism, seismogenic stress, seismotectonics.*

Crustal earthquake focal mechanisms are reconsidered for the Calabrian Arc, southern Italy, where heterogeneous seismotectonic domains occur and where the causative faults of several destructive earthquakes are still unknown. An up-to-date database of earthquake focal mechanisms as reliable as possible is compiled by evaluating the quality metadata of existing mechanisms increased by 15 newly-computed ones. A total of 144 mechanisms are selected and included in the database: 134 mechanisms elaborated by waveform analysis and 10 mechanisms elaborated by using P-wave first motions of earthquakes with good network coverage and no less than 14 records. The database includes focal mechanisms from earthquakes up to a minimum of magnitude 3.0 for the mechanisms from waveform analysis, and magnitude 1.9 for the mechanisms from P-wave first motion.

Focal data from the database are grouped into five subsets and inverted to obtain the seismogenic stresses in the study area. Results are compatible with three major tectonic domains subject to markedly different regional stresses along the arc. Two transitional domains are also found separating the three major domains. The transitional domains, which are located on top of the Ionian subducting slab edges, are likely forced in their transfer kinematics by the different tectonic regimes occurring in the adjacent major domains rather than by the regional tectonics. This differential tectonics is at least in part interpreted as the surface expression of the different deep mechanisms occurring in correspondence of the narrow Ionian slab and their lateral edges. Open tectonic questions are emphasized and proposed for future studies. In particular, our database and the derived seismogenic stress fields provide an overall picture of the main tectonic regimes as revealed by the seismicity of the last c. 35 years, and may also represent useful tools for further neotectonic and seismic hazard studies.

Distribution of seismic anisotropy beneath central Italy and geodynamic implications for Northern Apennines

SALIMBENI S. (*), PONDRELLI S. (*), MARGHERITI L. (**), LEVIN V. (°) & PARK J. (°°)

Key words: *Northern Apennines, Seismic anisotropy, SKS Shear wave splitting, RETREAT project.*

Between various geological and geophysical fields involved on the RETREAT project, one of the most important is undoubtedly the seismological one. In particular some seismological techniques allow to analyse properties of upper mantle and crust obtaining information that help to understand and to discriminate between possible geodynamical models as for example the retreat of the Adriatic slab.

Here we present observations of seismic anisotropy obtained from analysis of SKS phases done using the data recorded by the temporary seismic network of RETREAT project. Using phases recorded from teleseismic earthquakes, the study of seismic anisotropy allow to obtain information about the deeper part of the lithosphere as well as the shallower part of the asthenosphere. This is done studying the orientation of the most important anisotropic mineral composing the mantle, i.e the olivine .During the geodynamical processes occurring on a particular region, as for example the Northern Apennines, the crystallographic a-axes of the mineral (named also “fast axes”) tend to rotate parallel to the main deformational direction of the process. In this manner, the analysis of seismic anisotropy allow us to obtain information about the deformational state of an area as a consequence of its geological evolution.

The results we present here, confirm the existence of two main anisotropic domains. The Tuscany one showing mostly NW-SE fast axes directions (a-axes of the olivine), with a rotation toward E-W moving toward the Tyrrhenian Sea. The Adria domain showing more scattered measurements, with prevailing N-S to NNE-SSW directions; a back-azimuthal dependence is evidenced as possible witness of a complex distribution of the anisotropic properties beneath the area. The transition between the two domains is abrupt in the northern part of the study region while southward it is more gradual. The anisotropy is located principally in the asthenosphere. Only beneath the Adria domain a lithospheric contribution is not excluded. An interpretation of the anisotropy pattern as produced by mantle deformation is used to describe a differential evolution of the trench retreat process along the Northern Apennines orogen. Compared to the anisotropy pattern of the typical slab retreat taking place perpendicular to the slab strike in the northernmost part of the orogen the anisotropy trend suggests that a more oblique retreat occurred in the most recent orogen history.

INTRODUCTION

The geological evolution of the western Mediterranean exhibits complicated interactions between orogenic processes and widespread extensional tectonics. The region is located in a convergent plate margin separating Africa and Europe, and consists of marine basins – the Alboran Sea, the Algerian-Provençal Basin, the Valencia trough, the Ligurian Sea and the Tyrrhenian Sea- which formed as back-arc basins since the Oligocene. In most reconstructions, it has been stressed that back-arc extension led to drifting of continental blocks and to large-scale block rotations. The opening of the Ligurian Sea. is in fact the result of counterclockwise rotation of Corsica and Sardinia.

From the point of view of seismicity, the south western Alps and northern part of the Ligurian basin are subject to frequent earthquakes of low to moderate magnitudes. However significantly destructive events are known to have occurred in the past (e.g. 1564 and 1887). Apart from these rare large events, regional studies agree in concluding that the important local microseismicity appears to be poorly focused (e.g., COURBOULEX *et alii*, 2007) and that, if some tectonic lines are documented onland (COURBOULEX *et alii*, 2001), the active structures at sea remain unknown. It is therefore an essential prerequisite to gain better insight into the deep seismogenic structures along the North Ligurian margin and even farther offshore, in the identified oceanic domain. The fact that some of these structures can undergo ruptures of Mw~6.5, such as the 1887 event (BAKUN & SCOTTI, 2006), suggests that, at least to some extent, instrumental insufficiencies in the detection and location of microseismicity is a limit to identify active faults that have not experienced large instrumented ruptures to date.

The irregular coverage provided by regional seismic networks produces a bias in the recording of local seismicity. Permanent stations are naturally limited to land areas and fail to properly constrain seismicity offshore. Taking into consideration the peculiarities of regional dynamics (low strain rates, rare large events and a regular seismic activity limited to small events with $M < 3$-4), even onshore seismicity is insufficiently covered by permanent networks and requires dense temporary instrumenting by mobile stations.

Considering the potential threat of strong offshore earthquakes, it is of first importance to characterize faults that are prone to rupture in order to quantify associated seismic and tsunami hazards. Assuming some weak seismicity exists along these faults and remains undetected by onland networks, some marine stations are necessary to address instrumental remoteness and help delineate active structures.

Moreover, since the velocity models used for locations are obtained by inverting seismic data and the reliability of their locations depend, in turn, from the quality of the velocity model used for their hypocentral parameters, the constraints on the seismic path provided by a more dense seismic network may contribute to a more accurate reference model.

In this study, we profited from the recent developments in sea bottom seismic instrumentation to deploy OBSs above the zones of the North Ligurian to perform seismic shots and obtain the distribution of seismic velocities with 3D active tomography. We also took the opportunity of the long term (6 months) OBSs reduced array to decrease both the detection threshold and recording distances so as to obtain more complete catalogs and better localisations.

DATA ACQUISITION

The GROSMarin ("Grand Réseau d'Observation Sous-Marin") marine cruise – part of the project as a whole – was devoted to the deployment of OBSs and to the realisation of seismic shots. Marine operations took place in three phases, in April (deployments and seismic shots), June and October 2008 (recoveries).

Deployments of ocean bottom seismometers were first carried out onboard R/V l'Atalante. The array comprised twenty-one

OBSs of three types: ten recently developed stations of the Geoazur pool, six older instruments of UTIG design, from the same pool, and five instruments from KUM/IFM-GEOMAR featuring gimballed broadband sensors. All these instruments were fitted with 3-component geophones and a hydrophone. Fifteen of the twenty one stations were left for the whole duration of the passive recording phase whereas the six UTIG-type instruments were retrieved after two months, due to limited autonomy.

Intermediate (June) and final recoveries (October) were carried out onboard R/V Tethys II. Three instruments were reported missing after the June recoveries but two of these were later retrieved after drifting. Three other instruments failed to be released back during October recoveries, bringing the number of losses to 4 stations. Lost stations correspond to slots 6, 10, 13 and 19 (fig. 1) for which we have no data.

Fig. 1 – Map of the study area with seafloor bathymetry and land topography. The seismic acquisition device used during the GROSMarin experiment is displayed with the following code : permanent and temporary land stations on the French side are noted as yellow and orange squares respectively; same distinction on the Italian side with blue and light blue squares; OBS positions are given by red (AWI instruments), yellow (Geoazur 6-month deployed instruments) and green (2-month deployed instruments) circles. The seismic shooting route is indicated by the black and grey lines and follows the alignments of OBSs in both directions of the array.

The ocean bottom stations were deployed along a rectangular grid parallel to the margin. One slot was left empty close to the coast and two instruments extending the network 12.5 km seaward were placed to extend the box (fig. 1) and record potential events that would occur farther offshore. This geometry is a trade off between the number of stations available, the necessity to encompass active areas and that of keeping sufficiently small distances between stations to ensure a precise location of events and an acceptable resolution to the 3D tomographic model to be derived from the active data.

The recording array was complemented onland by mobile stations to densify the permanent networks; moreover, the regional velocimetric and accelerometric stations of the French (TGRS, ReNaSS and RAP) and Italian (RSNI) networks were included. The temporary land network was left for the same duration as its marine counterpart.

Immediately after OBS deployments, seismic shots were fired from a deep refraction seismic source towed by R/V l'Atalante. The shooting route is coincident with the grid of OBSs (fig. 1), yielding the acquisition of five ~105 km-long lines across the margin (lines from West to East) and four ~165 km-long lines along (lines from the basin to the coast) – the landwardmost shorter due to the concavity of the coast. The geometry of acquisition and planned tomography being 3 dimensional, shots kept on being fired while joining profiles, providing additional directions of coverage, in particular along the ~75 km-long oblique profile that connects the series of transverse to longitudinal profiles. The two landwardmost WSW-ENE profiles include significant departures from the theoretical straight route due to cruising constraints, which is not an issue for 3D analysis.

RESULTS AND DISCUSSION

Recorded data were corrected from clock drift. The data corresponding to the period of active seismic shots were merged with the acquisition file to make seg-y files suitable for wide-aperture seismic data analysis. Data were cut line by line; bandpass filtering and velocity reduction were applied before proceeding with manual picking of first arrival refracted phases. These first arrival picks were gathered in subsets that showed good trace-to-trace coherency and an homogeneous signal to noise ratio; each subset was consequently assigned a picking uncertainty through visual assessment.

In order to perform tomographic inversion of the picked travel times, a box (182 x 120 x 30 km , with x parallel to the margin and y perpendicular to it) was thus built that encompasses all our acquisition geometry.

A compilation of local 25 and 50 m multibeam bathymetric grids was used to get an accurate interpolated bathymetry inside our frame. The tomographic approach we use here is a linearised algorithm where the inverse problem of first arrival travel time misfits is solved iteratively with regularisation constraints to keep stability and some smoothness to the model and avoid ray prints (ZELT & BARTON, 1998). Ray paths are calculated by back propagation through travel time maps that are obtained by a finite difference Eikonal solver (HOLE & ZELT, 1995). A starting model that ensures convergence of the inverse problem is required. In practice, we used a layered model of realistic and continuous velocities increasing linearly with depth and added bathymetry on top.

The results were obtained after eight non linear iterations within each of which three linearised iterations were performed to seek for the best weighting coefficients of regularization constraints. The RMS dropped from 319 ms down to 76 ms during the inversion.

Tomographic models based on inversion of first arrival travel times are inherently of low resolution. The results show a variability in the distribution of velocities that is mainly oriented perpendicular to the margin, as expected. Although some information on bathymetry is included in the starting model, it turns out that the bathymetric imprint is actually stronger in the final model. This observation tends to show that the shallow velocity structure and bathymetry are linked and that, at a given depth within upper sediments, higher velocities are found where bathymetry is lower (i.e., where water depth is less), which can be interpreted as a likely effect of greater compaction of sediments where the overlying stratigraphic pile is thicker.

Between 3 and 6 km depth, we observe generally lower velocities in the lower right part of the horizontal tomographic model than elsewhere. This large zone of comparatively lower velocities diminishes in extent as depth increases. Beyond 6 km and down to 11 km, there is no more clear and coherent velocity variation along strike.

Deeper down, velocities of 7-7.5 km.s-1 are encountered between 11 and 13 km depth. These values are greater than what is classically observed in continental or oceanic deep crusts. A possible interpretation would be that the Moho is crossed around these depths and that we observe a transition to mantle velocities that is smoothed by refraction tomography.

The preliminary analysis of the seismicity leads to some observations. We recorded some events in the foreland area, especially inside the zone our land network covers, with hypocentral depths generally less than 5 km, as already evidenced there by local studies. Some clusters of shallow events can be observed nearby known tectonic lines such as the Blausasc fault (COURBOULEX *et alii*, 2007), and Saorge-Taggia line (TURINO *et alii*, 2009). A few events are identified at sea, mainly below the continental slope. A large part of these events lie in our network and two small clusters are recorded slightly east of it, offshore Imperia. One event is detected in the basin so far, below the Var channel. Hypocentral depths for offshore events fall in a 5-15 km range, which is deeper than for nearby onshore events. This discrepancy between depths in the foreland and on the margin hint at distinct patterns with a seismicity that essentially affects the sedimentary cover of the subalpine domains on land and a deep-seated activity within the thinned continental crust and contiguous transitional and oceanic domains at sea.

An important result lies in the fact that several events identified and located using all French and Italian permanent stations failed to be detected without the data provided by the Italian network, especially for five events below the margin, albeit four of these events happen to be located offshore France. Statistically, it is also important to point out that for those events that were already detected by French stations, the addition of data from the Italian side allowed to qualitatively improve locations and to reduce error on hypocentre. For events at sea, the error was brought from ~10 km down to ~5 km on average, which underlines the importance of azimuthal coverage.

In conclusion, our tomographic investigation reveals that the velocity structure at the scale of the whole basement in the landwardmost part of the deep basin is very reminiscent to that observed across the Gulf of Lions. A characteristic feature we observe is the high velocity zone at the base of the seismic crust that is most likely related to the presence of serpentinites. Such a unit is considered to characterize the transitional zone that separates well identified thinned continental and oceanic domains on several other non volcanic rifted margins, in particular along the Gulf of Lions.

Our results also hint at a more progressive seaward crustal thinning at depth below the margin slope on the western part of our zone than on the eastern one, an observation we tentatively relate to the coincident morphological change of the margin along strike. It can also be observed that this change coincides with the apparition of a significant seismicity in the margin and contiguous basin east of the Var river, the activity being much more limited west of it.

Results from the seismological component of CAT/SCAN, the Calabria-Apennine Tyrrhenian/Subduction-Collision-Accretion–Network

STECKLER M.S. (*), GUERRA I. (°), AMATO A. (°°), ARMBRUSTER J. (*), BACCHESCHI P. (°°), DILUCCIO F. (°°), GERVASI A. (°) (°°), GU Y.J. (**), LERNER-LAM A. (*), MARGHERITI L. (**), PIANA AGOSTINETTI N. (°°°) & SEEBER L. (*)

Key words: *Calabrian Arc, CAT/SCAN network, Local seismicity, Receiver function.*

The Calabrian Arc is the final remnant of a Western Mediterranean microplate driven by rollback. The Calabrian-Apennine-Tyrrhenian/Subduction-Collision-Accretion Seismic Network (CAT/SCAN) was a passive seismic experiment to study of the Calabrian Arc and its transition to the southern Apennines. The follow up Calabrian Arc project added a multidisciplinary (seismology, geology, geomorphology, geochronology, GPS, etc.) approach to better understand the tectonics of southern Italy imaged by the CAT/SCAN experiment. Here we focus on the seismological results of the two projects.

The CAT/SCAN land deployment consisted of three phases. The initial phase included an array of 39 broadband seismometers onshore, deployed during the winter of 2003/4. In September 2004, the array was reduced and in April 2005, the array was reduced once again. The field deployment was completed in October 2005. Offshore, 12 broadband Ocean Bottom Seismometers (OBSs) were deployed in the beginning of October 2004. However, only 1 was recovered normally while several others were recovered after being disturbed by trawling. The experiment goal was to determine the structure of the Calabrian subduction and southern Apennine collision systems and the structure of the transition from oceanic subduction in Calabria to continental collision in the southern Apennines.

Seismic imaging using receiver functions (RF) shows a structure for the Southern Apennines that is most consistent with a thick-skin, basement involved model of the orogen.

Surface waves imaged a crustal low velocity zone beneath the Southern Apennines and another smaller one beneath Mt. Vulture. A different structure is seen in Calabria, where the RF images the sharp bending of the Adria plate from the shallow subduction zone to a steeply-dipping slab. This transition corresponds to where the surface tectonics switches from an uplifting plateau (Sila Plateau) to an extensional basin (Crati Valley). The nose of the mantle wedge does not extend past western Calabria. Local seismicity is consistent with surface structure in showing extension normal and parallel to the Calabrian forearc. The RF image also shows a 10-km thick low-velocity zone below the 25-km thick Plateau that we interpret as imbricated sediments and/or the upper portion of the oceanic crust offscraped from the downgoing plate. At greater depth, shear-wave splitting delineates a strong anisotropy with a fast direction that follows the curved arc. The zone of high anisotropy is limited to a zone of ~100 km in front of the slab. There is a possible flow around the edge of the slab below Sicily in the west. Another possible flow around the other edge of the slab is seen north of the Southern Apennines at 41°N. No flow is detected at the suspected slab gap below the Southern Apennines. This flow may not be seen because it is too small and recent to have reoriented the anisotropy. Together these suggest a previously larger Calabrian slab split in two relatively recently after the Southern Apennines collided with Apulia. The anisotropy beneath the Tyrrhenian Sea is weaker, but shows frequency dependence suggesting small pockets of high anisotropy in the mantle wedge. Rays propagating up the slab establishes that it has very little anisotropy. Many questions remain, but these seismological results, in conjunction with the multidisciplinary observations are beginning to form a coherent picture of Calabria tectonics, clarifying fundamental issues about rollback subduction and collision - the trademarks of Mediterranean tectonics.

Seismological contribution to STEP fault detection in the Calabrian subduction zone, south Italy

TOTARO C. (*), ORECCHIO B. (*), PRESTI D. (*), GERVASI A. (**,°), GUERRA I. (**) & NERI G. (*)

Key words: *Calabrian Arc, Focal Mechanisms, STEP faults, Seismotectonic*.

The Calabrian Arc system (southern Italy) is characterized by the presence of the southeast-ward retreating Ionian slab subducting beneath the southern Tyrrhenian region.

Recent intermediate tomographies indicated that the Ionian slab is continuous in depth beneath the central part of the Arc (central Calabria-Messina Straits), while detachment of the deep portion of the subducting structure may have already taken place beneath the edges of the Arc itself (southern Apennines and Sicilian Maghrebides). Geophysical investigations, including seismic tomography, gravity analyses, earthquake and geologic data, led us to better identify the transitional zones between different subduction modes in correspondence of the NW-trending seismogenic faults of Tindari and Crotone Basin, respectively (see NERI *et alii*, 2012). According to the model introduced by GOVERS & WORTEL (2005) and adopted also by other investigators for describing the dynamics at the borders of retreating subduction slabs, we suggested that these seismogenic faults may work as Subduction-Transform Edge Propagator (STEP) faults in the Calabrian subduction system.

In order to investigate these STEP fault zones, we have applied in the present study the waveform inversion method known as Cut And Paste (ZHAO & HELMBERGER, 1994; ZHU & HELMBERGER, 1996) for computation of seismic moment, depth and focal mechanism of earthquakes with magnitude greater or equal to 3 occurred in the Calabrian Arc region between 2004 and 2011. This method allowed us to obtain high quality results even for low magnitude earthquakes (M ca 3) and to significantly improve the database of focal mechanisms available to date, especially in northern Calabria. The results obtained in the present study are reported together with good quality solutions taken from the main national databases (Italian CMT, RCMT, TDMT, www.ingv.it).

An extensional stress regime can be observed in southern Calabria with NW-SE opening direction. Transtensional regime of stress can be detected at the borders of the subducting slab (northern Calabria and north-eastern Sicily, respectively).

We also selected shallow-to-deep earthquakes of magnitude over 2.5 occurred in the study region between 1997 and 2011 and performed hypocenter locations by using the most recent 3D velocity model (NERI *et alii*, 2012), linearized methods like Simulps and also the probabilistic non-linear location method Bayloc (PRESTI *et alii*, 2004 and 2008). The latter has been used, in particular, in order to identify and characterize the main seismolineaments of the area, even by means of particular implementations aimed at recognizing seismogenic structures.

The joint interpretation of focal mechanisms combined with the results derived from seismicity analysis lead us to suggest that the wide seismogenic fault zones identified at the borders of the retreating Calabrian subduction slab effectively work as "STEP zones" in the local subduction system.

Audiomagnetotelluric study at the hotsprings of the northern segment of the La Candelaria Range: preliminary results

H. BARCELONA (*), C. UNGARELLI (*), A. FAVETTO (*), C. POMPOSIELLO (*) & V. PERI (*)

Key words: *audiomagnetotellurics, geothermal, NW Argentina*.

INTRODUCTION

Usually, the complexity of a geothermal field a in depth is constrained by a number of factors, such as the geological framework, the deep fluid circulation associated to the fractures control and the geometry of the system. Furthermore, the relationship between such factor and superficial manifestations is quite complex and do not provide direct information pertaining to the geometry and th energy content of reservoir. The northern segment of the La Candelaria Range (LCR) is an example of such complex relations and shows several kinds of geothermal manifestations, including hyperthermal hot springs. Seggiaro et al. (1997) proposed a geothermal water circulation model based on infiltration of meteoric water in the upper highland areas where permeable rocks are exposed. Several discontinuities allow the conduction of water in depth where its temperature rises and emerges at lower topographic levels at the northern apex range. This theoretical system of water circulation appears to be plausible. However, no detailed data is available and very little is known about the deep configuration of the geothermal system at the hot springs zone.

The aim of our work is to define the resistivity distribution of the northern segment of LCR. Particularly, the work focuses on the hot springs zones in order to determine the geometry and extension of the geothermal system. For this purpose, MT data were recorded in the area. We then carried out a detailed distortion and dimensional analyses of the soundings. Several two-dimensional inversions were performed along different profiles and a series of conductive anomalies were defined.

(**)WesternGeco GeoSolutions – Integrated EM Center of Excellence, Milan, Italy.

GEOLOGICAL SETTING

LCR is located between the Cordillera Oriental and Santa Barbara system morphotectonic units, northwestern Argentina. Regionally, is part of a N-S fault and thrust system evolved in response to the stress transference from Western Cordillera to foreland during the final stages of Andean deformation (Ramos, 1999). Also, LCR represent a thick-skinned deformation front which a Miocene-Pliocene main event (Mon, 2001). The stratigraphic column shows the basement deformation and describes a tectonic events sequence associated to the evolution of the cretaceous rift system until the thermal subsidence stage interrupted by Andean orogeny deposits (Iaffa et al., 2011). Locally, two anticlines are the major structures of the zone. These anticlines and the NW-SE, E-W inherited fractures are supposed to be the structural framework to all the geothermal system.

AMT ACQUISITION AND PROCESSING

The audiomagnetotelluric method is based on the measure of high frequencies variations of the horizontal components of the magnetic and electric fields. A total of 30 AMT sites were surveyed using a Geometrics STRATAGEM equipment during October of 2011. The frequency range used during this acqusition was set between 10 Hz and 1000 Hz; in some cases, data were also acquired at higher frequencies (up to 10000 Hz) in order to achieve more sensitivity for very shallow depths (the first tens of meters).

The geometric arrange of the sites was roughly an orthogonal mesh with a preferential E-W orientation, according to the geological features of the area. The sites were placed at a relative distance of about 1Km; on the edge of the survey area the inter-stations distance was shorter to obtain a better image of the hot springs. For each site the estimate of the full impedance tensor in the given frequency range was obtained processing the AMT magnetic and electric time records using IMAGE software. Also, a dimensionality and distortion analysis was carried out.

PRELIMINARY RESULTS

Using the processed data and the results of the dimensionality and distortion analysis, we carried out a series of two-dimensional inversions along four E-W oriented profiles and along one N-S profile in order to characterize the resistivity distribution in depth. The inversion algorithm adopted was the one by Rodi & Mackie (2001). The resulting models produced a satisfactory misfit (RMS at most 1.6). Starting from those resistivity models, a series of shallow conductive anomalies were identified at the four E-W profiles, characterized by a decreasing - from north to south - thickness. Furthemore, The resistivity distribution along the N-S profile, which partially crosses the hot springs area, turns out to be characterized by a shallow resistive medium (>20 Ωm) and a more conductive (~ 8 Ωm) structure below 100 m depth. Also, a superficial conductive anomaly extending in depth is present in the model just below the hot springs area.

CONCLUSIONS

In this work we have applied the AMT method in order to characterize the hot springs field at the northern segment of LCR. The processing and modeling of AMT data allowed to estimate a resistivity distribution was determined and to identify shallow and deep conductive anomalies.

The distribution of such anomalies turns out to be in agreement with the hydrogeological features of the area. In particular, the deep conductive anomaly on the summit of LCR is consistent with the presence of geothermal fluids.

Those preliminary results indicate that the shallow conductive anomalies should be carefully interpreted within a geological, hydrological and topographical framework. Additional geophysics studies are needed to fully investigate the geometry and main features of such geothermal system at higher depths.

ACKOWLEDGEMENTS

We thank Geotermia Andina for providing financial support. Also, we kindly thank. E. Llambias for his invaluable help during the AMT survey.

Integrating geology and magnetotelluric data in geothermal exploration: an example from West Anatolia

ALESSANDRA GIOVANNA BATTAGLINI (*), IVAN GUERRA (*) & CARLO UNGARELLI (*)

Key words: *Geologic Interpretation, Geothermal exploration, Electromagnetic Methods, Electrical Resistivity, Magnetotellurics, Structural Geology.*

SUMMARY

The magnetotelluric method is often used to assess geothermal reservoirs and to shape geologic settings required for these types of reservoirs. When any specific measurement is given for the lithology context, the geologic interpretation can help identify the existence of tectonic elements such as fracturing and fault systems. This paper shows an example of how magnetotelluric acquisition and modeling can be integrated with geologic interpretation for a successful geothermal exploration.

INTRODUCTION

In recent years, electromagnetic (EM) methods were extensively applied to geothermal exploration (see Spichak and Manzella (2009) for a recent review). Such methods provide – through imaging of the electrical resistivity in the subsurface – useful information pertaining to the geologic, compositional and hydraulic conditions of geothermal systems.

Amongst the various methods, magnetotellurics (MT) is based upon the measurement of the fluctuations of the natural electromagnetic (EM) field at the earth's surface over a wide frequency range (10^{-3} to 10^{4} Hz). Given the diffusive nature of the EM field in the earth, the method allows reaching high depths at low frequencies; on the other hand, cultural noise can severely affect the results of MT soundings, and dedicated, robust processing procedures must be implemented.

Focusing – for the sake of simplicity – to convective hydrothermal resources, the main target for geothermal exploration is a region characterized by fractures and faults filled with hydrothermal alteration products and overlaid by a low-resistivity clay cap. Within such a framework, the resistivity anomaly from a deep conductive reservoir with a larger, more conductive clay cap is not due to EM induction, but rather is caused by the occurrence of electrical charges at the boundary between the two conductors. Hence, methods based upon the simultaneous measurement of both electric and magnetic fields such as MT are the most effective in imaging the reservoir (Pellerin et al., 1986). Furthermore, various studies pertaining to volcanic geothermal areas have confirmed that MT imaging of geothermal zones is quite effective for gaining information on both the base of the conductive clay cap and on the location of low-resistivity anomalies, i.e., possible candidates for the geothermal reservoir (see Spichak and Manzella (2009) and references therein).

In this paper, we present the results of a case study carried out in West Anatolia where the MT method (acquisition, processing, and modeling) was integrated with a geologic interpretation to maximize the chance of success for geothermal exploration. From the geologic point of view, the area object of this study is located in the Anatolian Peninsula, a zone of complex regional tectonics associated with the interaction of four of the earth's major lithospheric plates: Arabia, Somalia, Nubia, and Eurasia (Reilinger et al., 2006).

This area is also one of the most seismically active regions in the world (McKenzie et al., 1972). Past geologic studies and GPS measurements indicate that the Anatolian Peninsula is an example of tectonic extrusion towards W-SW along the North Anatolian Fault Zone (NAFZ) to the North and the East Anatolian Fault Zone (EAFZ) to the SE (Reilinger et al., 2006). In this context, extensional and trans-tensional tectonic features formed (horst-graben systems) in the whole Anatolian Peninsula, with a gradient that identifies a general trans-tensional behaviour in the East Anatolia and a more extensional regime in the West Anatolia (the "Aegean graben system" in the sense of Seyitoglu et al., 1992). This geologic setting makes the Anatolian Peninsula one of the most promising areas for performing geothermal exploration.

In the next section, we will describe the main features of the MT survey and the associated data processing workflow. The following section will be devoted to the three-dimensional inversion of MT data and modeling results.

(*) WesternGeco GeoSolutions - Integrated EM Center of Excellence

In the last section, we will analyze the corresponding results for the resistivity distribution within a geologic framework, followed by some conclusions.

ACQUIRING AND PROCESSING MT DATA

For this case study, we used a data set comprising more than 100 MT stations surveyed in Turkey. The magnetic and electric time records were acquired using five-channel ADU-06 Metronix receivers equipped with non-polarizeable Pb-PbCl electrodes and induction coil magnetic sensors and using a set of sampling frequencies to cover a broad frequency band (0.001 Hz to 10000 Hz). For most of the stations, the total observation time was 12 hours. For each station, the electric field was recorded along two orthogonal directions (typically N-S, E-W), while the magnetic field was measured also along the vertical direction.

For each site, the full set of time records was used to obtain, over the above mentioned frequency band, a reliable estimate for the full magnetotelluric transfer function (both the impedance tensor and the tipper vector). Because natural magnetotelluric signal are superimposed with "noise" signals produced by nearby environmental, man-made sources, the remote reference method (Gamble et al., 1979) was adopted within a data analysis workflow where two different robust processing algorithms were used (Larsen et al., 1996, Chave and Thompson, 1992). The implementation of such a work flow allowed us to obtain, on average, good-quality estimates of the magnetotelluric transfer function.

THREE-DIMENSIONAL INVERSION AND MODELING OF MT DATA

The data were interpreted using 3D forward and inverse modeling to derive a reliable Earth model consistent with observations. The inversion algorithm used the NLCG (Non Linear Conjugate Gradient) method to search the solution space for models that minimize the objective function, i.e., the sum of the normalized data misfits and a term related to model smoothness (Mackie and Madden, 1993; Rodi and Mackie, 2001). The frequencies over which the model responses were computed ranged from 0.001 to 1000 Hz, with a constant logarithmic spacing. By varying the relative weight between the data misfit and the smoothness of the resistivity distribution, the most stable result (i.e., the most reliable model) turned out to be characterized by a low global RMS (1.5, being 1 the ideal target value). Figure 1 shows a horizontal section (at an elevation of -1500 m) of

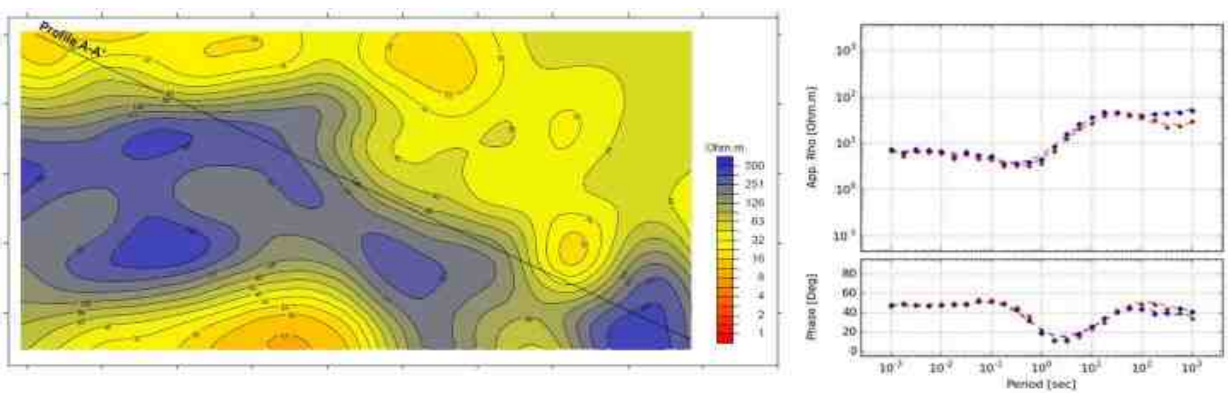

Fig. 1 - Resistivity map obtained from the 3D resistivity model at constant elevation of -1500 m above sea level (left). Example of indicative sounding data fit (right), the RMS for this site is 1.3.

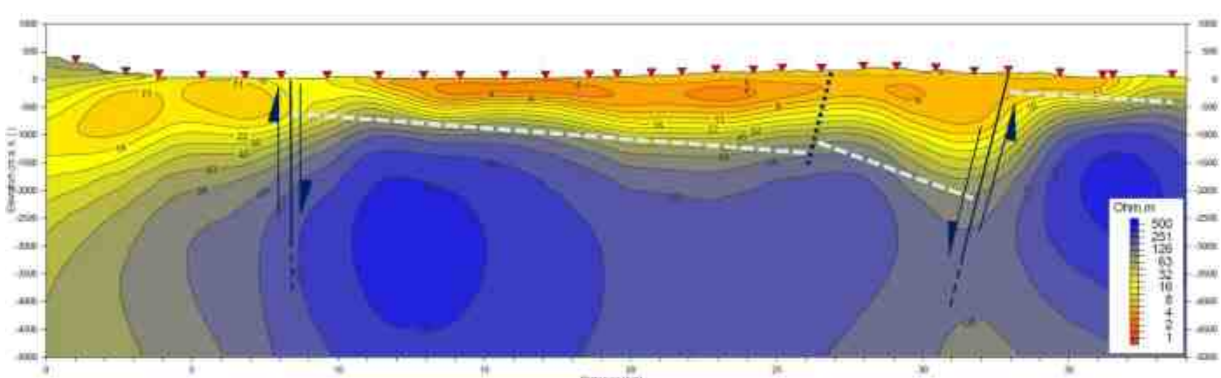

Fig. 2 - Resistivity cross section through the 3D resistivity model along Profile A-A' (see Figure 4, NNE is to the left) with a corresponding geologic interpretation.

the resistivity distribution obtained by the three-dimensional inversion of the MT data, giving the lateral boundaries of the resistive body at high depth. Figure 2 shows a resistivity cross section along a profile oriented NNE. This profile shows some interesting features.

First, at shallow depths, a conductive layer is present roughly above the deeper resistive body (blue layer). This conductive layer seems to become thicker towards the SE, and is consistent with two major faults forming the shoulders of a main horst-graben-horst system. Moreover, between these two faults, it is possible to infer a second-order fault that dislocates the graben. The material into the graben seems to be tilted towards the SE, as indicated by the dashed white horizons drawn in Figure 2. Furthermore, the resistive body present in depth is interrupted near vertically on both ends by a “channel” of more conductive material.

CONCLUSIONS

3D MT inversion and geologic interpretation of the obtained data allow a better understanding of the study area for geothermal exploration purposes.

A key cross section through the 3D MT resistivity mesh shows a highly resistive body in the centre of the section, from a depth of about 1000 m downwards. This body is limited on both sides by less resistive material that forms two nearly vertical “channels”. Roughly above the resistive body, at shallow depths, there is a highly conductive layer that seems to become thicker towards the SE. This highly conductive layer is not present at both sides of the section.

Looking at these data from a geologic perspective and with a background given by the existing literature on the study area, it is possible to interpret the two nearly vertical “channels” as major trans-tensional faults. These two lineaments are part of the main trans-tensional system classically invoked to explain the extrusion of the Anatolian plate along the North Anatolian Fault Zone, the Bitlis Suture Zone, and the East Anatolian Fault Zone (Reilinger et al., 2006). This interpretation is consistent with the local structural setting of the study area, where two major structural lineaments crosscut the key section at the point where the 3D MT inversion isolates the highly resistive body in depth. The interpretation of the key section (Figure 2) also highlights a highly conductive body at shallow levels. The thickening of this conductive body to the SE could suggests, 1) a differential subsidence within the graben, with the south-eastern part subsiding quicker than the north-western one, or 2) a syntectonic sedimentation active from NW to SE. The conductive sediments have been eroded on the two graben shoulders, completely to the NW and partially to the SE.

This integrated case study gives important information about the tectonic framework in which a geothermal field could be developed. These results can be directly applied to recognize preferential paths for heat flow and, consequently, for placing infrastructures related to the exploitation of geothermal energy.

Chemical and isotope characteristics of the Rosario de la Frontera geothermal fluids, La Candelaria Range (Salta, Argentina)

A. CHIODI (*), F. TASSI (**) W. BAEZ (*) R. MAFFUCCI (°) L. DI PAOLO (°) J. VIRAMONTE (*)

Key words: *Geothermal fluids; Rosario de la Frontera; geochemistry of fluids; geothermal prospecting.*

The present study is a part of a multidisciplinary investigation of the thermal springs in the area of Rosario de la Frontera, carried out in order to produce a preliminary evaluation of geothermal potential of this system. These thermal manifestations, whose temperature varies from 22.7 to 93.3 °C, are located in the northern sector of the La Candelaria Range, Salta province, Argentina (MORENO *et al*. 1975) (Fig.1). This study is based on analytical evidence of the chemical and isotopic composition ($\delta^{18}O_2$, δD e $\delta^{13}C$-CO_2) of 13 water and 5 gas samples taken from the springs.

The water samples shows relatively low salinity (TDS < 1000 mg/L), with the exception of 3 sources (Agua Laxante, Vicky and Salada) which are characterized by TDS values between 5500 and 30000 mg / L. All the water samples are sodium chloride composition (Fig.2a), and 3 of them has significant concentrations of sulfate ion (up to 3000 mg / L). Samples does not show significant enrichment in ammonium ion (<0.28 mg/L) and boron (<0.51 mg/L), commonly used as tracers for fluids of hydrothermal origin. The values of the isotopic ratios of water (respectively -6.7 e -37 ‰ V-SMOW for $\delta^{18}O_2$ δD), suggest predominantly meteoric origin for these fluids (GONFIANTINI 1978; CLARK & FRITZ, 1997; CRAIG 1961.) (Fig.2b).

The gaseous phases associated to the thermal water as a bubbling gas, are mainly constituted by CO_2 (between 550 and 960 mmol / mol) with significant concentrations of N_2 (>28 mmol/mol), that in the case of Zarza and Silicosa samples (385 and 415 mmol / mol) are comparable to the CO_2 content. The 3 gas samples with high CO_2 content (Sulfurosa de la Vieja Quemada, Sulfurosa and Aguas Chicas) presents higher concentration of H_2S (up to 3.6 mmol / mol), H_2 (up to 0022 mmol / mol) and CH_4 (up to 0087 mmol / mol), and the lowest concentrations in atmospheric gases (O_2, Ar and Ne), compared to the 2 gas samples rich in N_2. The $^{13}C/^{12}C$ ratios in CO_2 ($\delta^{13}C$-CO_2 from -5.16 to -3.66 ‰ V-PDB) are consistent with a mantle

Deep water hydrothermalism in the southern Tyrrhenian Sea: potential field features of the Marsili and Palinuro volcanic seamounts

LUCA COCCHI (*), FILIPPO MUCCINI (*) , COSMO CARMISCIANO (*), GIOVANNI BORTOLUZZI (**) & FABIO CARATORI TONTINI (°)

Key words: *Earth's Magnetic field, gravity anomaly, volcanic seamounts, geothermal system, Tyrrhenian Sea, hydrothermalism.*

INTRODUCTION

Discovery and exploitation of renewable energy resources represents one of the major tasks of the Horizon 2020 European Research Project, particularly in fields of pollution and CO2 emission reduction. The geothermal energy may be considered as one the principal renewable resources, and could effectively take over the use of fossil fuels for heat and electricity production and distribution. The exploitation and exploration of this resource in Italy is yet limited, being localized mainly on land, where high gradients are correlated to recent or past volcanic activity. The geothermal potential of Italy could be largely increased by taking into account normal gradient areas, e.g. the Garda Lake and surrounding Gardesan South alpine Sector, as well as the off-shore marine reservoirs associated with back-arc volcanic seamounts, e.g. in the SE Tyrrhenian Sea

Volcanic seamount of the Tyrrhenian Sea such as the Marsili, Palinuro and others of the Aeolian arc are all characterized by shallow manifestation of hydrothermal alteration because of a deep circulation of hot geothermal fluids. The investigation and the description of these peculiarities are not easily achieved using the common geophysical methodologies applied on-land for geothermal purpose. The offshore geothermal prospection approach combines different techniques using also not-conventional methodologies such as the joint modelling and interpretation of the magnetic and gravity datasets.

Here we present the results of research prospection based on high resolution potential field dataset on the Marsili and Palinuro volcanic structures that were acquired during surveys of 2006 (*MAR06*, PALTRINIERI *et alii*., 2006), 2008 (on board of Nave Aretusa of Hydrographic Institute of Italian Navy (IIM)) and during the most recent 2011 oceanographic campaign with R/V Urania of CNR. Although with different distribution and intensity, Palinuro and Marsili seamounts are both affected by intense hydrothermal alteration associated with a high rate of heat flow. The geothermal features of these two seamounts are described observing the anomalous variation of the Earth's magnetic field coupled to the local discrepancy of the density values within the upper crustal portion of the seamounts. In the case of the Marsili the hydrothermal alteration is strongly connected to a shallow geothermal reservoir localized around the summit area with an extension of about 2 km just above a active magma chamber (CARATORI TONTINI *et alii*., 2010).

PALINURO VOLCANIC COMPLEX

The Palinuro volcanic edifice rises from 3000 to 80 m b.s.l (figure 1). It consists of some separate volcanic bodies that are basally connected to form a continuous volcanic ridge (MARANI AND GAMBERI, 2004). The E–W orientation of these small summit cones may represent evidence of the supposed strike-slip fault (COLANTONI *et alii*., 1981; DEL BEN *et alii*., 2008) which may have triggered the genesis of the Palinuro complex. It appears that the topography of the seamount shows a N–S asymmetric shape, with the crest separating a southern portion, characterized by steep scarps reaching a depth of about 3000 m, from the northern portion that decreases to about 1800 m with a lower topographic gradient, whilst approaching the continental margin.

In 2008 a detailed potential field geophysics survey of the Palinuro was carried out on board of Nave Aretusa of IIM. The entire apparatus was covered recording the local variation of magnetic and gravity fields. Quantitative interpretation of local gravity anomalies along a N-S transect identified a clear differentiation of the density of the crustal portion passing from the oceanic structure of the Marsili basin (at south) to the northern continental domain.

These evidences allowed us to interpret the local morphologic high, where the Palinuro was established, as the local oceanic-continental crustal boundary (MUCCINI *et alii*., 2008). Sea surface magnetic data acquired during the 2008 survey indentified a low-magnetization area localized within of a circular morphologic structure interpreted as a caldera rim (MARANI AND GAMBERI, 2004).

This area shows a clear vanishing magnetization pattern (or approximately around 0 A/m values) which is strongly confined within the caldera structure. This sector of the edifice is characterized by surface incipient alteration associated to mineral deposits and sulphides chimney, although these latter are often covered by thick sedimentary deposits. In 2011, we performed a near-bottom magnetic investigation (on board of R/V Urania) with a clear enhancing of the magnetic signature of this volcanic sector permitting a clear description of the 2D distribution of the hydrothermal alteration.

MARSILI VOLCANO

Marsili seamount a 70 km long, 30 km wide volcanic edifice elongated NNE–SSW, rises 3000 m from the relatively flat 3500 m deep southern Tyrrhenian Sea back- arc basin, where extensional tectonics related to the subduction of the Ionian slab has generated spreading and injection of oceanic- type basalts in the last 2.0 Myr (KASTENS *et alii*., 1998; MARANI AND TRUA, 2002). COCCHI *et alii*. (2009) also showed that Marsili started its vertical accretion approximately 1 My ago; it can be interpreted as a super inflated ridge due to a strong pulse of magma upwelling through a tear in the subducted Ionian slab (MARANI AND TRUA, 2002).

Geophysical pattern of this volcanic edifice is peculiar with a strong variation of the magnetic signal along the ridge portion.

The volcano's summit is characterized by a geothermal reservoir that manifests itself with a well hydrothermal alteration. This rock-alteration consists mainly of Fe-altered basalts and sulphides deposits and chimneys and alteration of hyaloclastites deposits (correlated to the huge amount of pillows lava). This volcanic area is characterized by vanishing

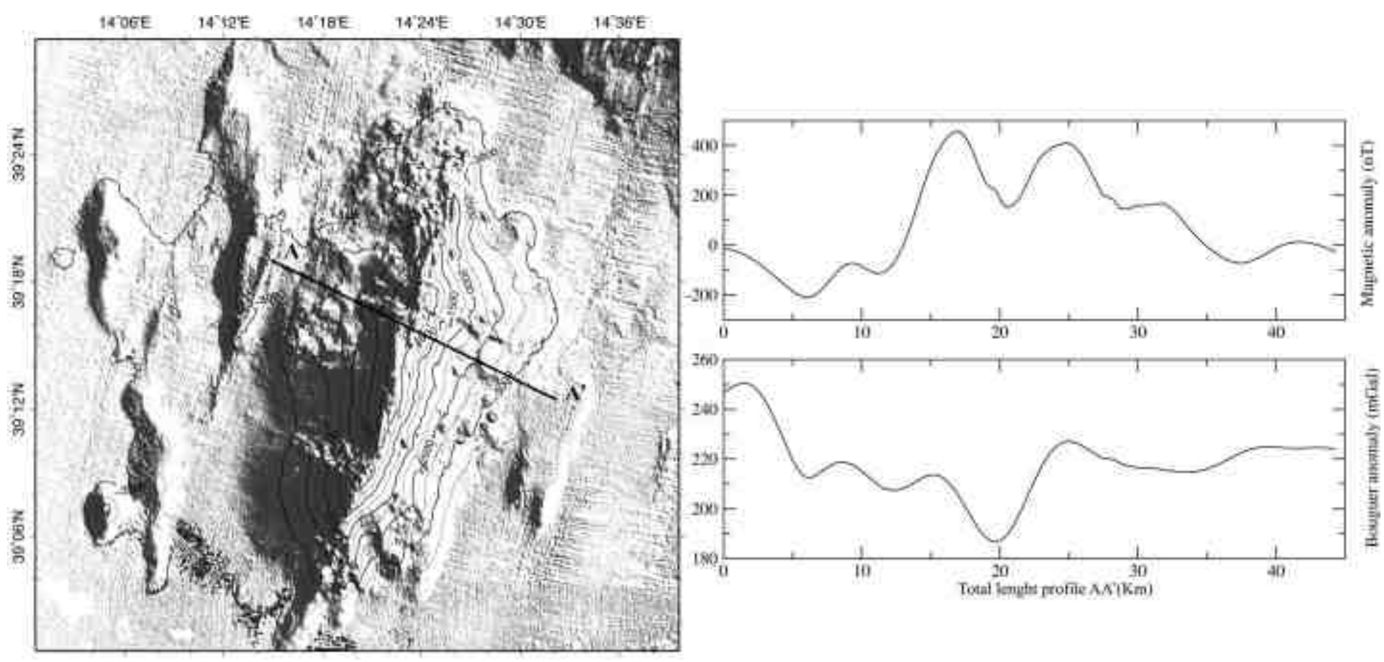

Fig. 2 –High resolution multibeam data (Ismar–Cnr data) of the Marsili seamount. In the right panel we report the variation of magnetic and Bouguer (computed using 2.67 g/cm^3) anomalies along the profile AA' (track profile reported over the bathymetry map). The volcano's summit is characterized by unexpected gravity and magnetic lows.

magnetic anomaly coupled to a clear localized gravimetric low (decreasing of about 40 mGal) (figure 2). As stated by CARATORI TONTINI *et alii*. (2010), the joint interpretative modelling of magnetic and gravity data permitted to quantify the geometry of the altered region defining thus the area of potential instability of the volcano. Considering the distribution of rock characterized by null-magnetization value, we estimated the geometry and the volume of the supposed geothermal reservoir (assuming a mutual relationship between altered region and geothermal field). By inverting the magnetic signal we computed the volume of crustal portion affected by low magnetization (-0.01 to +0.01 A/m) and thus being able to quantify the 3D dimensional distribution of the geothermal reservoir. This result represents the first quantitative assessment of the geothermal potential of the Marsili volcano.

CONCLUSION

In this note we present the results of several geophysical investigations of two submerged volcanic structures of the southern Tyrrhenian Sea. Palinuro and Marsili seamounts are both young volcanoes having a recent activity but also affected by a diffuse hydrothermal alteration. In both the two cases the rock alteration is correlated to an geothermal system localized in the shallow crustal levels. The geothermal systems were established as consequences of a decreasing of the volcanic activity and at the same time it was favoured by the high thermal gradient typical of the volcanic system.

Potential field data can represent a valid investigative tool, although unconventional, for the description of deep-water hydrothermally altered region and consequently for the assessment of the related geothermal potential. In addition the geophysical prospection can depict the deep geologic setting of these volcanic structures providing new insights about their activity, the time-evolution, their instability and the associated risk.

This work is aimed to introduce the potential field investigation as unconventional method for the geothermal prospection and at the same time, to highlight the high geothermal potential associated to the seamount structures of the Tyrrhenian Sea that can represent a stimulating target for the renewable energy investigation in the next future.

Morphotectonics of fissure ridge travertines from geothermal areas of Mammoth Hot Springs (Wyoming) and Bridgeport (California)

LUIGI DE FILIPPIS (*) & ANDREA BILLI (**)

Key words: *travertine, fissure ridge, geothermal outflow, active tectonics, fluid pressure.*

ABSTRACT

Eleven Quaternary fissure ridge travertines from Mammoth Hot Springs (Wyoming) and seventeen ones from Bridgeport (California) were mapped and studied with a morphotectonic approach to understand possible relationships between travertines and active versus passive tectonics. Results are compared with other known geothermal fissure ridges on the Earth. The studied fissure ridges are all located in the hangingwall of normal faults, but the fissure ridges appear as non-dislocated by faults, rather by axial fissures. Both in the two principal study areas and elsewhere, azimuthal analyses of faults and fissure ridges show that the distribution of fissure ridge long axis is rather dispersed around the strike of the local normal faults. No correlation occurs between the fissure ridge length and the angle between the strike of the normal fault and the strike of fissure ridges. The studied fissure ridges are 2 to 360 m long (mean length: 72.1 m), 1 to 15 m wide (mean width: 6.7 m), and 0.5 to 8 m high (mean height: 3.9 m). Fissure ridge aspect ratios show a moderate correlation between the length and both the width and the height of fissure ridges, whereas the correlation between width and height is less marked. The growth in height and width of ridges appears as much more inhibited than in length. A model is proposed in which fissure ridge travertines grow with enhanced elongation along one sub-horizontal direction, which seems moderately controlled by the associated normal fault and the regional extension. Other factors, such as the inherited fracture network and the geothermal and artesian pressure of fluids (fluid discharge) may be important in the development of the studied fissure ridges. Results from this study may contribute to the knowledge of factors that control the long-term geothermal circulation and also the long-term hermetic durability of CO_2 subsurface repositories. Further details are are available in DE FILIPPIS & BILLI (2012) and DE FILIPPIS *et alii* (2012).

Growth of fissure ridge travertines from geothermal springs of Denizli basin, western Turkey

LUIGI DE FILIPPIS (*), CLAUDIO FACCENNA (*), ANDREA BILLI (**), ERLISIANA ANZALONE (***), MAURO BRILLI (**), MEHMET OZKUL (°), MICHELE SOLIGO (*), PAOLA TUCCIMEI (*), IGOR M. VILLA (°°)

ABSTRACT

Fissure ridge travertines grown from geothermal springs of Denizli basin, southwestern Turkey, are investigated through stratigraphic, structural, geochemical, and geochronological methods, with the aim of understanding the growth of these elongate mound-shaped structures. Two main types of travertine deposits are recognized: (1) bedded travertines, which grew as flowstone on sloping surfaces and form the bulk of fissure ridges, and (2) banded travertines, which grew as veins within the bedded travertine chiefly along its central feeding conduit. Stratigraphic and structural observations shed light on the bedded-banded travertine relationships, where the banded features grew through successive accretion phases, cross-cutting the bedded travertine or forming sill-like structures. The bedded and banded travertines alternated their growth as demonstrated by complicated cross-cutting relationships and by the upward suture, in places, of banded travertine by bedded travertine that was, in turn, cross-cut by younger banded travertine. The bedded travertine is often tilted away from the central axis of the fissure ridge, thus leaving more room for the central banded travertine to form. U-series ages confirm the bedded-banded travertine temporal relationships and show that the growth of the studied fissure ridges lasted up to several tens of ka during Quaternary time. The banded travertine deposited mainly during cold events possibly in coincidence with seismic events that might have triggered the outflow of deep geothermal fluids. C and O stable isotope and REE data indicate a shallow feeding circuit for the studied structures with a fluid component deriving from a deeper geothermal circuit. A crack-and-seal mechanism of fissure ridge growth is proposed, modulated by the interplay of local and regional influencing factors and mechanisms such as geothermal fluid discharge, paleoclimate, tectonics, and the progressive tilting of bedded travertine limbs over a soft substratum creating the necessary space for the central veins to grow. Further details are available in DE FILIPPIS & BILLI (2012) and DE FILIPPIS *et alii* (2012).

Modelling of organic and inorganic paleo-thermal indicators to constrain the evolution of the geothermal system of Rosario de La Frontera (La Candelaria Ridge, NW Argentina): a new tool for geothermal exploration

L. DI PAOLO (*), L. ALDEGA (**), S. CORRADO (*), G. GIORDANO (*) & C. INVERNIZZI (***)

Key words: *geothermal systems, inorganic and organic thermal indicators, NW Argentina, 1-D thermal modelling.*

INTRODUCTION

X-ray diffraction of clay grain-size fraction of sediments, organic matter optical analysis and micro-thermometric study of fluid inclusions are widely used in oil exploration for determining the thermal maturity of sedimentary successions and basin evolution (from tens to hundred million years) by means of thermal modelling (ROURE *et alii*, 2010). The quantitative investigation of organic matter physico-chemical variations by optical measurements (e.g., vitrinite reflectance), of clay minerals structural and compositional changes (e.g., mixed layer illite-smectite) by X-ray diffraction and of micro-thermometry recorded by fluid inclusions (e.g., Th and Tm) allows to determine the thermal maturity of sediments, from diagenesis to very low-grade metamorphism, and to constrain the maximum temperatures experienced by rocks (e.g., MAZZOLI *et alii*, 2008).

As a matter of fact this multi-method approach is much less applied to detect paleo-temperatures in fossil and active geothermal systems, despite the validity of the single techniques has been tested in several case histories of geothermal interest to characterise modes of fluid-rock interaction and abnormally high geothermal gradients at shallow crustal levels (ALDEGA *et alii*, 2010).

In the last year, we have been fully developing this integrated methodology to reconstruct the thermal evolution of *Rosario de La Frontera* active geothermal system (ESPELTA *et alii*, 1975), located in the *Santa Barbara* System, in NW Argentina in the foothills of the Cordillera. In this contribution we present the preliminary analytical and modelling results concerning the paleo-thermal conditions recorded by the sedimentary succession cropping out along *La Candelaria Ridge* that hosts the aforementioned system.

GEOLOGICAL SETTING

In NW Argentina, the externalmost and less culminated structures of the Andean retro-wedge crop out in the *Santa Barbara* System. These structures thrust with a regional top-to-the-ESE sense of transport onto the undeformed foreland, locally preserving huge thicknesses of syn-orogenic siliciclastics. These structures may host hot springs and thermal manifestations along a regional NNE-SSW alignment currently characterised by strong along-strike variations of heat flux, with values locally exceeding 3-4 HFU.

La Candelaria Ridge is one of these structures cropping out between the provinces of *Salta* and *Tucuman*. It is a ca. 50 km-long and up to ten km-wide asymmetrical macro-anticline cored by neo-Proterozoic phyllite basement and draped by a Cretaceous-Quaternary sedimentary succession, strongly plunging both to the North (below the *Metan* alluvial plain) and to the South. The sedimentary succession, made up of continental syn- and post-rift sequences (Cretaceous to Eocene in age) and syn-orogenic siliciclastics (Oligocene-to present in age) hosts the geothermal system with the main reservoir represented by coarse syn-rift clastics sealed by post-rift and syn-orogenic units at low permeability. In correspondence of the northern plunge, the well-known hot springs and thermal spa of *Las Termas* and *Los Baños* (a few km apart from *Rosario de La Frontera* village) develop with water temperatures up to 99°C and high concentrations of NaCl and $CaSO_4 \cdot 2H_2O$.

Lavoro eseguito nell'ambito del progetto CUIA (coordinatore C. Invernizzi) dal titolo: "Esplorazione e utilizzo di risorse geotermiche di media e bassa entalpia in area sub-andina per lo sviluppo energetico sostenibile delle città delle province di Jujuy e Salta" con il contributo finanziario dell'Università degli Studi "Roma Tre" e del Consorzio CUIA

METHODS AND MATERIALS

Samples for XRD and organic matter investigations derive from the main reservoir and seal units collected along the ridge either in undeformed or highly fractured outcrops, whereas samples for fluid inclusions analysis are from calcite syn-tectonic extensional veins developed at various stages during the tectonic evolution since Cretaceous times.

Analytical inorganic and organic thermal indicators concern:

- mean vitrinite reflectance of organic matter dispersed in sediments,
- stacking order and illite content in mixed layers illite-smectite observed in <2μm grain-size fraction of sediments;
- Th and Tm from fluid inclusions.

Furthermore XRD patterns on whole rock samples were also performed to characterize the mineralogical assemblages and alteration facies.

Preliminary thermal models were then performed by means of 1-D Basin-mod software and calibrated against our organic and inorganic thermal indicators, on the basis of published stratigraphic-structural framework, to devise scenarios of temperature distribution and evolution as a function of depth.

PRELIMINARY RESULTS

The thermal signature recorded by unfractured lithostratigraphic units along *La Candelaria* Ridge is sensibly stronger than that expected by performed models that trace the paleo-thermal history of the analysed succession from the Cretaceous rift to the Tertiary foredeep basin disregarding the present-day heat flow anomaly.

The paleo-thermal signature along *La Candelaria* is higher than that recorded at depth by vitrinite reflectance in the productive oil fields, located a few tens of km to the north of *Rosario de La Frontera*, where, at present, heat flux is substantially lower (ca. about 1 HFU) than in the area of *Rosario de La Frontera*.

Moreover, data from samples collected in correspondence of highly fractured outcrops in *Las Termas* and *Los Baños* localities indicate a strong interaction between circulating hot fluids and the host rock and, locally, higher paleo-temperatures of the hosting rock when compared to the rest of *La Candelaria* structure.

CONCLUSIONS

The multi-method approach proposed in this contribution turned out to be particularly useful in discriminating among regional and local causes of thermal evolution of the sub-Andean Meso-Cenozoic sedimentary succession which are the result of simple burial and fluid interaction at shallow crustal levels respectively. Thus this approach turned out to be quite promising as a low-cost tool for investigating the thermal evolutions of geothermal systems hosted in sedimentary contexts.

ACKOWLEDGEMENTS

We kindly acknowledge Josè Viramonte, Pablo Caffè, Agostina Chiodi and Walter Baez as C.U.I.A. project partners, for their precious help in the field. Thanks are also due to Diego Santarelli for his logistic support in Buenos Aires.

Shallow geothermal energy use: mapping of geothermal potential and legal status in Italy

E. DI SIPIO (*), E. DESTRO (*), A. GALGARO (**), S. CHIESA (°), A. MANZELLA(*)

Key words: *ground coupled heat pump, low enthalpy energy source, geothermal potential map, geothermal directives, Italy*

INTRODUCTION

The European Directive 2009/28/EC and the related national codes on building energy saving aim at reducing the energy consumption in new buildings and in renovated ones. The energy saving objectives in Italy, nowadays referred especially to the winter heating consumption, may be achieved on one side by increasing the performance of the building and on the other side by adopting heating systems more efficient than traditional combustion ones. In addition, the energy request for summer cooling is rapidly growing.

In this regard, the use of low enthalpy geothermal energy resources represents an interesting opportunity to renew and improve the traditional conditioning in buildings, maintaining high performance and decreasing the greenhouse emissions.

In fact, the ground is a thermally more stable heat exchange medium than air, essentially unlimited and always available, and can be used as a heat source in heating and as a heat sink in cooling mode operation. By the use of Ground Coupled Heat Pump (GCHP), heat is exchanged with the ground: in the heating mode, a GCHP absorbs heat from the ground and uses it to heat the residence or building; in the cooling mode, heat is absorbed from the conditioned space and transferred to the ground through a heat exchangers. Basically, a GCHP consists of either a ground heat exchanger (closed loop system) or a system fed by ground water from a well (open loop system). The heat can be extracted from the ground through groundwater wells (open systems), borehole heat exchangers (BHE), horizontal heat exchanger pipes (including compact systems with trenches, spirals etc.), geostructures (foundation piles equipped with heat exchangers).

The almost constant temperatures in the subsoil (from a depth of 25 to 100 m) can be utilized particularly economically in terms of energy and operating processes for geothermal heating/cooling. The performances of low-enthalpy systems depends on the thermal conductivity of the geological formation, the heat capacity of the soil, the material and type of the heat exchanger and the filling of the annulus (borehole thermal resistance), the existence of groundwater flows, the distance between the heat exchanger, the operation (heat source and/or sink, continuous or intermittent operation) and the building's heating/cooling demand, that can be summarized in thematic maps.

The almost constant temperatures in the subsoil (from a depth of 25 to 100 m) can be utilized particularly economically in terms of energy and operating processes for geothermal heating/cooling. The performances of low-enthalpy systems depends on the thermal conductivity of the geological formation, the heat capacity of the soil, the material and type of the heat exchanger and the filling of the annulus (borehole thermal resistance), the existence of groundwater flows, the distance between the heat exchanger, the operation (heat source and/or sink, continuous or intermittent operation) and the building's heating/cooling demand, that can be summarized in thematic maps.

GEO-EXCHANGE POTENTIAL MAPS

In Northern Europe installations of open and closed systems for conditioning of residential, industrial or commercial buildings is a long established practice. In Italy, in recent years, the use of low-enthalpy geothermal energy for heating and cooling purposes of single housing unit increased mainly in the northern regions. In the southern ones, the development of these solutions involves primarily the cooling phase during summer season, subject of territorial suitability studies performed in the POI regions, as provided by the ongoing national project VIGOR (CNR).

To identify the different eligibility of the territory to the use of geothermal heat pump systems, local authorities as Regions (Lombardia, Emilia Romagna, Toscana, Calabria, Campania, Puglia, Sicilia), and Provinces (Venice, Treviso, Bolzano and Trento) have produced thematic cartography devoted to the classification of "geo-exchange potential". However, the criteria adopted to create these maps and evaluate the low enthalpy geothermal energy are not uniform, depending also on

(*) CNR-IGG Institute for Geosciences and Earth Resources

(**) Department of Geosciences – University of Padua

(°)3 CNR-IDPA Institute for the Dynamics of Environmental Processes

VIGOR is a project funded by the Ministry of Economic Development (MISE) within the POI " Renewable Energy and Energy Conservation 2007/2013 "

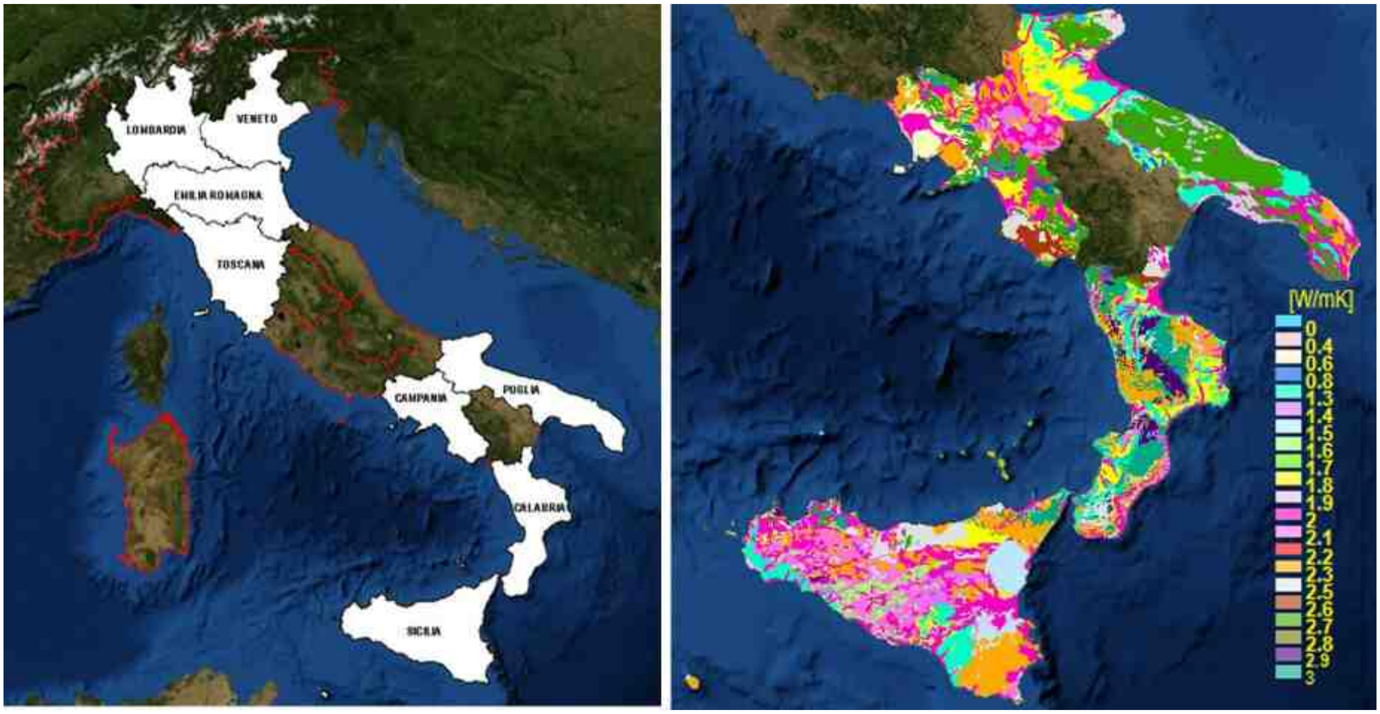

Fig. 1 – Italian region where geo-exchange potential maps, realized with different criteria, are currently available; maps of thermal conductivity of superficial rocks and sediments, determined on bibliographic data, for Apulia, Calabria, Sicily and Campania (VIGOR Project)

number and type of data at disposal. Aims of this study are to give an overview of all the digital mapping available, to focus on the different results obtained and to suggest a homogeneous methodological approach according to the different geological, hydrogeological, thermodynamic, climatic contexts detected.
To evaluate the potential of a territory for heat pump heat exchange, it is necessary:

- to collect basic information (geological, stratigraphic, hydrogeological…), selecting in particular data from 30 to 100 m depth, to create a GIS database (DTM, litho-stratigraphic information, depth to groundwater…) related to the geological environment and the different substrate involved
- to characterize the thermal properties of subsoil (thermal conductivity data, ecc…)
- to determine the hydrogeology of the territory as the depth of saturation level, that allows to evaluate the "thermal conductivity" in wet or dry condition
- to identify the annual mean temperature of air, based on ten years time series, representative of the average temperature of subsoil up to 10 m of depth
- to recognize areas affected by legal constraints, indicating their compatibility of the territory to the planned solution

In details, the preliminary results obtained for the creation of a geo-exchange potential map in the four regions of VIGOR Project (Puglia, Calabria, Campania and Sicily) are presented (Fig.1).

LEGAL STATUS

Another aspect to take into consideration is that, in Italy, legally binding regulations or guidelines concerning shallow geothermal energy use can vary from region to region, depending on the local directives.

The number of shallow geothermal installations has been continually increasing over the last decades. An expected proliferation in the future substantiates the need for a concerted regulative framework. This is particularly crucial, as shallow geothermal systems once installed, are operated for decades. Precautionary principles would require complying with well-defined sustainability standards while minimizing associated adverse environmental impacts.

In Italy, the D.Lgs. n.28 of 03/03//2011 defines tools, mechanisms, incentives and institutional, financial and legal status, necessary to achieve 20% improvement in energy efficiency by 2020 through energy renewable sources implementation, following the UE Directive 2009/28/EC. Moreover, the directive D.Lgs. n.22 of 11/02/2010 regulates the use of geothermal resources by identifying the normal procedures and procedures for experimental facilities, defining as small local plants those that have less than 2 MW thermal power and have been obtained through the execution of wells up to 400 meters depth. Then, at regional level, local authorities (Provice, Region, ecc...) can define specific regulations concerning closed loop and open loop systems. Therefore, an assessment of the existing legal management for shallow geothermal installations is necessary. The comparison of legislation for a proper and rational use of thermal energy could shed new light towards a common procedure, useful to develop the green entrepreneurial possibilities related to the sustainable use of low-medium enthalpy basins.

CONCLUSION

This study shows how the geo-exchange potential mapping realized to date in Italy is incomplete and not homogeneous. The VIGOR Project seeks to propose a methodology based on criteria valid at national level allowing the implementation of a shared and functional mapping. Moreover, the existence of several regional and sub-regional legislation requires a unifying effort to identify common guidelines useful for technicians and experts employed in this sector throughout the country.

Geothermal, hydro-structural and neo-tectonic features of the Sciacca basin

DIPASQUALE MARIO (*), MONTELEONE SALVATORE (**)

Keywords: *geothermy, neotectonics, hydro-structures, karsism, Sciacca*

INTRODUCTION

The present paper illustrates the results of the researches carried out in the southernmost area of the Sicani Mountains, aiming at defining the hydrothermal characteristics of the Sciacca basin.
The geological and geological-structural preliminary surveys, on a suitable scale, have made it possible to draw up both the geological and the hydro-structural maps of the study area.
We examined in detail the rock-outcrops – mainly those belonging to the Mesozoic era – carrying out twenty geomechanical measurements in benchmark point of observation.
Afterwards, we have sorted out six hydrogeological complexes drawing up the relating map, in which we have highlighted the aquifers, the aquitards, the aquicludes and their mutual relationships.
Moreover, using the measurements made along the fault lines, we have stressed the characteristics of the fractures degree and its role in facilitating the fluid circulation in such rocks, that are permeable due to cracks and karstic phenomena.
The scientific collaboration with the Ente Terme di Sciacca (the institution in charge in managing the spa in Sciacca) and with IAMC-CNR (Institute for Coastal Marine Environment of the National Research Council) in Mazara del Vallo allowed to sample several geothermic fluids, aiming at updating the chemical data of the spring waters in the study area (see Piper and Schoeller-Berkaloff diagrams) and at defining the characteristics of the hydrothermal basin.
The average heights of water recharge in the hydrothermal basin have been calculated using the oxygen isotopes while fig. 2 shows the conceptual model of the deep water circuits.

GEOLOGICAL SETTING (SICILY SW)

From a geological point of view, mainly from Upper Paleozoic to Pleistocene, Sicily was characterized by very warped events.

(*) PhD geologist at DISTEM Department, Palermo University
(**) Full Professor at DISTEM Department, Palermo University

The main elements of these events (Catalano et alii, 1995) are clear in the Apennine-Maghrebide Chain, where they represent a megasuture interposed between the limit of the African plate (SE) and the European one (NW).
The opening of the Tyrrhenian basin (back-arc basin), dating back even to the Serravallian age, caused a consequent and progressive migration of the thrustbelt-foredeep system towards the foreland areas (Catalano, 1982, 1995).
The stratigraphic-structural arrangement of NW Sicily, from the most internal areas to the most external ones, is characterized by a series of south-sloping tectonic contacts (Nigro & Renda, 2002).
The distensive Pleistocene deformations, have further dissected the carbonatic structure into overlapping aquifers, and caused a succession of horsts and grabens.
This arrangement does not stop neither the physical continuity between the rock-outcrops with those under the ground, nor the development of deep water circuits (Fancelli et al., 1991).

GEOMECHANICAL MEASUREMENTS

The geo-mechanical measures carried out in twenty points of observation allowed us to describe the cracks characteristics of the rock-outcrops we surveyed.
The points of observation have been chosen with the aim of making a survey – as homogeneous as possible – of the study area. For this purpose, we have spotted and selected some outcrops (quarries, excavations, natural walls), in which we measured the cracks in the three directions thanks to the presence of orthogonal walls.

HYDRO-GEOLOGICAL FEATURES OF THE THERMAL BASIN

The structural and hydro-structural geologic model designed for the study area allows us to focus on the role played by the carbonate outcrops of Rocca Nadore and Mount San Calogero, that are described as follows.

ROCCA NADORE

This outcrop stretches for about 2.5 km^2, with a total perimeter of approx. 10 km. The most significant morphological peaks are: Rocca Nadore (599 mt) and Rocca Porcaria (543 mt).

It is an anticlinal, northward-plunging ramp, connected in depth to the underlying unity S.S. of San Calogero Mount (see Fig.2).
Along the northern and southern slopes we can see a series of slight springs: Sorgente del Salto, Ficarelle, Nadorello and Nadore which are linked to subsurface circuits of cold waters.
The whole area accounts for the internal feeding area of the geothermal basin.

MOUNT SAN CALOGERO

The hydro-structure stretches irregularly for about 3 km^2, with a total perimeter of approx. 12 km.

Fig. 1 – Connections between pneumatolytic appearance, fracturative degree and karsts development at Mount St. Calogero's top.

The main heights are: Mount San Calogero (396 mt) and Rocca della Guardia (188 mt).
There are some springs with different features, well-known since the ancient times (Selinunte springs, Acqua Santa, Molinelli and Fontana Calda), as well as are the famous pneumatolithic phenomena (emissions of hot vapors) near the top of San Calogero Mount.
There are also some watering troughs, with cold waters, such as that in the Montagnola area.

DISCONTINUITY FAMILIES, KARSTIC PHENOMENON AND STEAM FLOW

The geo-structural and geo-mechanical surveys have allowed us to verify that the steam flow does not develop randomly, but according to clear tectonic directions, especially those concerning set n.1 (total best fit = 287°/75°) showing the following characteristics: I. presence of a minimum fault-core thickness, at least a few centimetres; II. thickness affected by processes of chemical dissolution and physical degradation.
The surveys carried out inside the Saint's Cave, allowed us to verify that the development of the karst phenomena are more widespread near the faults which can be associated to sets 1 and 2 (Fig.1).

NEW SAMPLING CAMPAIGN

After an accurate analysis and interpretation of many previously found geochemical data (Aureli, 1996; Berbenni & Ariati, 1978) and a new sampling campaign concerning some of the main water points in the Sciacca thermal basin (financed by the Ente Terme di Sciacca), we have described the conceptual model of the Sciacca thermal basin.

Fig. 2 shows the possible conceptual model of the Sciacca basin thermal circuit. We used the *Hydro-geothermal profile along the line Rocca Nadore-Sciacca*, direction NNE-SSW, for a thickness of about 2 km (Catalano et al., 2000).
Considering the stratigraphic succession and the stratigraphic tectonic relationships, we have clustered the different lithologies, according to their hydro-geologic behaviour, thus identifying: a. surface aquifers (terraces and alluvium); b. Neozoic aquicludes (Plio-Pleistocene clays and trubi); c. Cenozoic aquitards (Helvetian marly sandstones, Burdigalian marly limestones and Eocene marls); d. thermal Mesozoic aquifer (Triassic dolomites and Lias limestones).

CONCLUSIONS

The purpose of this note is to make a short description of some peculiar characteristics of the Sciacca hydrothermal basin – in the Sciacca territory, the most external area of the complex, mostly south sloping system of the Sicilian orogenic belt.
This area was concerned by the Mio-Pliocenic tectonic folding and Pleistocenic distensive phases, that have distributed the whole orogenic belt and caused a series horsts and grabens.
The hydrothermal basin shows a clear relationship with the carbonate lithotypes outcropping in the surroundings of San Calogero Mount, whose age ranges from Trias to Eocene.
Hydro-chemical and isotopic data of the water points surveyed (wells and springs), allowed us to verify (see Piper and Schoeller-Berkaloff diagrams) the close links between the various fluids, sampled in spite of their different features.
These chemical features result from the mixing of waters with different origin (local and regional circuits), linked to the stratigraphic-structural arrangements found in this area.
Moreover, the hydro-structural and geo-mechanical studies have allowed us to define the cracks features and the potentiality of infiltration of the main absorbing cores (Rocca Nadore and San Calogero Mount).
Finally we hope that our collaboration with the Ente Terme di Sciacca will go on, in order to further investigate:
a) the hydro geothermal potentialities of the study area;
b) a wiser use of the available water resources;
c) the protection of the thermal basin and the revaluation of the considerable historical-naturalistic heritage.

From diagenesis to hydrothermalism within the Tuscan Nappe of the Monte Amiata geothermal area (Italy): implications for CO_2 geological storage

MARTA GASPARRINI (*), GIOVANNI RUGGIERI (**) , GIOVANNI CHIODINI (×) & ANDREA BROGI (°)

Key words: *Tuscany, water-rock interaction, fluid iclusions, isotopes, CO_2.*

INTRODUCTION

On the eastern flank of the Monte Amiata volcanic complex (Southern Tuscany), near the locality of Bagni San Filippo, calcite veins are hosted within the Lower Jurassic dominantly carbonatic succession of the Tuscan Nappe, close to the contact with the Liguride Complex (Bertini et al. 1995, Giolito 2005). The area is at present the site of a shallow hydrothermal system, with warm springs discharging on surface from the same trap reservoirs, capped by siliciclastics (Chiodini et al. 1995). The sources are fed by Cl-poor fluids of meteoric recharge, heated at depth in response of a local thermal anomaly (reservoir fluids at 80°C and 10Bar CO2; Chiodini et al., 1995). Gas emissions dominated by deeply originated CO2 (> 90 vol%) leak through faults from the same system (Chiodini et al., 2004, Frondini et al., 2010).

Tuscan Nappe outcrops at Bagni San Filippo were sampled for this study in close vicinity of thermal sources and gas emissions.

The veins were characterized by means of conventional and cathodoluminescence (CL) petrography, O, C and Sr isotopes, trace elements, combined with microthermometry and Raman spectroscopy on Fluid Inclusions (FIs).

The aim of the study was to constrain the relative timing of vein formation, as well as temperature and composition of the fluids in order to relate their origin with the geological evolution of the area and in particular with the CO2 migration events. The final goal was to sketch the evolution of the hydrothermal system from past to present and to asses the geochemistry of the host-rocks having interacted with the different fluids.

RESULTS

The vein mineralization consists of milky white calcite. Different phases were petrographically distinguished and inserted in a paragenetic scenario. Two of them (Cal 1 and Cal 3) are the object of the study, together with the host carbonates in the close vicinity of the veins.

Cal 1 veins display a fibrous to elongated blocky texture and gradual transition to the host rock. The crystals have straight twins and dull red CL. $\delta^{18}O$ is -4.8 to -2.7 and $\delta^{13}C$ is 1.6 to 2.2 ‰ PDB, whereas $^{87}Sr/^{86}Sr$ is 0,7076 to 0,7088, all values which overlap those of the hosts. These latter have slightly lower C and O isotope ratios and slightly more radiogenic Sr composition than the one expected for marine carbonates (Veizer & Hoefes, 1976; Burke, 1982). They result to be isotopically similar to diagenetically altered carbonates of the Tuscan Nappe from areas not expected to have interacted with hydrothermal fluids (Cortecci & Lupi, 1994).

Cal 3 veins consist of spatic rhombohedra and blocky crystals having sharp contact with the host carbonate. The crystals display straight, curved or patchy twins and bright orange CL. $\delta^{18}O$ is -9.0 to -7.4 and $\delta^{13}C$ is -2.6 to 0.6 ‰ PDB, whereas $^{87}Sr/^{86}Sr$ is 0,708 to 0,7119, therefore values fairly different from the previously described carbonates. The hosts reflect the isotope composition of Cal 3 and display strongly depleted $\delta^{18}O$ and $\delta^{13}C$, as well as more radiogenic Sr, compared to the undisturbed Tuscan Nappe carbonates (Cortecci & Lupi 1994).

A similar trend is recorded by the distribution of some minor elements, with the composition of the host carbonates being buffered by the composition of the Cal 3 fluid.

Two-phase liquid-rich FIs were investigated. FIs in Cal 1 homogenize between 130 and 320 °C (rough mode at 185 °C). The higher values indicate thermal reequilibration of the FIs. Eutectic point occurred at temperatures lower than -40 °C. Ice melted between -26 and -15 °C (mode -22 °C), whereas salt-hydrate crystals melted last with metastable behavior.

The presence of gas within two-phase Cal 3 FIs is suggested by moderate bubble expansion after crushing. Raman spectroscopy could identify the presence of CO2 in the largest FIs. Homogenization temperatures are various, but mainly between 140 and 220 °C, with a mode at 170 °C. A first liquid was optically observed at -12 °C. In spatic rhombohedra final melting of ice is between -2.6 and -0.8 °C (mode -1.0 °C). In blocky crystals ice melts between -12.5 and -0.7 °C, with a mode at -1.0 °C, though some inclusions record higher salinities.

DISCUSSION

Salinity calculation together with thermal and geochemical data allowed to reconstruct two main episodes of fluid circulation:

1. A high salinity (>23.2 wt % NaCl eq.) FLUID 1 precipitated Cal 1 during syn-deformation burial diagensis from highly saline fluids which possibly interacted with the underlying Triassic Burano anhydrites. The thermal reequilibration of the FIs reflects later rock overheating possibly due to the overthrusting of the Ligurian Units on the top of the Tuscan Nappe during the Appenine compressional tectonics;

2. A low salinity (<1.7 wt % NaCl eq.) FLUID 2 generated Cal 3 and locally recrystallized Cal 1. The newly precipitated CAL 3 is recorded by the calcite rhombohedra, containing only one low salinity fluid. In the replacive blocky Cal 3 crystals some highly saline FLUID 1 inclusions were only partially refilled by the low salinity FLUID 2, giving intermediate salinities (11.7 to 16.3 wt % NaCl eq.).

FLUID 2 was a moderately hot (> 150 °C), poorly saline, CO2-bearing aqueous fluid, possibly related to the "fossil" hydrothermal activity of the studied system. It originated from meteoric water which became richer in ^{87}Sr and ^{18}O after long-lasting interaction with the subsurface rocks.

The temperature information from Cal 3 FIs (no pressure correction applied, in the hypothesis of a shallow depth circulation) was combined with the oxygen isotope composition of the mineral. Cal 3 formed from a fluid having δ^{18}O of 8,2 to 11,8 ‰ SMOW. Present day fluids from the hydrothermal reservoir have δ^{18}O of 8,2 ‰ SMOW (Fancelli & Nuti, 1975), whereas rain water in the area is characterized by δ^{18}O of -7,5 to -8,0 ‰ SMOW (Frondini et al., 2010). It results that FLUID 2 was enriched in ^{18}O compared with the present day fluids emerging from the reservoir, which possibly reflect a less effective interaction with ^{18}O-rich carbonatic and siliciclastic rocks. Fluid/rock interaction mainly depends on fluid temperature and time of interaction. Present day fluids from the shallow reservoir have T=80 °C (Chiodini et al. 1995), i. e. fairly lower than FLUID 2. Therefore, a deeper circuit in the ancient hydrothermal system at the time of FLUID 2 circulation would have provided both higher T and longer time for interaction.

The geochemistry of the carbonates hosting the veins seem to be quite different depending on the fluid system they have interacted with. In particular, those hosting Cal 3 veins result to be buffered by the hydrothermal and CO_2-bearing FLUID 2 as they carry depleted δ^{18}O and δ^{13}C and more radiogenic Sr. Nevertheless, the burial diagenetic signature preserved in the Cal 1 hosts suggests that water-rock interaction processes were possibly restricted to the fracture vicinity. Irrespectively from the lateral extension of these processes away from the fractures, it is clear that some portions of the host-rocks interacted with CO_2-rich fluids in the past. As a consequence, textural and mineralogical modifications of the rock matrix are expected to have occurred if compared to the same succession from areas not affected by hydrothermalism. In this respect, the rocks of the Tuscan Nappe may serve as analogue for understanding the diagenesis provoked by CO_2-rich fluids on this type of reservoirs, in order to feed geochemical models addressed to the prediction of modifications induced in the reservoirs after CO2 geological storage.

CONCLUSIONS

- Two different fluid systems were characterized from the studied veins: FLUID 1 originated in the burial diagenetic realm and FLUID 2 related to a fossil geothermal system, fed by low salinity meteoric fluids enriched in CO2 of deep origin.
- Comparison with the present-day system suggests the possibility that the reservoir fluids were hotter and water-rock interaction more effective during FLUID 2 circulation and then became cooler towards present conditions.
- The geochemistry of the carbonates hosting the last vein sets results to be buffered by the hydrothermal and CO2-bearing FLUID 2.
- In the vein host-rocks which interacted with CO2-rich fluids in the past, textural and mineralogical modifications of the rock matrix are expected to have occurred.

Preliminary investigation on soil CO_2 and soil CH_4 effluxes from a geothermal area near Palagonia (Sicily, Italy)

SALVATORE GIAMMANCO (*), PIETRO BONFANTI (*), MARIA LUISA CARAPEZZA (°), NICOLA PAGLIUCA (°), FEDORA QUATTROCCHI (°), TULLIO RICCI (°), ALESSANDRA SCIARRA (°) & LETIZIA SPAMPINATO (*)

Key words: *East Sicily, geothermal systems, mantle degassing, Soil CO_2 efflux, Soil CH_4 efflux.*

INTRODUCTION

The central part of eastern Sicily is characterized by several areas of strong crustal degassing. These gases are mostly carbon dioxide and methane and are particularly concentrated in some focused emissions (gas vents, mud volcanoes) or as diffuse degassing along major faults. In this study, the extent and orientation of soil CO_2 and soil CH_4 effluxes were investigated on a wide area (about 40 km^2) located about 50 km southwest of Mt. Etna (Fig. 1). From a structural point of view, this area lays on a typical foredeep - foreland system that marks the boundary between the southern part of the Eurasian plate and the northern part of the African plate in the central Mediterranean. The situation was further complicated by the tectonic subsidence of the foredeep to the north of the northern Hyblean margin (YELLIN-DROR *et alii*, 1997; CARBONE et al., 1982) and the formation of a series of ENE-WSW oriented grabens and horsts, the Lentini Graben being the most important of these structures.

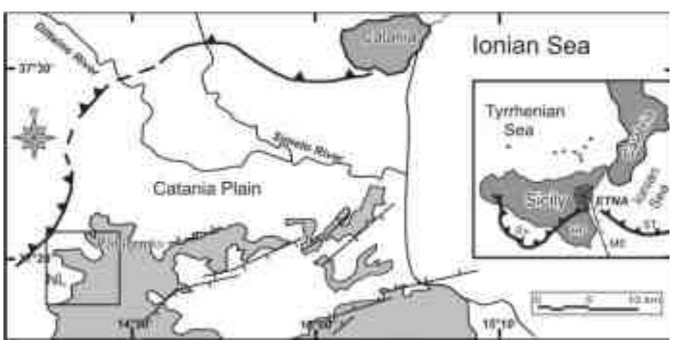

Fig. 1 – Schematic geologic and structural map (modified from CATALANO *et alii*, 2004 and BEHNCKE, 2004) of northern Hyblean margin. The square delimits the study area. NL = Naftìa Lake. Gray surfaces indicate outcrops of

(°) Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Roma 1, Roma

Lavoro eseguito bell'ambito del progetto VIGOR con il contributo finanziario fornito dalla convenzione tra CNR-DTA e INGV

This area was characterized by both submarine and subaerial volcanism until 1.7-2 Ma (BARBERI *et alii*, 1974; GRASSO *et alii*, 1983; GURENKO AND SCHMINCKE, 2002; SCHMINCKE *et alii*, 1997; TRUA *et alii*, 1997), and it was affected by strong seismicity in historical times. The surface geology consists of recent alluvial deposits and Plio-Pleistocene clays and sands interbedded with coeval basaltic lavas and pyroclastics of alkaline affinity (CARBONE *et alii*, 1987).

Strong gas emissions in this area have been known since pre-Greek times, as reported by FERRARA (1805). PONTE (1919, 1934) showed that the gas that erupted through Naftìa Lake (located just southwest of the village of Palagonia, see Fig. 1) was pure carbon dioxide and calculated total emissions at about 80,000 t d^{-1}. Today, the main gas emission is exploited for commercial use (Mofeta dei Palici plant, CO_2 output estimated as about 250 t d^{-1}, R. Romano pers. comm., 1998). The area is also characterized by several water well with warm (20-50 °C) water. Recent geochemical studies on this area (DE GREGORIO *et alii*, 2002; CARACAUSI *et alii*, 2003a, 2003b; GIAMMANCO *et alii*, 2007) showed that anomalous CO_2 degassing has a hydrothermal or magmatic origin and it is linked to the dynamics of Mt. Etna's plumbing system.

METHODS

Diffuse CO_2 and CH_4 emissions were measured using the accumulation chamber method, which consists of measuring the rate of increase of the CO_2 (or CH_4) concentration inside a cylindrical chamber opened at its bottom placed on the ground surface. The chamber is provided with an internal fan to achieve an efficient gas mixing and is connected with a portable NDIR (nondispersive infrared) spectrophotometer (PP Systems, UK, mod. EGM4; West System, Italy, mod. PFM-D). The increase in concentration during the initial measurement is proportional to the efflux of gas (TONANI & MIELE, 1991; CHIODINI *et alii*, 1998). This is an absolute method that does not require corrections linked to the physical characteristics of the soil.

RESULTS AND DISCUSSION

In the study area, 516 measurements of soil CO_2 efflux and

123 measurements of soil CH_4 efflux were carried out from May 17 to May 20 2012, under stable weather conditions. Soil CO_2 effluxes ranged from 0.31 to 1502 g m^{-2} d^{-1}, with mean value of 51.5 g m^{-2} d^{-1} and standard deviation of 157.0 g m^{-2} d^{-1}. Soil CH_4 effluxes ranged from 0 to 8.8 g m^{-2} d^{-1}, with mean value of 1.5 g m^{-2} d^{-1} and standard deviation of 1.4 g m^{-2} d^{-1}.

Soil gas data were processed using the Kriging method (Swan and Sandilands, 1995). The large majority of soil gas effluxes were very low in absolute terms, most likely as a result of the low soil permeability. The crust in the study area is composed of low-permeability sediments (clays, marly clays, cemented alluvial deposits, etc.). Soil CO_2 emissions from these sediments, therefore, derive chiefly, if not exclusively, from soil and/or roots respiration.

The zones of higher CO_2 degassing in the study area appear to be elongated mostly according to preferential NE-SW-trending directions (Fig. 2), which therefore suggest the presence of some sub-parallel faults, with a mean strike N50°E. This trend is in agreement with that major faults in the area (CATALANO *et alii*, 2004; BEHNCKE, 2004). However, some high degassing sites seem to be connected with a possible NNW-SSE-trending direction, which is also likely in the study area. The highest degassing was recorded in a small area located just northwest of the village of Palagonia (black square in Fig. 2). In this area, soil CO_2 degassing showed a preferential NNE-SSW-trending orientation, but in a larger scale the anomalous degassing seem to conform to one of the above mentioned NE-SW-trending directions.

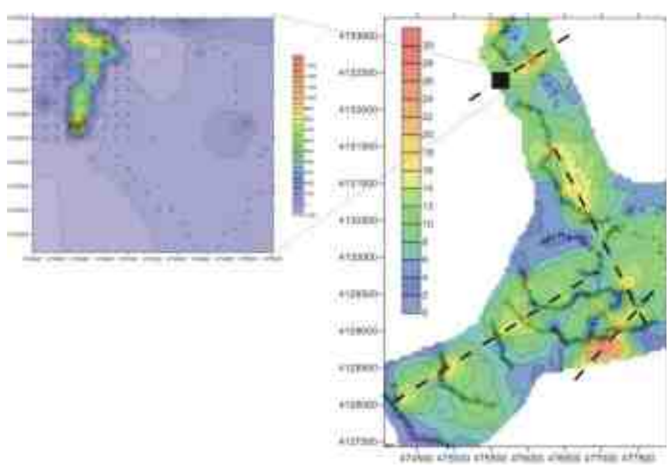

Fig. 2 – Spatial distribution of soil CO_2 effluxes in the study area. Dotted lines indicate the possible directions suggested by the soil gas data. The black square indicate the area with the highest degassing. The spatial distribution of diffuse CO_2 degassing in the latter is shown in the exploded box.

Correlation between soil CO_2 and soil CH_4 efflux values (Fig. 3) showed two distinct behaviors, with some sites showing almost constant and low CO_2 values and highly variable CH_4, whereas other sites showed a slight positive correlation between the two gases. The first group would suggest a different origin of the two gases, with possibly organic CO_2 and shallow methane from hydrocarbon reservoirs; the other group would suggest a

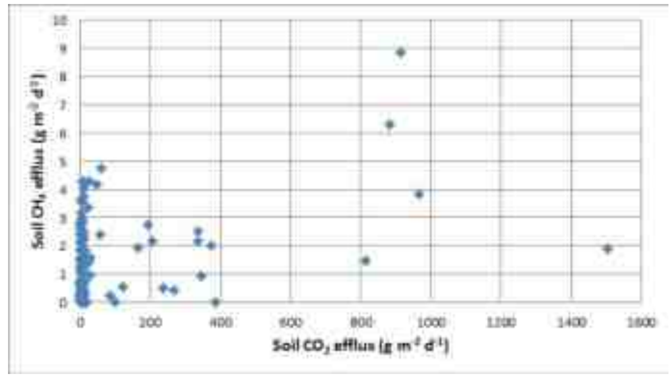

Fig. 3 – Correlation between soil CO_2 effluxes and soil CH_4 effluxes measured in the study area.

common origin or transport mechanism of the two gases, with possibly a deeper origin of CO_2 and a hydrothermal contribution of methane. The deep origin of CO_2 is inferred from the very high efflux values measured in these second group, that are well above the threshold normally considered for biogenic CO_2 or from soil respiration. In particular, CO_2 effluxes associated with areas characterized by scarce vegetation, uncultivated meadows, mediterranean maquis or semiarid steppe have average values of 7.6 g m^{-2} d^{-1}, with maximum values around 40-50 g m^{-2} d^{-1} during the summer season (e.g., FRANK *et alii*, 2002; MAESTRE & CORTINA, 2003; OBRIST *et alii*, 2003; RAICH & TUFEKCIOGLU, 2000; RETH *et alii*, 2005).

Further studies are needed to better investigate the origin of the gases in the studied area, possibly with isotopic analyses of carbon both of CO_2 and of CH_4. However, the results clearly indicate the role of faults in draining deep gases to the surface and the possible existence of a hydrothermal reservoir where part of the methane gas released in the area is produced.

Characterization of medium enthalpy geothermal resource in the Campania region (Southern Apennines, Italy), within the framework of the VIGOR project: from geological data to resource modeling

INVERSI B. (2) (1), SCROCCA D. (1), MONTEGROSSI G. (3), PETRACCHINI L. (4) (1), LIVANI M. (1)(2) , BRILLI M. (1) , BRANDANO M. (2) (1) & ROMI A. (5)

Key words: *3D models, Campania, Geothermal resources.*

INTRODUCTION

The operative agreement between the Italian Ministry of Economic Development (Directorate General for Nuclear Energy, Renewable Energy, and Energy Efficiency) and the Italian National Research Council (Department of Earth and Environment), signed in 2010, promoted a new project (VIGOR project) to evaluate the geothermal potential and the implementation of innovative use of geothermal resources in the so-called Regions of Convergence (i.e., Campania, Puglia, Calabria, and Sicilia).

Within this context, a characterization of medium enthalpy geothermal resources have been carried out in the promising "Guardia dei Lombardi" area, located in the Campania region (Southern Italy, Province of Avellino).

Intense subsurface hydrocarbon exploration has been carried out in the area over the last decades (particularly during the 1956-1996 period), providing large quantities of seismic and geochemical data. This exploration activity has demonstrated the presence of a fractured carbonate reservoir, that is constituted by the Cretaceous-Eocene sequence of the Apulian shallow water carbonate platform (e.g., SCROCCA, 2010 and reference therein). Following the Apennine orogenesis, the platform was deformed to shape a buried antiformal stack (NICOLAI & GAMBINI, 2007). In the study area the culmination of the uppermost thrust unit reaches a depth of about -250 m below the sea level (i.e. about 1125 m below the ground level).

The reservoir fluids are mainly composed of CO_2, which rests above an accumulation of brackish water in the central and upper part of the culmination of the deep carbonatic aquifer (e.g., Monte Forcuso 1 and 2 wells), and saline water along the flank of the buried anticline (e.g., Bonito 1 Dir, Ciccone 1 wells).

In previous assessment mainly made by ENEL (1987; 1994), a reservoir fluid has been estimated in the area that reaches temperature of 120°C at the depth of 3000 m below ground level, associated to a heat flow of 90 mW/m^2. (DELLA VEDOVA *et alii*, 2001). These parameters suggest the presence of a medium enthalpy geothermal resource.

The presence of thermal waters in the area (Terme di San Teodoro) provides further constrain about the geochemical characteristics of the reservoir water.. Reservoir fluid temperature up to about 124°C were calculated using different geothermometers (DUCHI *et alii*, 1995).

In this study, the overall structural-stratigraphic setting of the reservoir/caprock system has been defined on the basis of the integrated interpretation of a composite dataset of surface and subsurface geological, geophysical and geochemical information. In particular, thanks to the cooperation of ENI Company, we have had access to a wide dataset composed by seismic reflection profiles, well data, logs and cores.

A careful assessment of temperature field at depth has been carried out analyzing the well logs through Horner plot construction (RIDER, 1996 and reference therein). Where the data were scarce, the approach proposed by DELLA VEDOVA, *et alii* (2001) has been applied.

On the basis of well tests, cores analysis and mud losses/absorptions, it has been possible to re-estimate the reservoir properties, confirming quite good permeabilities for the fractured carbonate reservoir.

One of the main results of this research is the development of an integrated 3D geological model which provides the base for a detailed assessment of the possible geothermal exploitation of the carbonate reservoir. The preliminary results of our analysis suggest that the "Guardia dei Lombardi" site could be indicated as an interesting area for the geothermal medium enthalpy exploitation, although the presence of the CO_2 gas cap should be carefully evaluated.

INTRODUCTION

In the last decades, the progressive exhausting of the conventional power resources (like coal oil and natural gas) have given a new impulse to renewable energy exploitation. Main renewable resources can be summarized in the follow types: hydroelectric; biomass, photovoltaic, solar thermal, aeolic onshore, aeolic offshore, geothermal. Among these sources, the geothermal is poorly exploited.

Geothermal energy can be considered the renewable type that best represents Italy. In fact, the small village of Larderello, in the "Valle del Diavolo" (Devil's Valley) in Tuscany, was named after François Jacques de Larderel, a French manufacturer who first extracted boric acid from volcanic mud by using volcanic steam in early 19th Century. In 1904, the Italian contractor and politician Piero Ginori Conti tested the first geothermal power generator in the world at the Larderello dry steam field; seven years later, the world's first geothermal power plant was built in the Devil's Valley.

Today, the Italian electric production from renewable sources is about 7% of the national production; its 10% is derived from geothermal energy. Mapping the geothermal potential of a given territory and exemplifying its peculiar types of exploitation are the first steps for increasing the awareness among the population and for stimulating the exploitation of this renewable source.

Below, the main goals of the VIGOR Project plus a short explanation of the activities carried out in Calabria and of preliminary results are summarized.

THE PROJECT

The Project VIGOR is aimed at evaluating of the geothermal potential in the Italian regions of "convergence" – i.e. Campania, Calabria, Puglia and Sicilia (Fig. 1). The project is funded by the Italian Economic Development Ministry (MISE) by means of FESR (European Funds for Regional Development) resources. It derives from an agreement between MISE (General Direction for the Nuclear Energy, the Renewable Energies and the Energetic Efficiency - DG ENRE) and the Italian National Research Council (CNR), within the frame of the Inter-Regional Operational Programme (POI) "Renewable Energies and Energy Saving 2007-2013", line of activity 1.4.

Fig. 1 – The regions of convergence analysed in the VIGOR Project.

For the considered regions, the main aims of the project are:

a) to examine the state of knowledge and standardize, where possible, the database;
b) to identify potential sources of geothermal energy utilization, and make an assessment of their geological, structural and hydrodynamics features;
c) to provide guidance and recommendations for expanding the use of geothermal resources, within the context of the EU commitment for sustainable energy, while ensuring the utmost respect for the environment;
d) to convey information and expertise, and intervention models derived from the implementation of the Project.

In addition to analysing the geothermal potential at regional scale, 8 study areas (2 per region) have been selected - in agreement with the interested Regions - for detailed evaluations, aimed at exemplifying types of possible utilization of the geothermal energy.

ACTIVITIES IN CALABRIA

In a first phase, performed activities mainly consisted of collection and analysis of data to properly evaluate the regional geothermal potential, and to define reliable geo-structural and hydrogeological models of the two study areas of Arcavacata and Terme Caronte (Fig. 2). Later on, two projects have been developed to exemplify the types of utilization of the geothermal energy in the study areas.

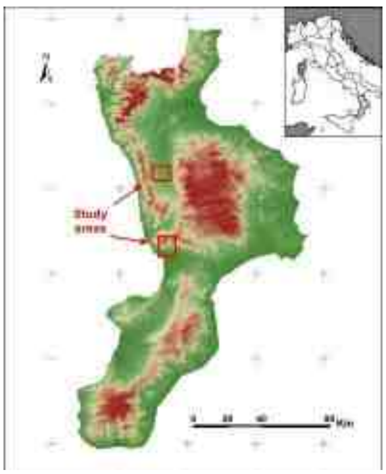

Fig. 2 – Location of the Arcavacata and Terme Caronte study areas.

Literature (scientific and technical reports, papers, maps, etc.) and stratigraphic/hydrogeologic data related to drillings and wells have been collected (mainly thanks to the willingness of many colleagues and enterprises), and included into a bibliographic (VIGOR-Bib) and into a cartographic database (Geo-Network), both accessible via internet. Altogether, ca.400 bibliographic references and ca.300 cartographic data have been stored. From these, derived maps have been obtained. In Fig.3, two examples of derived maps are shown, related to: A) the main lithological groups, as obtained from the Geological Map of Calabria (at 1:25,000 scale, BURTON, 1971) by merging the 365 basic formations, according to lithological analogies; B) the distribution of ca.3.500 wells, whose related stratigraphic and hydrogeological information have been organized in a WebGIS at CNR-IRPI U.O.S. of Cosenza (accessible via internet).

The Arcavacata study area

The Arcavacata study area includes the campus of the University of Calabria, that is supposed to harbour the planned scientific pole of CNR, and the industrial area of Rende (Fig. 4).

During the first phase of activity, available scientific and technical papers and thematic maps, plus information on drillings and wells (including groundwater chemical and physical features), have been collected. Accordingly, the stratigraphic and hydrogeologic characteristics of the area have been hypothesised, and a pre-feasibility report has been prepared. In such report, both direct and indirect investigations have been suggested for a better understanding of the geological characteristics and of geothermal potential of the area.

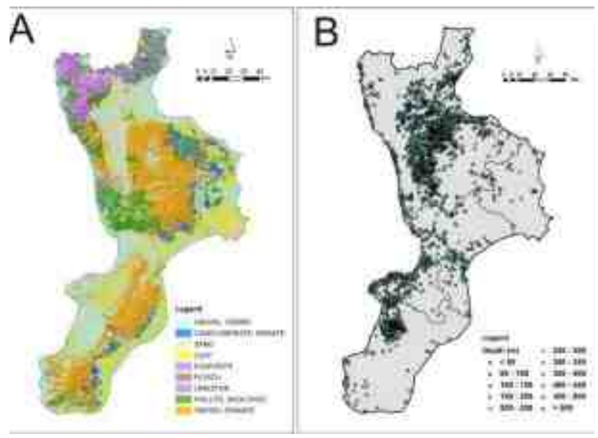

Fig. 3 – Lithological groups (A) and wells distribution (B).

Fig. 4 – The Arcavacata study area (base-map after Sorriso-Valvo & Tansi, 1996).

Aiming at better defining the geo-structural, geomorphologic and hydrogeologic features of the area, field surveys and aerial photographs interpretation have then been carried out. Successively, n.4 superficial geo-electric tomographies (940 m in length, investigating down to a depth of 170 m), and n.1 deeper geo-electric tomography (6,5 km in length, 900 m depth) have been performed (Fig.5).

Evidence collected during field investigations combined to literature information and new geophysical results (e.g. Fig.6) allowed to refine the initial geological/hydrogeological scheme of the area. Based on such information, a project for the air conditioning of the new CNR buildings based geothermal energy has been proposed, and the feasibility report prepared.

Fig. 5 – The Arcavacata study area: profiles of the geo-electric high-resolution tomographies (T1, T2 T3 e T4, in red) and of the deep tomography (DERT, in blue) performed by CNR-IMAA.

Fig. 6 – Preliminary results of superficial geo-electrical tomography (view from the South).

The Terme Caronte study area

In the second phase of activity, the Terme Caronte study area has been investigated, including Sambiase, Lamezia and its industrial area, and Terme Caronte thermal station (Fig.7). Again, literature and data collection have been performed, and a pre-feasibility report prepared.

Due to the high geo-structural complexity of the site, extensive field surveys have been carried out, in addition to interpretation of aerial photographs and literature data (Fig.8). Furthermore, a number of geophysical prospections (geo-electric tomography, electro-magnetic surveys) and deep drillings have been planned, both in the mountain and in the plain sectors.

Results have been finally interpreted, by using a specific 3D-modelling software, by also taking advantage of deep seismic profiles (courtesy of ENI). By considering such results, the geological scheme of the area could be refined. Accordingly, a project for the sludge treatment based geothermal energy has been proposed, and the feasibility report prepared.

INTRODUCTION

Within the scientific framework recently proposed by C.U.I.A. (*Consorzio Universitario Italiano per l'Argentina*) for the development of applied researches on the Argentina territory, several research groups, belonging to selected Italian and Argentina Universities, converged in the last year on the research line devoted to the "Sustainable development of future towns".

This contribution focuses on the preliminary results achieved by this collaboration among the Universities of Camerino, Jujuy, Roma Tre, Salta, Sapienza.

The project focuses on the application of robust methodologies and the development of new ones to explore the geothermal potential of the area of *Rosario de La Frontera* (NW Argentina) located at the northern edge of *La Candelaria Ridge*, one of positively inverted structures cropping out between the provinces of Salta and Tucuman. It belongs to the *Santa Barbara System* of the Andes retro-wedge.

This approach intends to contribute to the sustainable development of the town of *Rosario de La Frontera*, that can be potentially based on the exploitation of medium enthalpy (90°<T<150°C) geothermal resources.

The main goals of this project are:

- To constrain the origin of the geothermal anomaly that affects the study area by means of the reconstructions of the paleo-thermal, geochemical and morpho-structural evolution of *La Candelaria Ridge*. The first type of reconstruction is approached by means of 1D modeling of indicators of thermal exposure (e.g. vitrinite reflectance, clay minerals geo-thermometers and Th and Tm from fluid inclusions). The second is based on hydro-geochemical and isotopic investigations on waters sampled in the sites of thermal springs. The third is based on quantitative elaboration of aerial photos;
- To evaluate the size, fracture network and permeability of the potential geothermal reservoir and effectiveness of its cap-rock by means of traditional structural analyses at different scales and combined deterministic-stochastic reconstruction of the fracture network with the aid of dedicated software;
- To identify the recharge areas and deep fluid flow by means of geological and geophysical investigations (namely based on audiomagnetotelluric survey);
- To model the geothermal system.

The preliminary results related to the first three aforementioned objectives are presented in this scientific session with a series of companion posters.

We present the preliminary analytical and modelling results concerning the paleo-thermal conditions recorded by the sedimentary succession cropping out along *La Candelaria Ridge* that hosts the aforementioned system.

GEOLOGICAL SETTING

Structural setting

La Candelaria Ridge is one of the less culminated structures of the Andean retro-wedge cropping out between the provinces of Salta and Tucuman, in the Sub-andean foreland thrust belt. This ridge lies in the structural province of *Santa Barbara System* characterized by a thick-skinned compressive deformation (ALLMENDINGER *et alii*, 1983; JORDAN *et alii*, 1983; KLEY AND MONALDI, 1998; SEGGIARO AND HONGN, 1999) where structures thrust with a regional top-to-the-ESE sense of transport onto the undeformed foreland. The structure of *La Candelaria Ridge* consists of a broad anticline, uplifted by fault planes dipping to the west with a top-to-the-east sense of transport, ca. 60 km-long and up to 10-15 km-wide, strongly plunging both to the North and to the South. It shows evidences of a complex structural history characterized by two main tectonic events: an extensional one, Cretaceous in age, and a Neogenic tectonic inversion of the previous extensional structures (BIANUCCI *et alii*, 1982; GRIER *et alii*, 1991; SALFITY *et alii*, 1993; KRESS, 1995; CRISTALLINI *et alii*, 1997). Several hot springs, with temperatures at surface ranging between 50°C and 99°C, occur in correspondence of its

northern plunge, in the localities of *Los Banós* and *Las Termas* (Salta province).

Stratigraphic setting

The stratigraphic succession of *La Candelaria Ridge* comprises three major sequences extensively outcropping along a ca. 60 km long N-S anticline.

The older unit crops out in the core of the anticline. It is the Precambrian basement made up of low grade metasedimentary rocks (Medina Fm) that in the southern part of the anticline is overlain, with a regional unconformity, by a series of Late Cambrian to Ordovician marine siliciclastic sediments (Candelaria and Orcomato Fms).

These strata are disconformably overlain, in the northern portion and in the western limb of the anticline, by a predominantly continental succession of red beds with minor calcareous intercalations (Salta Group) of Cretaceous to Paleogene age. This marks a rift stage (SALFITY AND MARQUILLAS, 1994). The Salta Group is subdivided from bottom to top in the Pirgua, Balbuena and Santa Barbara subgroups (SALFITY AND MARQUILLAS, 1994). The Early to Late Cretaceous Pirgua subgroup consists mainly of red continental conglomerates and sandstones of 1000m average thickness (ESPELTA *et alii*, 1975). This subgroup represents the syn-rift stage and has been interpreted as the reservoir of the active geothermal system (ESPELTA *et alii*, 1975). The Latest Cretaceous to Early Paleocene Balbuena Subgroup is 180m thickness and comprises sandstones and limestones, whereas the Paleocene to Early Eocene Santa Barbara subgroup, with 330m thickness, is dominantly shaly with rare carbonate intercalations. The Balbuena and Santa Barbara subgroups represent the post-rift thermal subsidence stage (BIANUCCI *et alii*, 1981, COMINGUEZ AND RAMOS, 1995).

Post-rift deposits are in turn overlain by a thick continental foreland basin fill, related to the Andean mountain building, that was shed from Middle Miocene to Plio-Pleistocene times (GEBHARD *et alii*, 1974). The retrowedge basin fill includes two subgroups: Metán and Jujuy. They belong to the Oran Group (GEBHARD *et alii*, 1974). The principal outcrops of these subgroups cover the northern portion of *La Candelaria Ridge* at the lowest elevations. Main lithotypes include sandstones, siltstones and mudstones of the Anta Fm (Metán subgroup) with maximum thicknesses of about 700 m. This Fm is recognized as the most effective cap rock of the geothermal system.

PRELIMINARY RESULTS

Referring to the constraints on the origin of the geothermal anomaly that affects the study area:

- Present-day heat flow values are dramatically higher (3-4 HFU) than those expected in the peripheral portions of a retrowedge in an orogenic system;
- Paleo-thermal modeling allowed to discriminate between the regional and local causes of thermal anomalies recorded by the Meso-Cenozoic sedimentary succession. They are respectively burial due to sedimentary loading and fluid interaction at shallow crustal levels;
- Hydro-geochemical and isotopic preliminary results indicate a prevalent meteoric signal of the spring waters;
- Elaboration of aerial photos suggests a differential uplift of the structure with more mature landscape characterizing the northern portion of *La Candelaria Ridge* than the southern one where a relic paleo-surface is still partially preserved at the highest elevations;
- Preliminary results on the characteristics of the potential geothermal reservoir and cap-rock allow the identification of the main fracture systems and their relationships with lithology and structures at the macro-scale. Our study confirms that the Pirgua subgroup is the reservoir due to its lithology, secondary permeability (continous fractures) and thickness, while the Metán subgroup, although fractured, can still be a cap rock able to preserve temperature and pressure conditions of geothermal fluids where it is kept and mainly below the Quaternary deposits surrounding *La Candelaria Ridge*.

In detail, fractures orientations show four main different trends: N-S, NE-SW, NNW-SSE and E-W. Furthermore N-S and E-W trending fractures are concentrated in the northern periclinal area of the anticline where several hot springs occur with the E-W system probably exerting a structural control on the distribution of the chemical and physical features of waters. On the other hand NNW-SSE and NE-SW trending fractures are predominant in the reservoir rock cropping out along the eastern and western limbs of the anticline, respectively. Within the reservoir unit, fractures show a typical spacing of approximately 30 cm and aperture values that range from 3 mm up to 1 cm.

As a whole, the detected fracture systems affecting the principal reservoir enhanced its permeability;

- Preliminary modeling of audiomagnetotelluric data provide information pertaining to fractures and geometric properties of the geothermal field at depth.

CONCLUSIONS

Preliminary results concerning the multi-method characterization of the *Rosario de La Frontera* active geothermal system (NW Argentina) by means of geological, geochemical, paleo-geothermal, structural and geomorphological and geophysical investigations are summarized in this contribution.

Fracture Modeling applied to the geothermal system potential reservoir of Rosario de La Frontera (La Candelaria Ridge, NW Argentina)

R. MAFFUCCI (*), S. BIGI (**), S. CORRADO (*), L. DI PAOLO (*) & A. CHIODI (***)

Key words: *geothermal system, DFN modeling, faults and fractures, NW Argentina*

INTRODUCTION

Discrete fracture network (DFN) models are three-dimensional stochastic or combined stochastic/deterministic representations of natural fracture systems. They represent an important tool to investigate pathways for fluid flow in geothermal reservoir. Fractures not only improve the hydraulic conductivity of many reservoirs, but also induce significant permeability anisotropy due to the geometry and the type of the discrete fracture network. Thus, fracture system characterization represent an important tool to predict the anisotropy of the hydraulic conductivity in a geothermal reservoir and its effect on fluid flow.

We used this computer modeling approach to study the geothermal reservoir of *Rosario de La Frontera*, in the Salta province. Therefore, detailed field measurements of outcropping reservoir and seal were conducted to get a quantitative description of the DFN (e.g. fracture orientation, fracture length, fracture spacing and effective hydraulic aperture; e.g. LEE AND FARMER, 1993; PRIEST, 1993; MARCHEGIANI *et alii*, 2006). In this abstract we present the DFN models elaborated for the deep reservoir and for the seal of this active geothermal system. The purpose of this modeling is to create simulation fracture properties (such as porosity, permeability, connectivity) with the aim to predict the reservoir and seal behavior in prospect evaluation and reservoir management.

GEOLOGICAL SETTING

The study area lies within the structural province of the *Santa Barbara System*, in the Sub-andean foreland thrust belt, dominated by a thick-skinned compressive deformation (ALLMENDINGER *et* alii, 1983; JORDAN *et alii*, 1983; KLEY AND MONALDI, 1998; SEGGIARO AND HONGN, 1999). This province is characterized by predominantly broad, low-amplitude folds generated by mainly westward-vergent thrusting (ALLMENDINGER *et alii*, 1983) that represent the reactivation of normal faults generated during the Cretaceous rift (BIANUCCI *et* alii, 1982; GRIER *et alii*, 1991; SALFITY *et alii*, 1993; KRESS, 1995; CRISTALLINI *et alii*, 1997).

La Candelaria Ridge represent one of this broad anticline structures, uplifted by fault planes dipping to the west with a top-to-the-east sense of transport. It crop out in the province of Salta and Tucuman, elongated for ca.60 Km N-S and strongly plunging for both north and south directions. It exposes low grade metasedimentary Precambrian strata that are unconformably overlain by a thick sequence of predominantly continental Cretaceous to Paleogene strata (Salta Group) related to the rift stage (SALFITY AND MARQUILLAS, 1981, 1994). The Salta Group strata are capped by a thick continental foreland basin fill that was shed from Early Miocene to Recent time.

The thermal area of *Rosario de La Frontera*, characterized by several hot springs with temperatures at surface ranging between 50°C and 99°C, is located to the north of *La Candelaria Ridge*, in the Salta province. The permeable levels of the Salta Group represent the reservoir of this geothermal fluids that occur close the city of *Rosario de La Frontera*, in correspondence of the thermal area known as *Los Baños*, where syn-orogenic clastic sediments crop out. The post-rift and syn-orogenic impermeable levels provide the cap rock of the geothermal system.

METHODOLOGY

The sampling technique applied for the observation of the fracture network has concerned the acquisition of data along scan-lines and on scan-areas on the outcropping reservoir rocks in order to define the requested parameters needed to generate the DFN. In addition, these characterization was done in different areas of the studied anticline, along the forelimb, backlimb and plunging northern nose in order to relate, if possible, the fracture system characters to the folding process.

Discontinuities observed, such as fractures, joints, veins, etc., were investigated in terms of kinematics, orientation, dimension, spatial distribution, and surface texture. Mentioned data were used as statistical input data to generate a DFN model in 3-D volume of the deep geothermal reservoir. The volume of the potential reservoir was reconstructed from the geological model, based on geological maps and seismic-reflection profiles crossing the studied area. The seismic profiles were interpreted and depth converted, and the results integrated to the superficial data. The workflow was done using the software Move 2012 (Midland Valley).

PRELIMINARY RESULTS

Most of the structural analysis was carried out in the syn-rift sedimentary fractured strata of the Pirgua subgroup (conglomerates and sandstones), and in the syn-orogenic siltstones strata (Anta Formation). Fracture orientations result relatively complex with different trends N-S, NE-SW, NNW-SSE and E-W.

N-S and E-W trending fractures are present mainly in correspondence of the northern plunge of the anticline where occur several hot springs and Anta Formation (the main seal of the geothermal system) extensively crops out. The E-W trending fractures network seems to exert a structural control on the thermal springs distribution and geochemical characteristics producing a compartmentalization of the system.

NNW-SSE and NE-SW trending fractures are predominately visible in the reservoir rock outcropping in the eastern and western limbs of the anticline, respectively. Within the reservoir unit, fractures show a typical spacing of approximately 30 cm and apertures which ranges from 3mm up to 1 cm.

In addition, density values (number of fractures per meter) were obtained from quantitative analysis in order to elaborate a three-dimensional representation of the fractures network that characterize the deep reservoir. Furthermore, an upscaling phase was necessary to generate permeability and porosity properties distribution in order to compare the obtained data to other geophysical investigations, such as soil gas surveys, audiomagnetotelluric surveys, to better constrain the reservoir extension.

ACKOWLEDGEMENTS

We kindly acknowledge Agostina Chiodi and Walter Baez for their precious help in the field. Thanks are also due to Diego Santarelli for his logistic support in Buenos Aires.

Relationships between sinkholes areal distribution, tectonic alignments and recent seismicity in Abruzzo (Central Italy)

ANTONIO MORETTI (*), GIANLUCA FERRINI (*) & CARMELINA DE ROSE (*)

Key words: *Sinkhole, Abruzzi Region*.

INTRODUCTION

Central Apennines is genetically characterized by the gradual transition, from south to north, of areas constituted by terrains belonging to the Meso-Cenozoic "Latium-Abruzzi carbonate platform" sequence fading northward in the coeval "pelagic Umbria-Marche Basin" sequence. These different paleo-geographic domains, starting from the Upper Miocene, were affected by a general tectonic compression phase responsible of the formation of folds and thrust faults systems showing a predominant NW-SE trend and a general transport direction towards NE (see Patacca et al., 2008, and related bibl.). The compressive phase of the chain is followed by an extensional deformation active since late Pliocene up to Quaternary. These normal/oblique west dipping faults determined the formation of a series of inter montane basins filled by continental deposits. The directions of these faults are predominantly NW-SE or NNW-SSE and much of these are still active and responsible of the recent seismicity of the Apennines as demonstrated by the April 6 th 2009 earthquake.

The Aterno valley is one of the main inter-montane basins of Central Apennines Apennines and it is characterized by the presence of several large funnel-shaped morphologies locally named “fossa” (trench) or "canetra" (baskets) equally developed on the Mesozoic-tertiary carbonate bedrock (outcropping on the slopes of the valley) and on the Neogene sedimentary filling of the graben.

MORPHOLOGY

The *canetre* have a general morphology comparable to the classic karst dolines but present an average considerable size with diameters of some hundreds of meters and depth, from the outer rim, of several tens of meters.

Fig.1 – View of the “*Fossa di Spedino”* one of the most significant expression of the phenomenon in L’Aquila area.

Another peculiar characteristic of these features is that, at present, they do not have any relation with the regional or local water table and inside them no residual sedimentary deposits, comparable with the volume of the rock theoretically dissolved, are recognizable; surface karst dissolution phenomena are absent or poorly developed.

These structures are found only in this part of the Apennine chain concentrated along a specific alignment ending northward with the well-studied sulphurous lagoons of the active hydrothermal field of S.Vittorino (Rieti). Due to their typical morphology, to the close association with active fault systems and to the similarity with the active field quoted before we can refer the genesis of these features to a generic dissolution phenomena triggered by a deep acids/mineralized fluids rising (piping) and to a subsequent gravitational collapse in a classic evolutionary model of sinkhole.

SEISMOTECTONIC

Particularly interesting is the areal distribution of these features: in fact they are distributed along a WNW-ESE oriented band which runs, for more than 40 km, parallel to the main tectonic front of the Gran Sasso chain, tracing the seismogenic source of the April 6th 2009 earthquake and of the most important historical earthquakes reported for the region.

This continuous alignment is limited:

(*) Dipartimento di Scienze Ambientali Università dell’Aquila

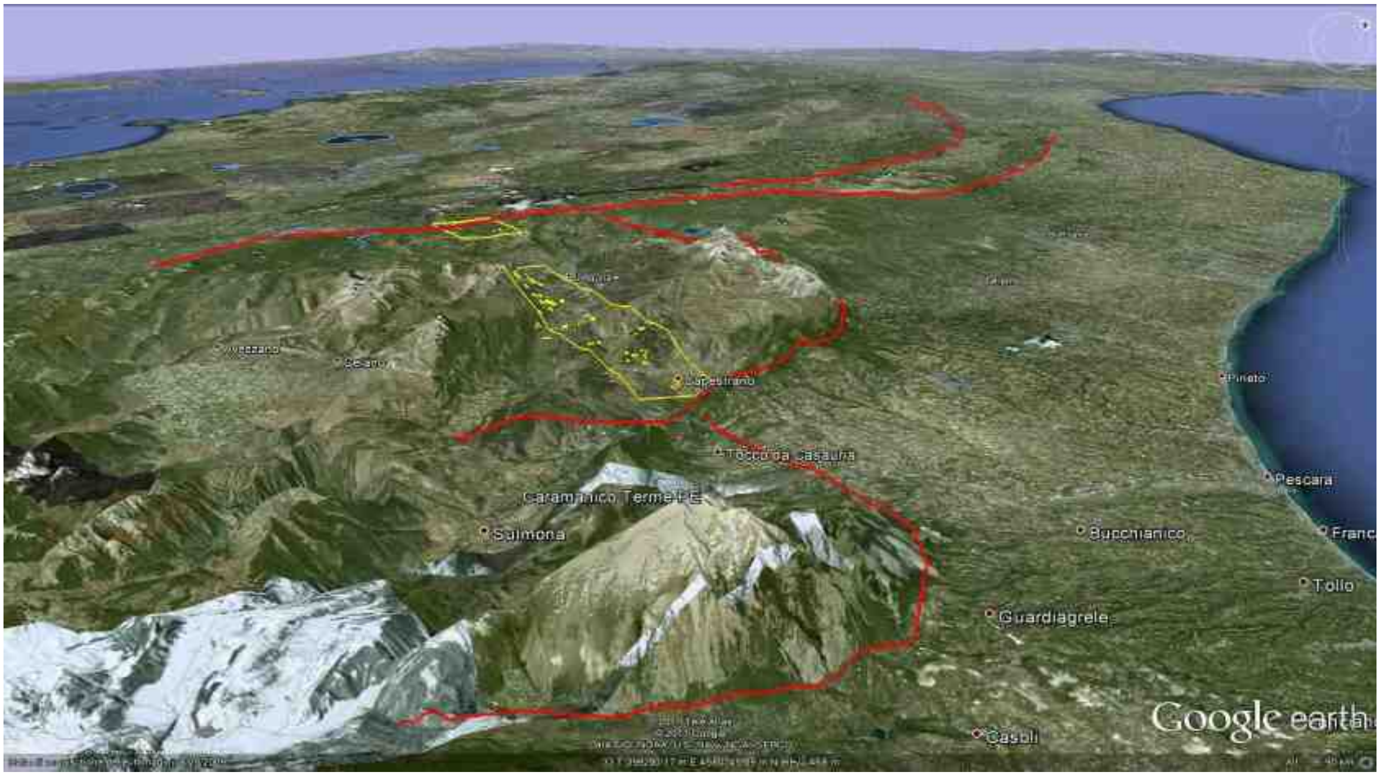

Fig. 2 – The sinkholes alignment (pointed out by the yellow box) respect 1) the Gran Sasso and Majella tectonic front (red line) and 2) the Ancona – Antrodoco . Anzio (Auctt) line.

- In the south-eastern edge by the transcurrent structure which bound the Gran Sasso overturned tectonic front;
- In the north segment by the intersection with the well know regional structure Olevano Androdoco (Ancona-Anzio auct.) considered the dividing line between the Northern and the Central Apennines; to note the development of the S.Vittorino hydrothermal field just in correspondence of this connection.

At present there is no current evidence of hydrothermal activity or gas emergences around the *canetre.* The elevation of the bottom of the features studied is progressively higher respect the elevation of the floodplain of the Aterno depending on their age of formation. Relict forms of circular features surveyed at higher elevation are the evidence of older developmental stages in the formation of the sinkholes and proof that the phenomenon has been active for a considerable period of time (in the order of hundreds of thousands of years considering the estimated slip-rate along the graben faults and those sinkhole formed in the large Middle Pleistocene alluvial fans extending at the foot of the Gran Sasso massif).

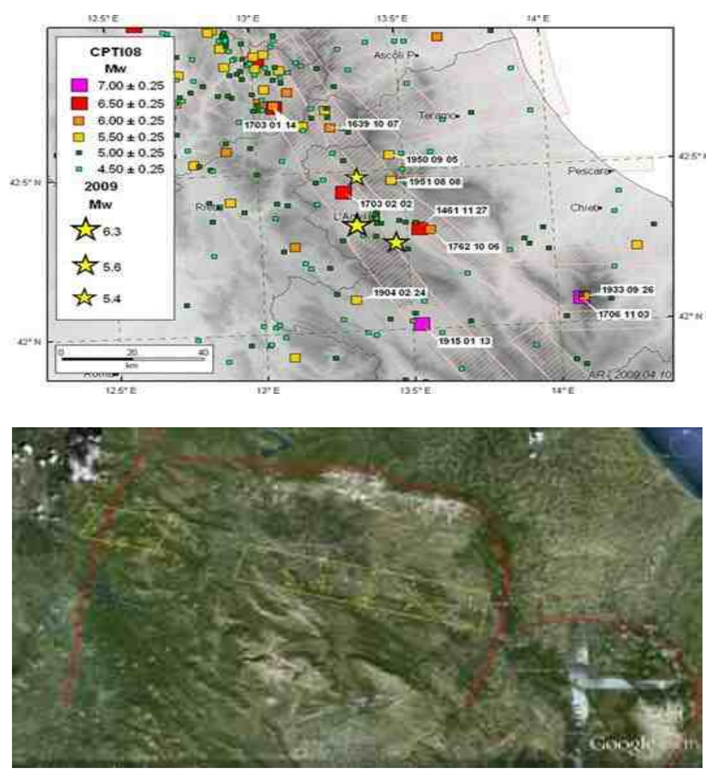

Fig. 3 – historical earthquake epicenters location map and sinkholes distribution.

CONCLUSIONS

The *canetre* alignment represents the morphological expression of a relict hydrothermal system, developed during the last 100-000 years, related to a crustal extension band formed in correspondence of the intersection between the master faults bounding the inner section of the Gran Sasso tectonic front and the antithetical structures which mark the opposite margin of the valley. The allocation of these important dissolution features fits with the distribution of the recent seismicity reported for the area. At present, even if we have no evidence of fluids rising, the phenomenon can hardly be considered exhausted; for this reason a systematic geochemistry campaign is going on to identify and characterize soil gas emissions. Goal of this effort is to find suitable sites for monitoring the fluid in relation to seismic activity and to evaluate the risk of potential and sudden gravitational collapse in the area.

The geothermal area of Venosa (Southern Italy): preliminary results of a multi-disciplinary analysis

ANGELA VITA PETRULLO (*), GIACOMO PROSSER (*), FABRIZIO AGOSTA (*), ENZO RIZZO (°), DOMENICO CHIARELLA (°°) & GIUSEPPE TAMBURRIELLO (*)

Key words: *Apulian carbonates, foredeep, southern Apennines, thermal anomaly.*

In this work, we present the preliminary results of a study conducted in a region located between the Vulture Mt. and the Murge area.

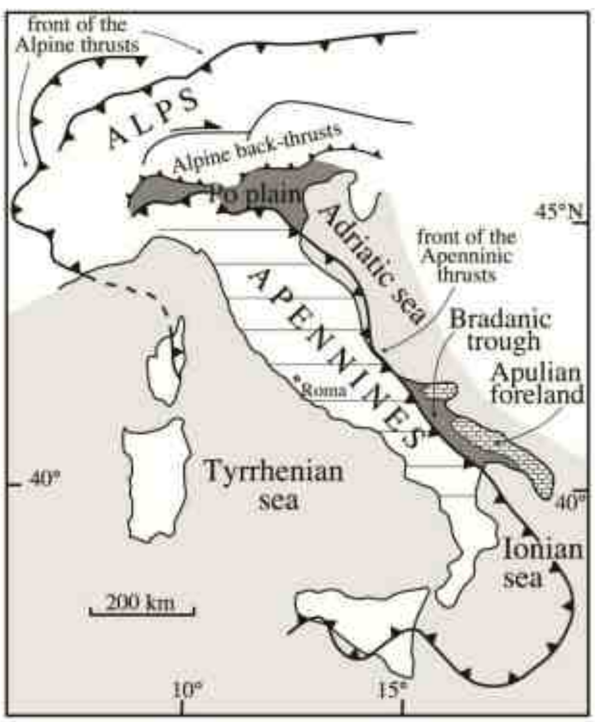

Fig. 1 - Schematic structural map of Italy. Po Plain, north-central Adriatic Sea, Bradanic Trough and Taranto Gulf (Ionian Sea) are sectors of the Plio-Quaternary Apennines Foredeep (Tropeano *et alii* 2002).

This region represents the Pliocene-Pleistocene foredeep depozone of the southern Apennines fold-and-thrust belt (Bradanic Trough) and the Apulian forebulge (Fig. 1). The substratum of the Pliocene foredeep deposits mainly consists of shallow-water carbonates, ranging in age from Early Triassic to Miocene, belonging to the Apulian platform. The study area is affected by a hydrothermal activity at low temperatures and in particular, near Venosa and Montemilone villages, previous works reported presence of water characterized by a high salt content and temperatures of about 35 °C within the Apulian carbonates at depths of about 550 to 800 m. The aforementioned temperatures may indicate circulation of geothermal fluids, possibly related to a thermal anomaly associated to the nearby Vulture volcano.

This works is aimed at a better understanding of the feeding system of the geothermal area and, in particular, of the role played by the high-angle faults crosscutting the Apulian carbonates on hydrothermal circulation at shallow crustal depths. Recently we started a geological-structural study of the area characterized by the aforementioned thermal anomalies. The first analyses focused on the interpolation of existing geological and geophysical data. Specifically, Spontaneous Potential and Resistivity data from well logs and 2D seismic lines were interpreted and compared with the present-day outcropping geology. Both well logs and seismic data derive mainly from the VIDEPI project. The results are consistent with presence of several structural highs bounded by NW-SE oriented high-angle faults in correspondence of the more pronounced thermal anomalies. Smaller scale high-angle faults oriented either E-W and/or NE-SW, possibly crosscut the structural highs.

In order to disentangle the structural grain of the Apulian carbonates and, hence, infer the subsurface circulation paths of the hydrothermal waters we plan to conduct several field activities aimed at: (i) defining the geometry, kinematics, abutting and crosscutting relationships of the different fault sets; (ii) assessing the relative timing of the various fault sets; (iii) defining the geochemical signature of hydrothermal waters. To achieve the aforementioned goals, we will perform detailed field structural analyses of exposed high-angle faults crosscutting the Apulian carbonates of the Murge area, acquire new geoelectrical and magnetotelluric data, and collect water samples from wells.

Hot faults: shallow processes or deep roots? Did past earthquakes leave a hot "path"? The power of fluid geochemistry data in a multidisciplinary approach

FEDORA QUATTROCCHI (*), ALESSANDRA SCIARRA (*), LUCA PIZZINO (*), SERGIO VINCIGUERRA (°), & ARIANNA PESCI (*)

Key words: *earthquakes, faults, geochemistry*.

ABSTRACT

This contribution reviews a set of case histories gathered by ING and INGV during the last 20 years, throughout the Italian peninsula, where hints of presence of blind and buried "hot" faults are located (i.e. Puglia, Calabria, Lazio, Toscana, Veneto, Lombardia, etc.), mainly on the basis of fluid geochemistry data reworked within a multidisciplinary approach. Apart the importance of faults, to discover the most prone areas where shallower heat is located and therefore possibly exploited, the faults, seismogenic and not, are now known only by certain aspects. In particolar, they are to be re-considered in details also for the important problems pertaining the hot fluids/electricity production, where faults are present, i.e., induced seismicity during the fluids injection/production and hydraulic fracturing. The geomechanical and geochemical aspects should be merged for "early alarm" subroutines too.

During the stimulation of experimental hot-dry-rock geothermal reservoirs, seismic, mechanical (deformations, i.e. by precision-GPS arrays) and geochemical monitoring should be carried out, deepening the 3D crustal block in a full multi-parametric approach, still lacking.

The studies on induced seismicity as well as those of fluids release at surface - possibly dangerous as bursts - started since the mid-1980s to estimate the extent and orientation of a stimulation, i.e. at Fenton Hill, New Mexico, where a stimulation involving 21,000 m^3 in 1983, yielded over 11,000 locatable seismic events. For this case mapped event cloud formed a 0.3-km^3 tabular volume surrounding the injection point not extending to a nearby well (200 m distant).

We will consider the "hot faults" where the exploitation and induced seismicity studies are most promising. An evaluation of the energy possibly produced by DS-HDR configurations for some of the discussed sites will be outlined too.

Hydrothermal mineralisation along the damage zone of the Boccheggiano normal fault, Tuscany, Italy

FEDERICO ROSSETTI (*), LUCA ALDEGA (**), FRANCESCA TECCE (°), FABRIZIO BALSAMO (°°), ANDREA BILLI (°) & MAURO BRILLI (°)

Key words: *normal fault, damage zone, geothermal outflow, fluid pressure.*

ABSTRACT

The Neogene extensional province of Southern Tuscany in central Italy provides an outstanding example of fossil and active structurally-controlled fluid flow and epithermal ore mineralisation associated with post-orogenic silicic magmatism. Characterisation of the hydrodynamic regime leading to the genesis of the polysulphide deposit (known as Filone di Boccheggiano) hosted within the damage zone of the Boccheggiano Fault is a key target to assess modes of fossil hydrothermal fluid circulation in the region and, more in general, to provide inferences on the fault-controlled hydrothermal fluid flow in extensional settings. We provide a detailed description of the fault zone architecture and alteration/mineralization associated with the Boccheggiano ore and report the results of fluid inclusion and stable oxygen isotope studies. This investigation shows that the Boccheggiano ore consists of an adularia/illite-type epithermal deposit and that sulphide ore deposition was controlled by channelling of dominant meteoric hydrothermal fluids within the highly anisotropic permeability structure of the Boccheggiano fault. The low permeability structure of the fault core compartmentalised the fluid outflow preventing cross-fault flow, with focused fluid flow occurring at the hangingwall of the fault controlled by fracture permeability. Fluid inclusion characteristics indicates that ore minerals were deposited between 280° and 350 °C in the upper levels of the brittle extending crust (lithostatic pressure in the order of 0.1 GPa). Abundant vapour-rich inclusions in ore-stage quartz are consistent with boiling and quartz ore vein textures, and suggest that mineralisation in the Boccheggiano ore was controlled by boiling in a deformation regime regulated by transient and fluctuating fluid pressure conditions. Results from this study (i) predict a strongly anisotropic permeability structure of the fault damage zone during crustal extension, and (ii) indicate the rate of secondary permeability creation and maintenance by active deformation in the hangingwall of extensional faults as the major factor leading to effective hydraulic transmissivity in extensional terrains. These features intimately link ore-grade mineralisation in extensional setting to telescoping of hydrothermal flow along the hangingwall block(s) of major extensional fault zones. Further details are available in ROSSETTI *et alii* (2011).

A multidisciplinary study of a natural site for CO_2 geological storage in central Italy

F. TRIPPETTA (*), C. COLLETTINI (**, °), M.R. BARCHI (**), A. LUPATTELLI (**), F. MIRABELLA (**)

Key words: *Underground storage, Natural CO2 reservoir, Central Italy, Triassic Evaporites, CCS, Long Term storage.*

ABSTRACT

Storage of CO_2 is an important strategy that helps in contrasting the negative environmental effects of the continued increase of anthropogenic greenhouse-gas emissions and in particular, geological storage is one of the most promising solutions.

Here we present a multidisciplinary study of a natural CO_2 geologic reservoir where fluid overpressure, measured at 85% of the lithostatic load, is trapped at 4700 m in the Northern Apennines of Italy.

Deep borehole data and seismic reflection profiles show that the observed CO_2 overpressure: a) is hosted in dome shaped structures (Fig. 1a) that are the result of the interplay between the compressional and extensional tectonic phases of the area b) is trapped between Triassic Evaporites that are composed by alternating Ca-Sulphates and Dolostones (Fig. 1b) and c) occurs within dolostones portions that are sealed by Ca-sulphates (anhydrites) horizons (Fig. 1c).

Field studies on outcropping evaporites, that represent exhumed analogues of the lithologies found at depth in the pressurised reservoir, show dolostones affected by fracturing and faulting and Ca-sulphates characterized by ductile folding without macroscopic fractures. Borehole and laboratory

P-wave velocities coincide for anhydrites (6.2-6.3 km/s) but are different for dolostones (6.2-6.3 km/s in situ and ~ 7.2 km/s in lab), confirming the different mode of deformation in the two rock types. Since anhydrites are not dominated by fractures, the very low permeability values, $\sim10^{-19}$ to $\sim10^{-22}$ m^2, recorded in laboratory experiments, can also be representative for in-situ conditions. These data confirm the sealing ability of the anhydrites also for high values of fluid pressure.

Field data show that brittle faulting within the TE promotes the development of a dolomite-rich fault core affected by cataclastic processes (Fig. 1d). These brittle faults represent a path for crustal scale fluid flow that can link different reservoirs hosted within the dolostones. At the same time no CO_2 can be stored within isolated blocks of dolostones surrounded by anhydrites (Fig. 1).

The integration of these datasets suggests that: 1) tectonics and structural position, and 2) lithology and associated mode of deformation, play a key role for channeling and trapping deep-seated CO_2-rich crustal fluids.

Preliminary hydro-geochemical and geological characterization of the thermal aquifer in the Guardia Piemontese area (Calabria, south Italy)

GIOVANNI VESPASIANO (*), FRANCESCO MUTO (*), CARMINE APOLLARO (*) & ROSANNA DE ROSA (*)

Key words: *Aquifer, Guardia Piemontese, geochemistry, thermal waters*

INTRODUCTION

A preliminary study of the thermal aquifer of Guardia Piemontese area (Calabria, south Italy) is carrying out. The studied area is characterized by metamorphic, igneous and sedimentary rocks.

In the Coastal Chain around the area of Guardia Piemontese is well exposed the tectonic overthrust of the Alpine chain units on the Apennine thrust stack. In the Bagni catchment the Apennine Units of Cetraro and Verbicaro outcrop in a tectonic window. The lower unit is made up of calcareous phyllites with interbedded quartzites and limestones, dolostones and evaporates (Cetraro Unit, Auct.); the upper unit consists of dolomitic limestone and dolostone (Verbicaro Unit, Auct.). The Alpine chain is represented by Frido, Gimigliano (AMODIO MORELLI L. *et alii*,1976), Bagni, and Sila units. Metamorphic and igneous rocks are sealed by Miocene deposits consisting in conglomerates, sandstones, clays and silty limestones with evaporates (DIETRICH D. 1976).

The study has been carried out following geological and hydrogeological approach, which have specifically concerned a preliminary geological survey followed by the characterization, in terms of hydrogeology and structure, of the outcropping rocks.

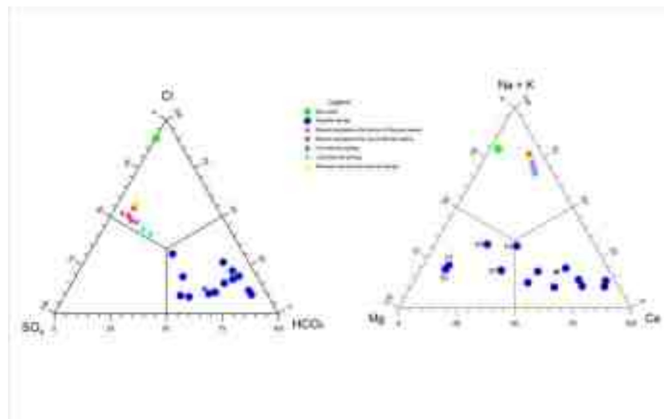

Fig. 1 – Ca-Mg-Na+K and Cl-SO_4-HCO_3 diagrams (LANGELIER, W. F., & H. F. LUDWIG 1942).

The major faults are NW-SE oriented and confined the Guardia Piemontese carbonate tectonic window. The upwelling of deep thermal waters occur along the Bagni catchment in correspondence of the major fracture and fault system. Finally we moved to the sampling and analysis of four thermal springs, twelve cold springs and a well, to characterize waters (APPELO C. *et alii*, 1996) (CELICO P., 1986).

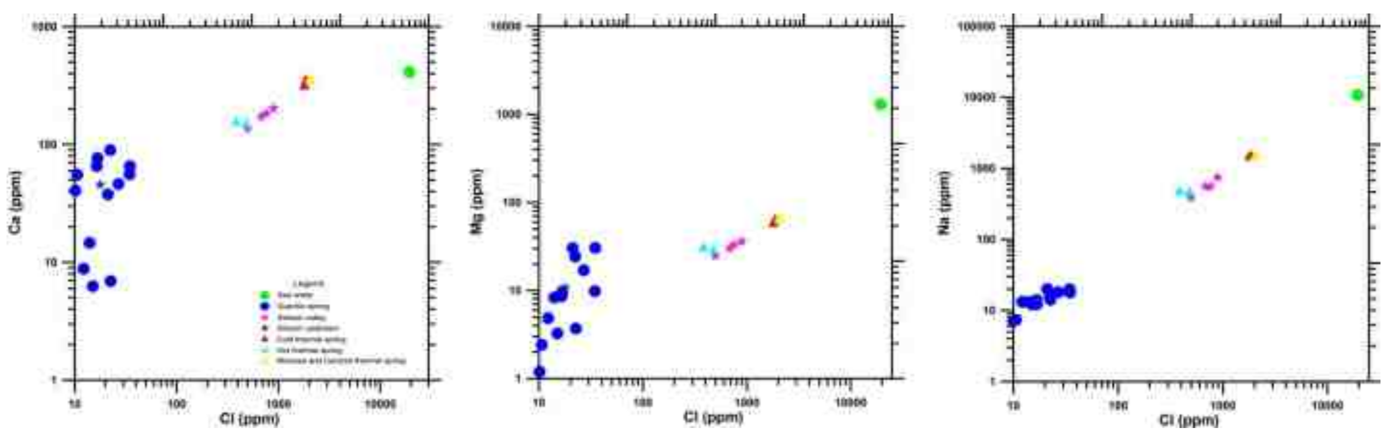

Fig. 2 – Ca/Cl – Mg/Cl- Na/Cl diagrams.

(*)Department of Earth Sciences, University of Calabria
The P.h.D. of Giovanni Vespasiano is co-financed by the Commissione Europea (FSE) and Regione Calabria (POR Calabria FSE 2007-2013).

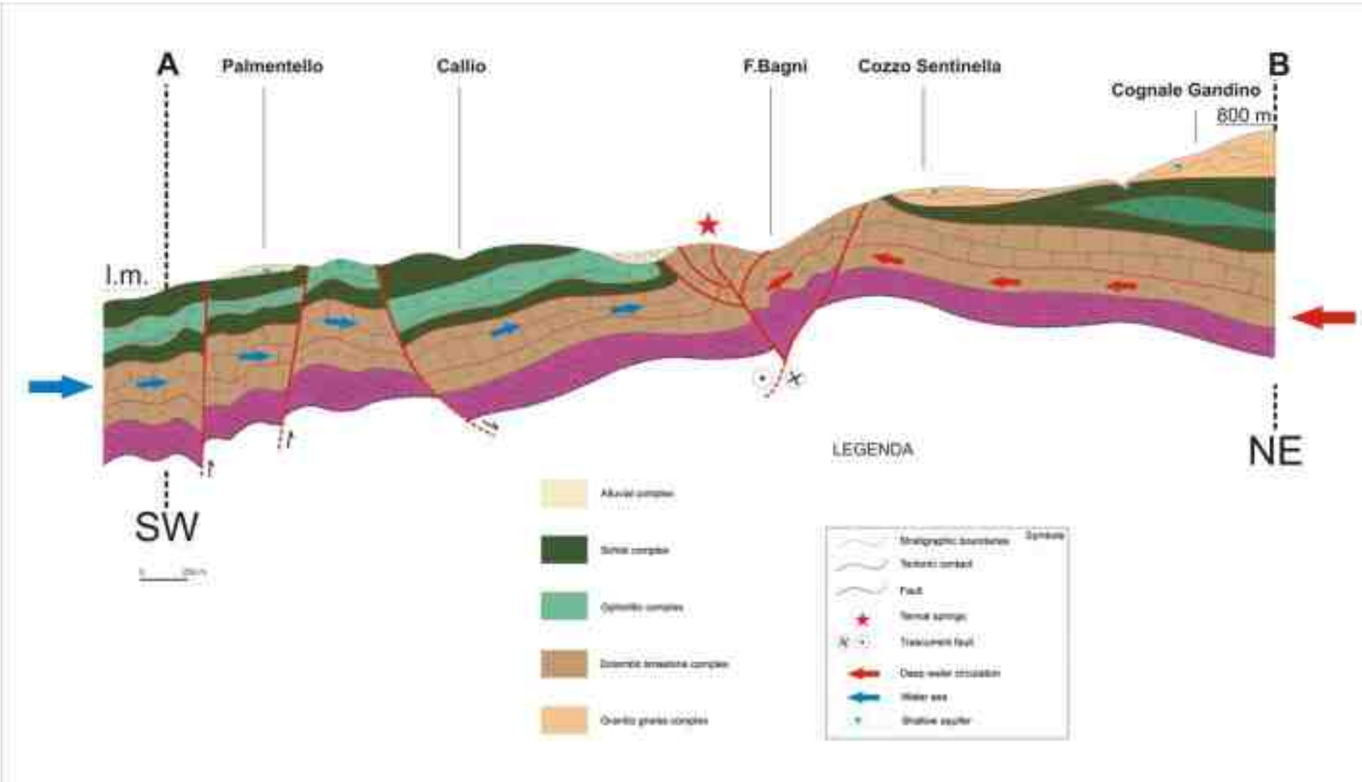

Fig. 3 – Schematic geological section of the Guardia Piemontese Basin.

Field and laboratory data allowed to recognize three groups of water: Ca – HCO_3 waters, Mg – HCO_3 waters and Na – Cl (SO_4) waters, furthermore the geochemical compositions and the geology allowed to identify a multi-aquifer system; one shallow with Ca–HCO_3 composition, originate by interaction with metabasites and carbonatic phyllites, and Mg–HCO_3 originate by interaction with gneiss enriched in biotite and garnet (Fig. 1)

The deep thermal aquifer with a Na–Cl(SO_4) composition probably derive by a mixing between a cold Ca–HCO_3 end–members and sea water (Fig 2). Furthermore the waters, during ascent, are enriched in SO_4 probably by interaction with intercalated evaporite belonging to the Triassic Cetraro Unit.

Preliminary geological survey and geochemical data have shown a preferential water ascent through high angle faults in the vicinity of thermal emergencies belonging to N–S and NW–SE trending systems (Fig. 3).

Geological cross section in figure 3 represents the geological structures and the hydro-geological complex in which the groundwater circulation occurs.

Structural and morphological features of the Torre Alfina geothermal area (central Italy)

GIANLUCA VIGNAROLI (*), ANNAMARIA PINTON (*), ARNALDO A. DE BENEDETTI (*), GUIDO GIORDANO & FEDERICO ROSSETTI

Key words: *structural geology, lineaments, Torre Alfina, geothermal field.*

INTRODUCTION

The Torre Alfina area defines one of the geothermal fields in Latium region (central Italy) that are considered for exploration.

The lower units of the Torre Alfina area are classically considered the southern prolongation of the Cetona Mount, a structural high composed by the Meso-Cenozoic carbonatic Tuscan series covered by the allochthonous flysch (PASSERINI, 1964). The Cenozoic compression involved these units producing imbricated thrust sheets during the fold-thrust-belt construction of the Apennines. Syn- and post-orogenic marine sediments, Miocene-Pliocene in age, sealed the compressive contacts and filled the tectonic depressions of the Siena-Radicofani and Paglia-Tevere grabens formed during crustal thinning in peri-Tyrrhenian domain. Quaternary volcanism developed in these extensional settings and constituted major (Amiata Mount and Vulsini Mounts) and minor (Radicofani and Torre Alfina) volcanic centres.

Since the 1970s, the Torre Alfina area (central Italy) has been involved in geological-geophysical studies for investigating the geothermal potential (e.g. COSTANTINI *et alii*, 1984; BUONASORTE *et alii*, 1988; BARBERI *et alii*, 1994; CHIARABBA *et alii*, 1995, CHIODINI *et alii*, 1995; DOVERI *et alii*, 2010). Integrated data identified that the carbonatic sequences constitute the reservoirs of the Torre Alfina geothernal field, as well as the allochthonous flysch and the Pliocene clays constitute the seal units. The Quaternary magmatism defines the main heat source.

Although very promising, the Torre Alfina geothermal field is not exploited. Deep bore-holes had been drilled with a series of failures as they randomly resulted unproductive or very productive within the same reservoirs. One of the reasons for this unsuccess depends on lack of characterisation of the main tectonic structures (in terms of kinematics and spatial distribution) that are responsible for the present-day structural setting of the area.

This work describes preliminary data on the structural and the morphological features of the Torre Alfina area, which suggest a primary role of tectonics for the evaluation of the geothermal potential.

METHODOLOGY AND RESULTS

We integrated data from both geological survey and lineaments analysis based on digital elevation model (DEM). The geological survey was addressed to collect structural data, to define (in terms of geometry and kinematics) and to map the main structural elements that involve the volcanic covers and, subordinately, the lower units. The lineaments analysis was carried out on two different satellite images with 60 m and 15 m of spatial resolution. We considered all morphological and geological linear features (or groups of lineaments) visible on images following WISE *et alii* (1985).

More than 600 structural data, at the meso-scale, have been collected. These are faults and fractures affecting both the Quaternary volcanic deposits (tephritic lavas and pyroclastites) and the allochthonous flysch. Faults define metric-to-decametric thick shear zones seldom showing the fault core-damage zone architecture (CAINE *et alii*, 1996). The thickness of the fault core, in competent pyroclastites, is less than 10 cm, while the damage zone can be up to 1 meter. Sulphate minerals have been observed in fault cores affecting the allochthonous flysch, while oxides are the principal mineral phases detected on fault surfaces in volcanic rocks. Faults are inclined (>30°) to sub-vertical, and they strike along two main orthogonal directions: NW-SE (dipping to NE) and NE-SW (dipping to SE). The analysis of shear criteria (e.g. PETIT, 1987) documents dextral strike-slip and, subordinate, normal movements for both fault systems. In few cases it has been observed that fault surfaces with strike-slip kinematics interrupt and dislocate normal-sense structures.

Fractures are both tensile- and shear-fractures (mode-I and mode-III of ATKINSON, 1987, respectively). They are tectonic discontinuities mainly connected with fault systems. In lavas, tectonic fractures have been discriminated by discontinuities of uncertain origin (for example due to lava cooling) by considering their geometrical properties (spacing, persistence, aperture) and the geometrical compatibility with fault systems. Fractures, also, can be grouped into two main directions: NNE-SSW and WNW-

(*) Dipartimento di Scienze Geologiche, Università Roma Tre, L.go S.L. Murialdo, 1 - 00146 Roma.

ESE, both of them sub-vertical.

Analysis of regional lineaments on the 60 m spatial resolution DEM identified 8359 features based on 8 shaded-relief models. Lineaments have lengths between 400 m and 8 km (with 1600-1800 m as a mean). Two main directions (NE-SW and NW-SE) and two subordinate directions (N-S and E-W) have been determined. Analysis of lineaments on a 15 m spatial resolution DEM allowed to group 4453 features along two main directions (NE-SW and SE-NW) and one minor direction (N-S). The lengths of these segments range between 200 m and 4 km (with a mean of 900-1000 m). Finally, the trend and distribution of the lineaments have been considered in function of the outcropping lithostratigraphic units (volcanic deposits, Pliocene-Quaternary marine sediments, and allochthonous flysch). The area covered by volcanic rocks is characterised by the occurrence of 657 lineaments (15 m DEM) aligned along NW-SE and NNE-SSW main directions. The N-S and NE-SW directions are subordinate. The length of lineaments ranges between 200 m and 3 km. Longer features are concentrated along the NNE-SSW direction.

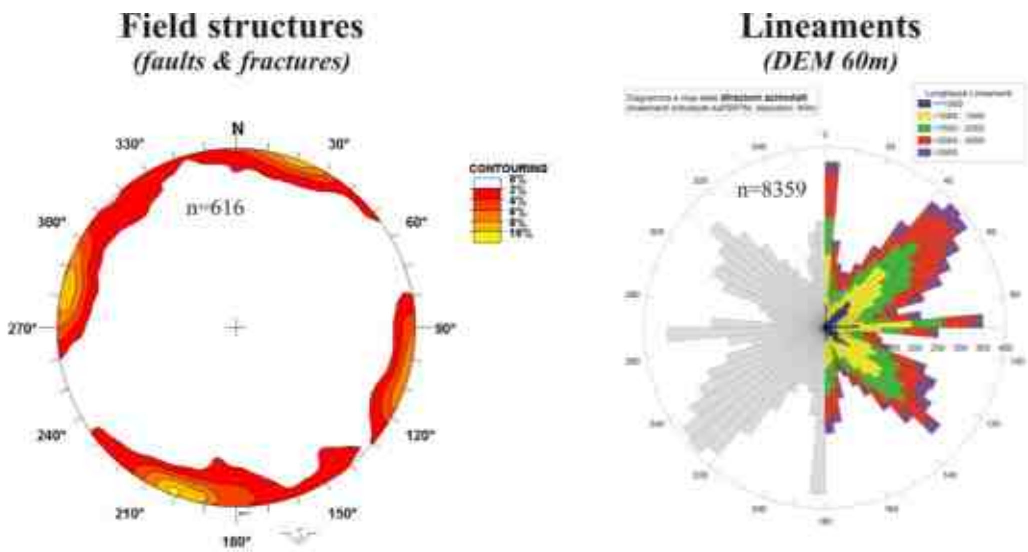

Fig. 1 – Stereographic projections (Schmidt net, lower hemisphere) comparing spatial distribution of field structures and geological lineaments deduced from DEM 60 m.

DISCUSSION AND IMPLICATIONS

A preliminary comparison between spatial distribution of tectonic features measured on the field and geological features deduced by DEM analysis is presented in the stereographic projections of Figure 1. It is evident that a first order fitting between different data can arise when comparing the main directions of geological lineaments. NE-SW and WNW-ESE are the main directions along which the structural and morphological features of the Torre Alfina area are aligned. The consistence of the lineaments analysis allows generalising to a regional scale the importance of the tectonic structures detected in the field. Pliocene-Quaternary strike-slip and normal fault systems are widely described for the peri-Tyrrhenian setting of the Apennines, in central Italy (e.g. BUONASORTE *et alii*, 1988; FACCENNA *et alii*, 1994a; 1994b). They are interpreted as resulting from the crustal thinning mechanism starting from the Tyrrhenian Sea and progressively migrating towards the Apennine belt (e.g. (MALINVERNO & RYAN, 1986; PATACCA *et alii*, 1992; LAVECCHIA *et alii*, 1994; PAUSELLI *et alii*, 2006). Our normal fault systems can be framed within this regional extensional process, in which the strike-slip kinematics adjusts the block arrangement and transfers the deformation between the main normal-sense shear zones.

It is demonstrated that brittle deformation influences the underground fluid circulation, promoting the increase of the permeability distribution within the rock mass and controlling the mode of hydrothermal flow (e.g. OLIVER, 1996). Within this concept, the Pliocene-Quaternary tectonic structures described for the peri-Tyrrhenian setting have been systematically related to volcanism and hydrothermal outflows (e.g. FACCENNA *et alii*, 1994b; BELLANI *et alii*, 2004; ROSSETTI *et alii*, 2011), considering their primary role into the endogenous fluid circulation. It is plausible to assume that recent deformation in the Torre Alfina area individuate preferential directions (NE-SW and WNW-ESE) along which fluids circulate throughout the reservoir. At the same time, our data show that these tectonic discontinuities (fault systems and associated fracture networks) can correspond to structural boundaries in which variation of the geological properties of the original rock volume (as grain-size comminution due to shearing and newly-formed mineralization) can be observed. These features argue for a permeability barrier to fluid circulation across the fault, separating rock volume with different underground drainage.

The main result of this preliminary work is that the Torre Alfina area can be imaged as a geothermal system composed by different compartments with inhomogeneous fluid network. Tectonic structures define the main boundaries between compartments, helping the understanding of why productive and non-productive wells were found in apparently similar structural settings within the Torre Alfina field (BUONASORTE *et alii*, 1988). Their study should therefore be considered during geothermal exploration.

Amphibole asbestos and other fibrous minerals in the meta-basalt of the Gimigliano-Mount Reventino Unit (Calabria, South-Italy)

ANDREA BLOISE (*), ELENA BELLUSO (**,°,+), TERESA CRITELLI (*), MANUELA CATALANO (***), CARMINE APOLLARO (*), DOMENICO MIRIELLO (*) & EUGENIO BARRESE (*)

Key words: *Amphibole asbestos, fibrous minerals, meta-basalts*

INTRODUCTION

The study concerns the investigation of amphibole asbestos and other fibrous minerals contained in the meta-ophiolitic sequence belonging to the Gimigliano-Mount Reventino Unit (GMRU, Fig. 1). This consists of meta-basalts, meta-gabbros/meta-dolerites and serpentinites with a sedimentary cover made up of marble alternating with calceschists and quarzites (PILUSO *et alii*, 2000; LIBERI *et alii*, 2006).

Some of these lithologies, called "green rocks", quarried for using as building and ornamental stones (ZAKRZEWSKA *et alii*, 2008), excavated for road yards, can contain asbestos minerals.

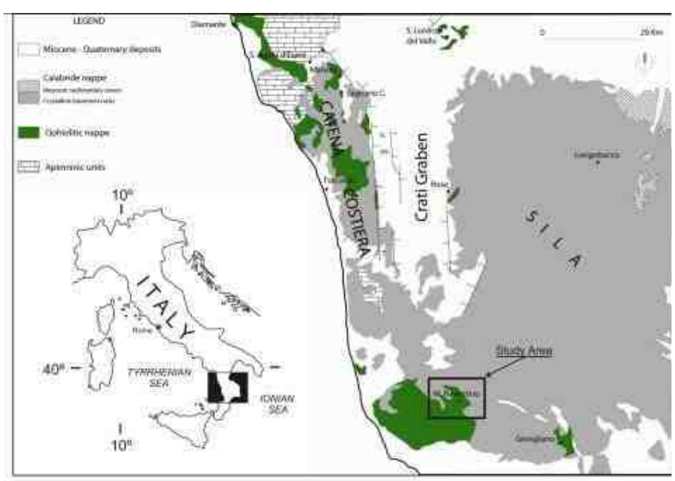

Fig. 1 – Geological map of the Northern Calabrian Arc and study area location.

These are five minerals belonging to amphibole group (i.e., tremolite, actinolite, anthophillite asbestos, crocidolite, and amosite) and chrysotile, all having length > 5 µm, width < 3 µm and aspect ratio length/ width > 3.

Owing to possible health problems due to asbestos fibre exposition, the works in the aforesaid quarries are regulated by the Italian law (DM 14/06/1996). The univocal distinction among asbestos and other fibrous minerals i) is not so easy because some mineral fibres can be mistaken for asbestos and vice versa and ii) it is very important because law demands the asbestos identification and quantification. Besides the Italian law (DM 18/03/2003) established to make a map of the asbestos presence in outcropping rocks.

Previous studies on the asbestos presence are referred to quarries and no detailed observations on fibrous amphiboles and other kind of fibrous minerals have been made (e.g. the different varieties of amphiboles have not been discriminated and characterized). For this aim, mineralogical studies and detailed characterizations of the meta-basalts are currently being carried out by polarized light microscopy (PLM), XRPD, SEM/EDS, TEM/EDS, TG/DSC, XRF investigations.

Preliminary results show that the most abundant minerals in all meta-basalts rocks are (in order of decreasing abundance): chlorite, epidote, amphiboles (asbestos actinolite, asbestos tremolite and riebeckite), serpentines, albite, muscovite, calcite.

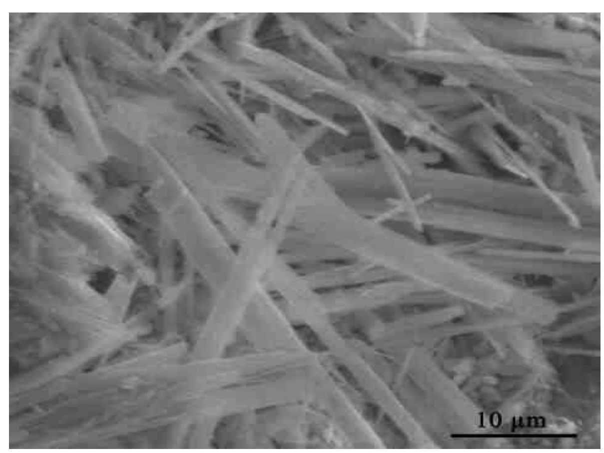

Fig. 2 – Secondary electron SEM image of actinolite asbestos.

(***) Department of Physic, University of Calabria.
(°) Institute of Geosciences and Earth Resources (CNR), Torino section, Torino.
(+) NIS Centre of Excellence, University of Torino.

Titanite, magnetite and clay minerals were also detected, but in low amounts and not in all samples. Concerning the morphology, the amphibole fibres, when observed by SEM, appear thin, rigid and approximately 30 µm in length (Fig. 2).

Amphiboles asbestos are typically intergrown with serpentine minerals and this makes difficult to evaluate the amount of each fibrous phase by SEM. TEM/EDS investigations show that amphibole asbestos display two main varieties: asbestos tremolite

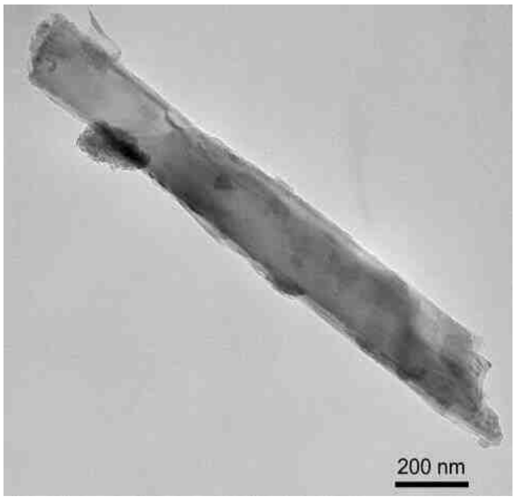

Fig. 3 – TEM images of asbestos tremolite fibre.

(Fig. 3) and asbestos actinolite. A hundred single fibres have been measured using TEM images: their width ranges from 200 to 430 nm.

As regards the serpentine minerals, chrysotile shows the classical cylindrical fibres (Fig. 4), antigorite is characterized by lamellar and fibrous shape, lizardite exhibits only plate-like morphology. The width of chrysotile fibres ranges from 40 to 340 nm, with an average value of 80 nm. TEM investigations revealed that chrysotile, asbestiform and massive antigorite and lizardite were found in order of decreasing abundance. Low amounts of polygonal serpentine were also detected in some samples.

Finally, the DSC curve for meta-basalt samples showed the characteristic endothermic peaks of amphibole asbestos and serpentine minerals ranging from 900 to 1000 °C and from 600 to

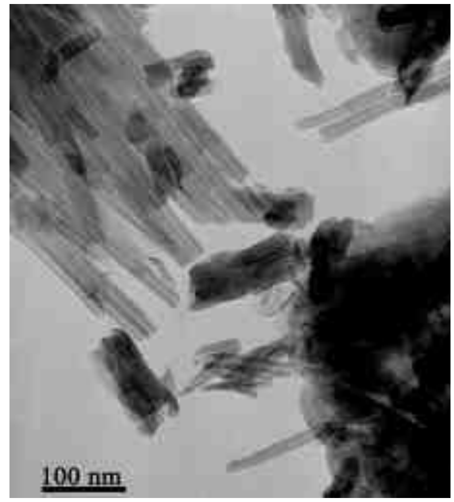

Fig. 4 – TEM image of chrysotile fibres.

750 °C, respectively.

These new knowledge, suitably deepened by further observations, can be used i) to identify eventually health hazard areas owing to amphibole fibres and other fibrous minerals presence, ii) to provide data for compulsory Italian mapping, iii) as markers of specific environmental conditions during amphibole asbestos and serpentine minerals formation.

Monitoring of heavy metal pollution in soils and waters of a Domitian coastline (Northern Campania)

M.M. CALANDRELLI (*) & R. CALANDRELLI (**)

Key words: *Environmental pollution, heavy metals, site of national interest.*

INTRODUZIONE

Soil is one of humanity's most precious assets. It allows plants, animals and man to live on the earth's surface (European Soil Charter, Council of Europe, 1972).

Soil is a limited resource whose functions are numerous, from simple physical support for the construction of human settlements and infrastructures, based on food and feed production, timber and other materials useful to man. It is warehouse and source of raw materials and has the function of maintaining regional planning, as a key factor for slope stability and the groundwater and surface waters circulation. The soil has also an important natural function as a habitat for a wide variety of plant and animal species as well as because the cycle of water and of other natural elements are completed in it. And, finally, it is an important element of the landscape that surrounds us and is part of our historical and cultural heritage (ARPAV).

These two definitions sum up in few words the immeasurable ecological and environmental value that the soil resource features. The processes of environmental pollution lead to the alteration of the chemical-physical and biological equilibrium of the soil and predispose it to erosion and landslides as well as allowing the input of harmful substances in the food chain.

In recent years considerable efforts have been made by the scientific community and Public Administration in order to understand the potential risks to humans and the ecosystem, caused by the presence of various contaminants. The presence of

Fig. 1 – Aerial view of the study area: Artificial lakes formed in old disused sand quarries are visible.

(*) Institute of Agro-environmental and Forest Biology, CNR, Naples
(**)Institute for International Legal Studies,, CNR, Naples

these substances is generally associated with various human activities such as waste incineration, chemicals manufacturing, metallurgical and energy production, vehicular burning, etc. (SCAZZOLA R. *et alii*., 2000).

The soil pollution by heavy metals is much more severe than that of air and water as pedosphere remains impaired for much longer, although the sources of contamination are removed. For the strict definition of pollution by heavy metals, it is essential to identify and quantify the forms under which they are present in pedosphere.

The present paper describes the investigation activities on the ground areas of a territory falling within the SNI Domitian Phlegrean and Agro Aversano Coast. The objective of this study is to provide an assessment of the environmental status of the study area through the implementation of a plan for monitoring the state of soils with special regard to the presence of heavy metals in land and water areas. It summarizes the general characteristics of the study area and the history of the human activities undertaken over time that may have caused a hazard to the environmental matrices.

The study focused on a portion of territory of about 30 acres occupied by two artificial lakes resulting from the reuse of disused quarries and areas adjacent to them where activities related to livestock farming and agricultural production are carried out.

In order to ascertain whether such an use of the land has resulted in a significant change in the natural levels of heavy metals in soil, a study was necessary to assess the need of adopting measures for emergency securing (D.M. 471/99).

The results of sampling and analysis activities are shown with the evaluation of non-compliance with law requirements (acceptable limit values of concentration in the soil, subsoil and groundwaters).

Aiming at supplying additional information on the environmental status of the study area, some pedological parameters were determined (granulometry, organic matter, pH) able to influence the processes of concentration of these contaminants in the soil.

The determination of the concentration of heavy metals (Sn, As, Be, Cr, Pb, Zn) and the definition of their distribution on the land, through the creation of thematic maps in a GIS environment, enabled to acquire information on the extent and provided evidence to assume the source and mode of contamination of soils.

A potential site suitable for CO_2 geological storage in the Po Plain (Italy)

D. CIVILE (*), M.F. LORETO (**), F. DONDA (*), V. VOLPI (*), E. FORLIN (*), M. ZECCHIN (*), B. MERSON (*), B. BOIARDI (°) & R. FANTONI (°)

Key words: *CO_2 geological storage, Po Plain, Anticline. trapping mechanisms*.

The Carbon Capture and Storage (CCS) technology has the potential to enable large reductions in global greenhouse gas emission by capturing the anthropogenic CO_2 from various sources, such as coal-fired power plants or manufacturing industries, and by injecting the CO_2 into deep geological formations like saline aquifers, depleted oil and gas fields and coal beds.

OGS analyzed the late Messinian to Quaternary siliciclastic foredeep succession of a portion of the Po Plain in order to identify and characterize a potential site suitable for the geological storage, in deep saline aquifers, of the CO_2 produced by a large industrial plant. This work, based on 21 composite logs and over 4500 km of 2D seismic lines, is the first detailed study carried out in this area. The analysis of data has allowed to identify an anticline located just beneath the plant that would represent an "ideal case" for the CO_2 geological storage.

The anticline developed for about 24 km and has a maximum width of 13 km for an areal extent of roughly 253 km^2. This structure is slightly asymmetric, with a NE-vergence and a sub-vertical NNW-SSE trending axial plane. Two reservoir-caprock systems have been detected:

- a deep system composed of a late Messinian sandy turbidite succession, having a thickness ranging between 350 m and 500 m and a porosity of 21-24%, sealed by lower Pliocene clayey deposits, about 150 m thick.
- a shallower system composed of a thick Pliocene turbidite succession characterized by a 260-400 m thick sandy lower part with a porosity of 27-30%, and a 200-300 m thick upper part containing several decametre-scale pelitic layers.

The anticline is not affected by faults that may represent potential ways for CO2 escape, and is located in an area characterized by very low seismicity, low heat flow (2,5°C/100 m) and hydrostatic pressure gradient in the analyzed succession. All these conditions are essential for the assessment of the suitability of a site in terms of the application of the CCS techniques.

A 3D geological model of the anticline has been made, allowing to obtain a volumetric model that has enabled to produce isopach maps of the two reservoirs and caprocks and to assess the anticline potential storage capacity (C). The storage capacity was calculated following the "volumetric method" proposed by the U.S. Department of Energy (2008):

$C= V*D_{CO2}*\phi*Cs$

V= volume calculated by the volumetric model considering only the porous and permeable portion of the reservoirs located above the spill points;

D = CO_2 density at the reservoirs depth and under standard temperature and pressure conditions at the surface;

ϕ = porosity of the reservoir;

Cs = coefficient of storage efficiency used for studies at site scale (0,2 and 0,4).

The total volume potentially available for the CO_2 storage in the whole anticline is about 163 km^3, i.e. 65,6 km^3 for the shallower reservoir and 97,3 km^3 for the deeper reservoir. The total available volume is strongly reduced down to 4,43 km3 (2,7 % of the total volume) considering the spill point position. Taking into account the last values of the reservoirs volume, the estimated storage capacity ranges from a minimum of about 162 Mt, considering the most cautionary storage efficiency of 0,2, to a maximum of about 324 Mt, using a storage efficiency of 0,4 (the highest value used for assessments to site scale). Considering that the current rate of CO_2 emissions from the industrial plant is approximately 2,16 Mt/year, the CO2 produced by this plant may be stored for about 75 years in the first case and for about 150 years in the more optimistic hypothesis.

These assessments consider only the structural trapping above the spill point, whereas others trapping mechanisms such as residual trapping, solubility trapping and mineral trapping have been not taken into account. Studies carried out by StatoilHydro for the Sleipner project in Norway (HERMANRUD *et alii*, 2009) have demonstrated that approximately 60% of the injected CO_2 in saline aquifers, consisting of sand-clay alternations similar to those found in the studied anticline, is trapped below the structural spill point during the CO_2 plume migration. This is due to hydrodynamic trapping (i.e. due to the combination of CO_2 solubility trapping in the brine, residual trapping and local stratigraphic and structural trapping) and mineral trapping. These considerations would support the

(°) eni e&p, Via Emilia 1 20097 San Donato Milanese (MI).

hypothesis that the total storage capacity of the selected site may be considerably higher.

In conclusion, the identified anticline represents an almost ideal case among the previously documented potential CO_2 storage sites. In fact, the structure is located in an area characterized by very low seismicity, low heat flow and hydrostatic pressure gradient, and it is not affected by detectable faults. The anticline hosts two potential reservoir-caprock systems, having considerable thickness and suitable petrophysical characteristics suitable for CO_2 injection and storage. The only critical but not negligible aspect is the considerable depth of the two reservoirs (over 2000 m), which could complicate the injection operations.

A very positive peculiar aspect concerns the position of the source of CO_2 considered in this study that is located in correspondence of the axial zone of the anticline, providing the following advantages: 1) possibility to realize the CO_2 injection system within the plant without additional costs for the creation of pipeline installation; 2) no CO_2 will be produced in relation with its injection; 3) reduction of the possible discomforts/impacts caused to the population and to the surrounding environment; 4) an authorization process probably easier and faster. Finally, the preliminary assessment for the storage capacity has shown that, in the most precautionary hypothesis, the selected site would be able to store the CO_2 produced by the industial plant for at least 75 years and considering only a structural trapping. Taking into account the CO_2 stored by other trapping mechanism below and above the spill point during CO_2 plume migration would allow to store higher amounts of CO_2, that could be better defined by further fluido-dynamic modelling.

ZeoLIFE, a project for water pollution reduction and water saving using a natural zeolitite cycle

M. COLTORTI (*), D. DI GIUSEPPE (*), B. FACCINI (*), E. PASSAGLIA (°), D. MALFERRARI (°), M. MASTROCICCO (*) & N. COLOMBANI (*)

Key words: *zeolitites, nitrate pollution, water saving*.

ZeoLIFE project has been conceived to test an innovative integrated zeolitite cycle aimed at reducing the NH_4^+ content in livestock effluents and correct agricultural soils, with improvement of the yield and economization of water for irrigation and fertilizers, leading to a reduction of surface water and groundwater pollution and excessive exploitation of the water resource.

Natural zeolitites are rocks containing more than 50% of zeolites, a kind of minerals with peculiar physical and chemical properties, like high and selective cation exchange capacity (CEC), molecular adsorption and reversible dehydration. Zeolitites are capable to uptake NH_4^+ from solutions and to release it gradually to the roots of the plants.

The project proposes an open-field experimentation of an integrated zeolitite cycle, for 2 year of cultivation. It foresees the construction of a prototype tank for swine manure treatment, where an appropriate quantity of natural K-zeolitite (Italian chabasite zeolitite) will be added and mechanically mixed. The zeolitite will then be left still to reach cationic equilibrium with the manure: in a time span of 12-18 hours it will subtract by selective cationic exchange a considerable amount of NH_4^+ from the liquid. The NH_4^+-charged zeolitite will then be removed and added to parcels of land, where it will release the nutrients only through cationic exchange induced by humic acids of plant roots and in proportion of the real needs of the cultures.

A surface of about 6 ha will be divided into various parcels. Control parcels will be cultivated and irrigated in traditional way; other parcels will be added with natural zeolitites and one will be mixed with NH_4^+-charged zeolites from the prototype tank. In the parcels amended with zeolitites both fertilization and irrigation water will be reduced by 30 and 50% respectively. A reduction of nitrate content in groundwater and surface waters is expected without any decrease of the yield.

Prototype working parameters need to be estimated in order to optimize the production of NH_4^+-charged zeolitites to be put in the experimental fields. In bench scale reactors a series of experiments were performed to test the exchange capacity of natural zeolites in contact with the manure solution. Each experiment was performed in triplicate, each time varying one single parameter (mixing time, zeolitite/manure ratio, resting time*)*. Over the whole duration of the experiment, samples of manure were taken from each of the reactor vessels at increasing time intervals, each sample were analyzed for NH_4^+ by ISE electrochemical sensor, for the quantification of the ammonium exchanged on chabasite. Results show that a zeolitite/manure ratio of 25 gr/l, a mixing time of 45 minutes and a resting time of 12 hours allow the zeolitite to take the maximum amount of ammonium from the solution, up to 30 mg/g.

After zeolitite addition each parcel will be monitored by periodic groundwater and surface water sampling and by a series of permanent devices, installed before the beginning of experimentation. The permanent monitoring stations include: a piezometer for groundwater sampling, multiple lysimeters for interstitial water sampling, a datalogger for physical-chemical parameter monitoring and interstitial water quantification, and an evaporimeter. An automated meteorological station has been also installed in order to quantify rainfalls and sun irradiation for water balance.

Hydrogeochemical investigation and relationship between mineralogy and groundwater composition. A case study from the Sila Massif (Calabria, Italy)

TERESA CRITELLI (*), CARMINE APOLLARO (*), ANDREA BLOISE (*), DOMENICO MIRIELLO (*), VINCENZA ARMANO & ROSANNA DE ROSA (*)

Key words: *Gneisses, groundwaters, hydrogeochemical, Sila Massif.*

INTRODUCTION

The study focus on the geochemical characterization of a gneissic-metamorphic aquifer in the Sila Massif.

The Sila Massif is a sector of the Calabrian Arc, or Calabrian Orogenic Wedge, a nappe-structured belt formed during the Alpine orogeny, preserving the oldest evidence of the ongoing subduction process of the Ionian oceanic slab, which lead (and still leads) to the consequent opening of the Tyrrhenian back-arc basin (FACCENNA *et alii*, 2004).

In order to investigate the interaction between the gneisses cropping out in the study area and the local groundwaters, seventeen samples, were collected from both springs and well in Fig. 1).

In the field, temperature, pH, Eh, alkalinity and electrical conductivity were determined by means of portable instruments. Groundwater samples were filtered in situ through a 0.4μm pore-size polycarbonate membrane filter although this method has some limitations because colloidal particles may pass through the filters (e.g., KENNEDY AND ZELLWEGER, 1974; LAXEN AND CHANDLER, 1982). In the laboratory, major dissolved anions and cations (Na^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, SO_4^{2-}, F^-, NO_3^-) were determined by HPLC (Dionex DX 120), whereas Si and several trace elements were analysed by a quadrupole ICP-MS (Perkin Elmer/ SCIEX). Data quality for major components was evaluated by charge balance. Precision and accuracy for minor and trace elements was checked by measuring the certified reference material NIST-1643E.

The mineralogy of the gneissic rocks, which has been examined using optical microscopy, X-ray diffraction and scanning electron microscopy (SEM) consists of quartz, plagioclase, garnet, biotite and sillimanite. Accessories include

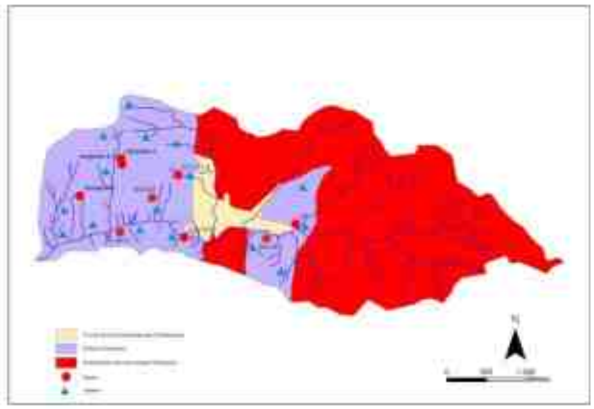

Fig. 1 – Geological sketch map of the study area. The location of samples of water and rocks is also shown.

opaque, muscovite and cordierite (Fig. 2). All these data are in agreement with the results of a previous study by BERTOLANI AND FOGGIA (1975).

The compositional features of water samples was characterized in terms of relative Cl, SO_4 and HCO_3 concentrations (Fig. 3a) and relative Na+K, Ca and Mg contents (Fig. 3b), all in equivalent units. In the triangular plot involving the three major anion (Fig. 3a) all the samples are

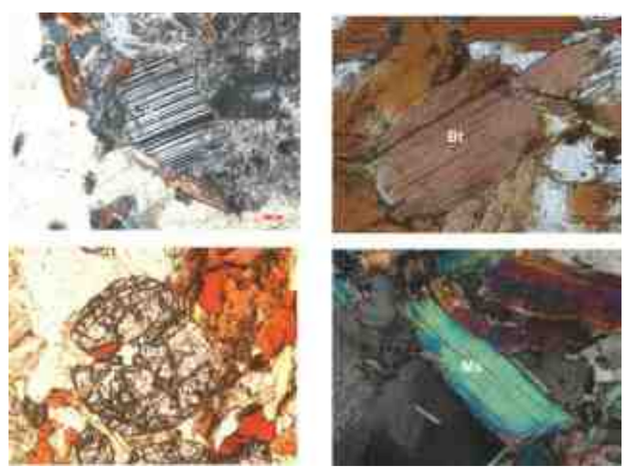

Fig. 2 – Optical microscopy observations of thin sections(Pl=plagioclase; Bt=biotite, Grt=garnet; Ms=muscovite).

(*) Department of Earth Sciences, University of Calabria
Via Ponte Pietro Bucci, 87036 - Arcavacata di Rende (CS), Italy
The P.h.D. of Teresa is co-financed by the Commissione Europea (FSE) and Regione Calabria (POR Calabria FSE 2007-2013).

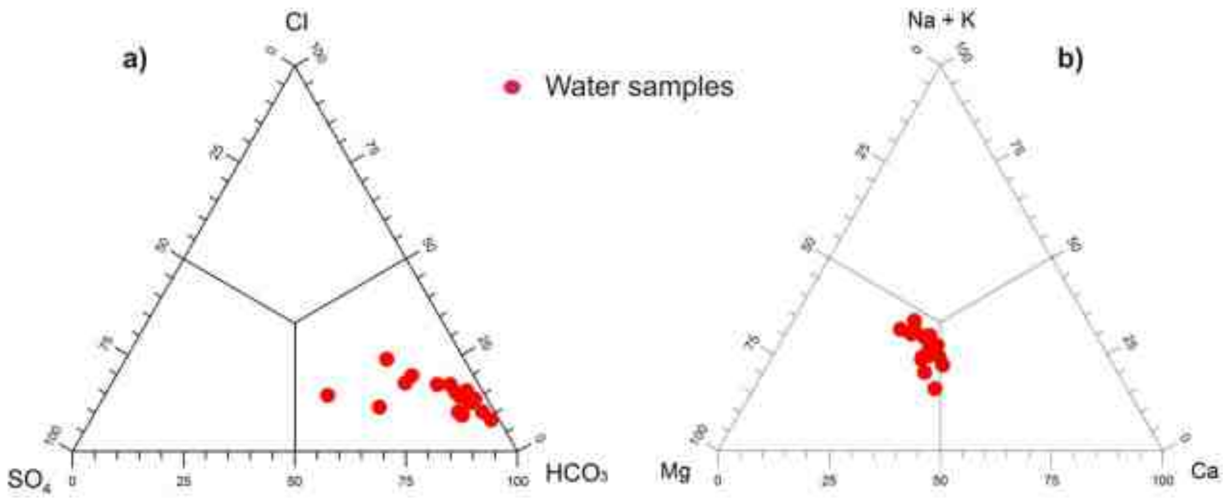

Fig. 3 – Triangular plot involving (a) HCO_3^-, SO_4^{2-}, and Cl^-, and (b) Ca^{2+}, Mg^{2+}, and Na^++K^+, both prepared from concentrations in equivalent units.

situated in the HCO_3^- field, indicating that the chemistry of local shallow groundwaters is chiefly dominated by conversion of CO_2 to the HCO_3^- ion through water-rock interaction (GARRELS, 1968).

In the triangular diagram involving the four major cations (Fig. 3b), most groundwaters are situated in the Mg^{2+}-Ca^{2+} field, indicating that the Mg-Ca-HCO_3 chemical composition of these springs is controlled by the dissolution of Mg-Ca-rich phases present in gneisses.

According to this preliminary data, it was possible to conclude that the release of major dissolved constituents and several trace elements to shallow groundwaters is probably controlled by weathering of minerals rich in Mg and Ca such as plagioclase and biotite.

The quality of groundwaters was investigated through the analyses of PHES (potentially harmful elements and species) such as Cr, Cd, Ni, U, As whose concentration are below the limits established by the guidelines of the World Health Organization for drinking water (W.H.O., 1993), so they do not pose a human health risk.

In order to reconstruct a reaction path modeling, other investigations are still in progress.

Contribution to the knowledge of hydrogeological characteristics of plain S. Eufemia Lamezia (Calabria) - first results

ENZO CUIULI (*)

Key words: *acquifer*, *Drenage areas*, *ground water*, *groundwater divide*, *piezometric map*, *recharge areas*

This study aims to the knowledge of the hydrogeological characteristics of the Plain of San Eufemia Lamezia, focusing on 'superficial aquifer more susceptible to anthropogenic impacts, the depletion of water resources, and exploitation of that begun by the late twenties when the area, once marshland, was reclaimed making fitted for human's settlement, development and farming. This study is based on the reconstruction and the subsequent comparison of piezometric maps of different years (1974, 1985, 1999, 2011) which embrace the time interval of the last forty years. The purpose is to provide a contribution to a better understanding of the superficial acquifer of the plane through the identification of the essential elements of last one, the schema definition of groundwater flow, an estimate of the depletion of groundwater. In general, the study area is part of the wider plain of S. Eufemia Lamezia, which is located in correspondence of the gulf, alongside the Tyrrhenian coast of central Calabria. In particular the studied area, of about 150 kmq, is enclosed, roughly, in a polygon whose vertices are the Capo Suvero (north) and Torre Mezza Praia (south) alongside the coast, the 'town of Lamezia Terme (North) and village Curinga (south) in the interior. At regional scale, the plain falls within the Tyrrhenian area of " Catanzaro's Graben" which crosses the central Calabria from east to west, cutting the mountains of Sila by Serre. This "Graben" is a tectonic structure of regional significance in the regional geological context of the Calabrian Arc (Amodio Morelli et al., 1976). The Graben is filled by Plio-Quaternary deposits, and was created by sub-vertical faults with a prevailing direction WNW - ESE with a component left lateral strike-slipe (Gulla et al., 2005). The rock types represented in the Structural-lithological map have been mainly determined on the basis from the Geological Map of Calabria (ex CASMEZ, 1967) and merged to derive the lithological types as homogeneous as possible. From lithological map was then derived the permeability map. To determine the structure of the superficial acquifer of S. Eufemia Lamezia plain, his relationships with surface water, and the changes experienced over time by the water resource have been reconstructed and compared piezometric maps of different years (1974, 1985, 1998, 2011).

For the preparation of piezometric map, relating to 1974, was used "l' Atlante delle carte isopiezometriche – Pr. Speciale 26" (CASMEZ 1977) showing, the piezometric line detected on 9/1974. For the preparation of piezometric map, relating to 1985, was conducted a deep literature research of previous studies (including unpublished) carried out in various ways by drilling companies, professionals, institutions.

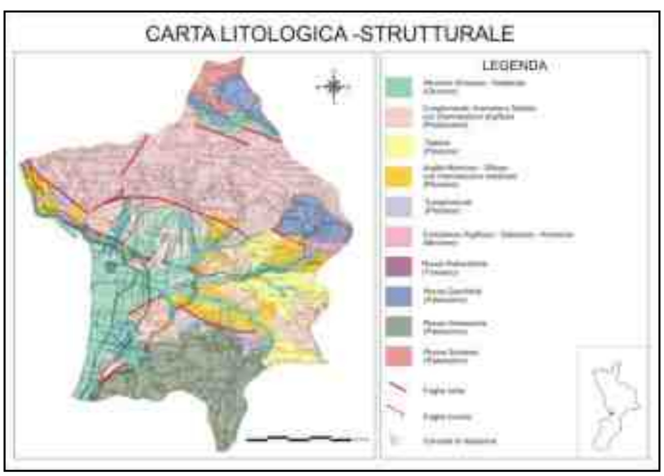

Fig. 1 – Structural – lithological map - plane of S.E.Lamezia.
[litholocical base(CASMEZ, 1967), rid. e mod. Stuctural base (SORRISO – VALVO & TANSI, 1986) rid. e mod..]

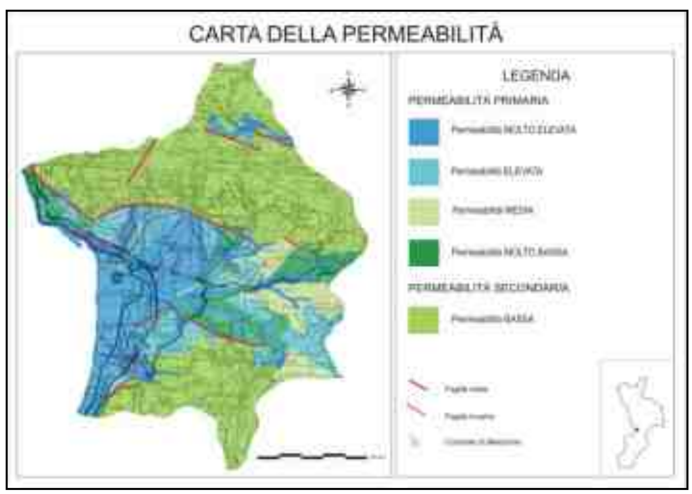

Fig. 2 – Permeability map - plane of S.E. Lamezia

(*) Geologo –; e.cuiuli@arpacal.it; cuiuli@libero.it

Fig. 3 – Piezometric map 1974 [Pr. Sp. 26 (CASMEZ 1977) rid e mod.].

For the preparation of piezometric map, relating to 1998, it was used the study of Sappa & Bianchini (1999). For the preparation of piezometric map, relating to 2011, during the summer months, was recorded and noted the static level of groundwater in many wells of the plain in order to reconstruct the piezometric present.

Fig. 5 - Piezometric map 1998 [piezometric map of Sappa & Bianchini (1999), rid. e mod.].

According to the study of the piezometric maps reconstructed, it outlines a pattern of groundwater flow, aquifer surface of the Plains of S. Eufemia, characterized by: **A**) Recharge Zone" of the aquifer located in the internal areas of the plain, near the foothills. These areas are distinguished by a high density of piezometric lines that present concave upward. The trend of the piezometric morphology suggests that in these areas there is a high hydraulic gradient, low transmissivity and low permeability. The flow lines are divergent and tend to flow towards the main axes of preferential drainage recognizable on map.

Fig. 4 – Piezometric map 1985 [data base:previous study carrier out by drilling companies, professionals ecc.].

Fig. 6 - Piezometric map 2011.

B) "Drainage areas" of the aquifer, represented by those areas, located downstream of the "recharge zone", and placed in the middle belt and the coastal plain. The “zones of recharge" are easily recognizable, on map, as characterized by a low density of isofreatic lines presenting concavity downwards and flow direction which tend to converge towards the axes of preferential drainage placed at the center of the isofreatic lines. This trend of piezometric morphology suggests that in these areas there is a low hydraulic gradient, high transmissivity and high permeability. **C**) "Groundwater divide" and "preferential drainage axes", as easily recognizable on the map, have been reconstructed basing on the interpretation of the isopiezometric morphology. The first being no flow horizons, influence the groundwater flow, the second representing the preferential flow paths of groundwater flow. On the basis of all these elements, identified through the reconstruction and interpretation of the isopiezometric surface, there has been a rapid assessment of the degree of depletion of the aquifer, in the time interval analyzed (1974 - 2011).Were draw, along the lines of maximum slope, three profiles of the piezometric surface with different color for each reference year.

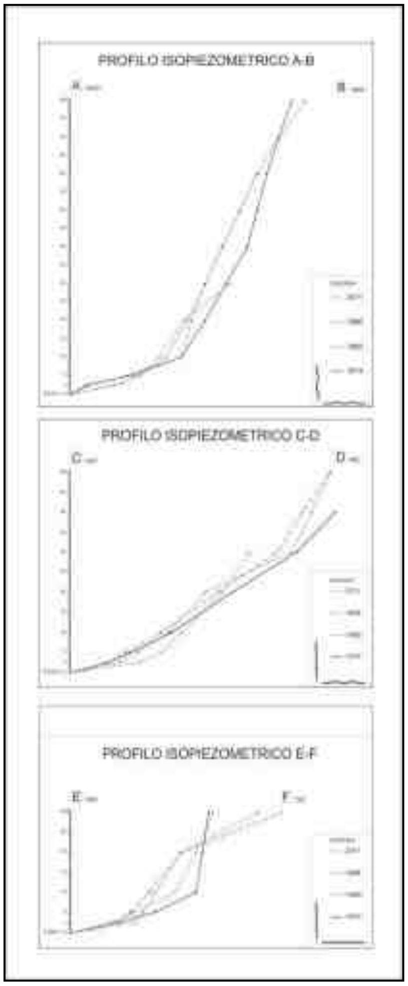

Fig.7- Piezometric profiles.

From these elaborate it's shows that between 1974 and 2011, compared with an increase of water resources, clear in the case of upstream (corresponding to the internal areas - areas of recharge), there was a progressive decrease of water resources in stretches of valley profiles (corresponding to the outer areas / coastal - areas of drainage). The decrease of water resources is most evident in the south of the plain (profile [EF]) subject to the removal of more water. In this sector, of the study area, there is the industrial complex of Lamezia Terme-S. Pietro Lametino and areas of the plane, committed to farming (agricultural / zootechnics). The presence of these activities, together with the presence alongside the coast, tourist facilities and private houses, often also equipped with wells, likely this reduction of water resources in the coastal area against an increase in the quantity of water in internal recharging areas. The increase of the water resource in the recharging area is instead probably to search in a variation of the rainfall area. In conclusion, therefore, the present study, aims to contribute a deeper understanding of superficial acquifer. All the described elements, taken together or individually, find many applications in the study of the dynamics of depletion and pollution groundwater. The superficial aquifer of the plain, subject to human pressure and the related impacts, resulting susceptible to degradation qualitative and quantitative of water resources both in terms of depletion and in terms of pollution loads that potentially insist on the aquifer originating from the presence of settlements (point and diffuse), farming activities, industrial activities that insist in a large part of the study area.

Environmental geochemistry of Peat-rich sediments in the Po river Delta area (Mezzano lowland, Ferrara)

DARIO DI GIUSEPPE (*), GIANLUCA BIANCHINI (*,**) CLAUDIO NATALI (*,**), LUIGI BECCALUVA (*)

Key words: *geochemistry, Po river.*

This study is focused on the easternmost part of the Po river alluvial Plain in northern Italy, i.e. a sedimentary basin bordered by the Alps and the Apennines, which hosts about 30–40% of the Italian population and most of the Nation's agricultural activities. In particular we investigated a specific sector of the Province of Ferrara known as "Valle del Mezzano" (45° 50' 33'' N and 12°05'40'' E) hereafter reported as Mezzano low-land (MLL) that is included in the Regional natural park of the River Po Delta.

The outcropping sedimentary facies (and the related soils) reflect climatic changes and human impacts that profoundly modified the configuration of the local drainage system, which is represented by the evolving Po river (AMOROSi *et alii.* 2002; BIANCHINI *et alii* 2002; STEFANI and VINCENZI 2005; SIMEONI and CORBAU 2009). In the easternmost terminal part of the basin the delta environment developed high lateral mobility of the active channel belts, permitting in historical times the development of fens and swamps characterised by peat deposition. When the high-energy alluvial deposition outranged the organic deposition, the peat levels were buried and incorporated into the stratigraphic record (MIOLA *et alii* 2006).

Therefore it has to be noted that the MLL outcropping soils are significantly different from those recorded in the surrounding part of the plain (AMOROSI *et alii* 2002; BIANCHINI *et alii* 2002), as they evolve from saline sedimentary deposits peculiarly rich in peat material. This site specificity is also related to the geomorphological history of the area deeply influenced by anthropogenic activities: MLL was a marsh wetland since fifty years ago (see the 1944 geographic map of the area) and has been drained and reclamated in several stages mainly during the years fifties and sixties. Nowadays MLL is mainly 3-4 m below sea level and drained by hydraulic pumping and a system of artificial channels.

The geochemical characterization of these deposits is very important taking into consideration that the local backgrounds of elements potentially toxic exceed those recorded in other sectors of the Padanian plain (AMOROSI *et alii*, 2002; BIANCHINI *et alii*, 2002). This is possibly related to a remarkable role of the organic fraction in the metal complexation.

The aim of this study is to evaluate possible geochemical risks of former wetland converted in agricultural areas, taking into consideration the nitrate pollution problem, as well as the potential bioaccumulation processes of heavy metals.

The analyses reported in this contribution include a) nutrient evaluation (TOC, and nitrogen measured as extracted nitrates); b) XRF data carried out on bulk soils; c) tests of metal extraction with both aqua regia and EDTA that highlight the distinct elemental mobility; d) tests of bioavailability realized analyzing lattuce (lactuca sativa acephala) grown on the studied soils.

This approach is useful provide guidelines for agricultural activities (i.e. mode and style of soil amendment and fertilization) and to evaluate possible geochemical risks, i.e. contamination of the local agricultural products by harmful elements in the food chain.

Heavy metals in soils and sedimentary deposits from Vigarano Mainarda (Ferrara, Northern Italy): characterisation and biomonitoring

DARIO DI GIUSEPPE (*), GIANLUCA BIANCHINI (*,**), CLAUDIO NATALI (*,**), LUIGI BECCALUVA (*)

Key words: *alluvial sediments, biomonitoring, extration test, heavy metals, Padanian Plain*.

This contribution investigates agricultural soils from Vigarano Mainarda in the province of Ferrara (Padanian alluvial Plain, Northern Italy), in order to provide insights into their genesis, to define the geochemical background of the area and to evaluate the existence of anthropogenic contamination. Moreover, environmental risk related to the presence of potentially toxic heavy metals that can be transferred into agricultural products (and consequently bio-accumulated in the food chain) is assessed.

The analyses, reported in an extensive supplementary dataset, include XRD, XRF, and ICP-MS data carried out on bulk sediments, tests of metal extraction with aqua regia, as well as analyses of local agricultural products, i.e. biomonitoring which is important in the evaluation of the element mobility.

Based on the results, GIS-based geochemical maps were produced and local backgrounds were defined. This approach demonstrated that a high concentration of Cr, Ni (Co, V) is a natural (geogenic) feature of the local alluvial terrains, which in turn is related to the origin and provenance of the sediments, as confirmed by the lack of top enrichment in all the investigated sites. Tests of metal extraction and analyses of agricultural products provide guidelines for agricultural activities, suggesting that extensive use of sewage sludge, industrial slurry and zootechnical manure (that are often rich in metals) should be minimised.

The extended dataset reported in this paper shows that the agricultural terrains of the studied alluvial plain are not characterised by anthropogenic heavy metal pollution. In spite of the elevated natural background of Cr and Ni, most of the local agricultural products do not show significant evidence of bio-magnification. Exceptions are represented by forage grass (alfa alfa) and corn (maize) that tend to uptake arsenic and nickel, respectively. This demonstrates that in agricultural areas, a geochemical risk assessment must include both soil and plant investigations.

Ammonium and nitrate zonation below marsh agricultural soils

DARIO DI GIUSEPPE (*), MICOL MASTROCICCO (*) , NICOLÒ COLOMBANI (*), BARBARA FACCINI (*), MASSIMO COLTORTI (*)

Key words: *groundwater qualy, inorganic nitrogen, marshes, permeabity, sediment heterogeneity*.

The inorganic nitrogen leaching from agriculture can have a severe and long-lasting effect on groundwater quality and it can also affect surface water quality since the contaminated groundwater can be discharged into drains in reclaimed lowland territories, like in the Po river delta. These lands lye below the actual sea level, thus they are continuously drained by pumping stations which collect the water from a capillary distributed network of channels and ditches. A complicating factor in understanding and quantify the effective leaching of nitrogen from agricultural fertilizers is the background ammonium presence in the sub-soils, due to peat layers, which provide a natural source of organic nitrogen slowly mineralized into ammonium. This implies that the geochemical inventory of ammonium-bearing sediments in peaty soils and sediments has an important control for the future development of groundwater quality in these areas. To estimate the mass of inorganic nitrogen present within the unsaturated zone below agricultural fields, a 6 ha wide site was characterized with high resolution core depth profiles. Cores were analyzed for inorganic nitrogen content (nitrate, nitrite and ammonium) and for bromide, used as nonreactive tracer. The soils and sediments within the site are highly heterogeneous, since many sedimentological environments overlapped during the last few centuries, creating vertical and lateral facies heteropies. These facies heteropies were reconstructed in a GIS environment via grain size analysis, soil organic matter content and detailed stratigraphic logs. The vertical distribution of inorganic nitrogen species is nitrate prevalent in the first meter of soil, where oxic condition prevailed (also induced by tillage and drains); ammonium is the major nitrogen species from 1 to 4 m below ground level. Where buried sandy sediments (paleochannels) are present beneath 1 m below ground level, nitrate can penetrate slightly deeper in the unsaturated zone. Nitrite is detected only in the oxic portion of the unsaturated zone, suggesting that denitrification takes place. Elevated ammonium, chloride and bromide contents are directly related with non-drained peaty sediments (lying below drains elevation), confirming their natural origin. Sharp vertical gradients were found between nitrate and ammonium/bromide, confirming that the recharge only affects the first meter of soil. The ammonium nitrogen inventory in the studied area is more than double with respect to nitrate nitrogen, and even two orders of magnitude higher than nitrite nitrogen. The impact of data quality and resolution on the derived inventory was investigated by varying the size of the considered subset of geological and geochemical data. We found that geological data resolution is less significant with respect to geochemical data. The large presence of ammonium-bearing sediments in these lowland territories makes very challenging to assess nitrogen pollution from agricultural activities, such as fertilizer spreading, but this natural source should be taken into account when groundwater monitoring campaigns are performed.

SINTACS method application for assessing the inherent vulnerability of the Venafro alluvial plain aquifer

ALBERTO DI LUDOVICO (*), CUCULO FEDELE (**), MARIA VITTORIA MAIORANO (*), MARIA PINA IZZO (**), ANNUNZIATA DI NIRO (**), PASQUALE COCCARO (***) & ALFONSO SCOCCA (*)

Key words: *Venafro alluvial plain, SINTACS method, aquifer vulnerability.*

ABSTRACT

As part of the monitoring and study of groundwater bodies, the assessment of the degree of aquifers intrinsic vulnerability plays a crucial role, since it represents a fundamental moment in the planning of the proper management of land and groundwater resources.

This study wants to propose the application of an analytical methodology in order to define the degree of vulnerability of Venafro alluvial plain aquifer, which plays a strategic role for the whole Molise Region, considering its geological and hydrogeological features and the importance of the socio-economic agricultural activity that takes place therein.

Among the various criteria developed in the field of vulnerability assessment of groundwater bodies, the choice fell on SINTACS method, applied with the procedure referred to in the GIS mapping overlays in order to allow modeling of the territory with the criterion of "finite element".

The SINTACS methodology, primarily developed since the 90s, has been applied to the Italian territory, obtaining a considerable success from the technical-scientific viewpoint: several research institutions tested it in experiments, finding a good correspondence with the Italian climatic and hydromorfologic dynamics. These results, together with the acquired knowledge about the reasons that determine the groundwater flow and the aquifer potential, allowed to draw a sufficiently comprehensive outline of the main critical factors of the territory, which is essential in the planning of protective actions and mitigation of water resources.

SINTACS METHOD

The pollution of groundwater, and therefore the degradation of their quality, depends not only on sources or centres of danger related to industrial, urban, agricultural, and other activities. It is also related to the inherent vulnerability of the aquifer, that is the attitude of the aquifer to ingest and disseminate a pollutant.

It depends on various factors, such as the depth of the aquifer, the presence or absence of soils which cause the self-purification, the connections between the water table and those streams that can act as receptors of polluting substances of the surface or can favour their intrusion in the groundwater.

In this work we examined the Venafro plain aquifer, of which an intrinsic vulnerability map was produced using the parametric method SINTACS.

The application of this method requires the discretization of the territory in a usually square grid. Within each unit cell forming the grid 7 parameters are considered, assigning each a score between 1 (minimum conditions for a vulnerability) and 10 (conditions of high vulnerability). Once it is defined for each cell the scores of the 7 parameters, a string of weights (a weight for each parameter), useful to give more or less importance to one or to another parameter, is applied to them depending on the hydrogeological context under consideration.

The authors of this method have identified in particular 5 types of strings corresponding to as many contexts (cracked areas, Karstic areas, etc. ..). Summing together the scores of weighted 7 parameters and multiplying them by a context factor, the vulnerability index is obtained for each cell.

The integration of the values thus obtained gives, for each grid, a numeric value that represents the inherent vulnerability of the related aquifer. These values, ranging from a minimum of 26 to a maximum of 260 points, are grouped into six classes of vulnerabilities, from "very low" to "very high".

GEOLOGICAL AND HYDROGEOLOGICAL SETTING

The Venafro Plain is placed in a south-central Apennines area which is particularly complex from the geological-structural point of view. Actually it is placed in a transition zone between the Abruzzese-Campana platform and Molise Basin, a slope environment in which lithologic limestone-marl-siliceous materials were sedimented , as well as debris in the area of the platform (from the Cretaceous to Paleogene).

The Venafro basin is a typical depression of tectonic origin, formed during the Apennine orogeny, which is directly caused by continental sedimentary series of lacustrine, fluvial and fluvial-

(*) ARPA Molise – Agenzia Regionale per la Protezione Ambientale

(**) Autorità di Bacino Interregionale dei Fiumi Trigno, Biferno e Minori, Fortore e Saccione.

(***)Autorità di Bacino dei Fiumi Liri-Garigliano e Volturno.

lacustrine-marsh nature made of Holocene-Pleistocene alluvial deposits. The latter are mainly represented by lenses and levels interdigitated with sandy gravel, silty sand, and secondarily with gravel-clay loam with sparse pyroclastic levels.

The Venafro flat elevation is between 150 m and 200 m above sea level and is made, in its central and southern portion, of a hydrological alluvial complex, while in its northern part is made of travertine; both parts are characterized by a medium-high degree of permeability. The area under study has a total extension of about 40 km^2 and is bounded to the east by Volturno river, which also forms the natural border with the Campania Region.

The water table of the Venafro floodplain aquifer (Figure 1) flows from NE to SW in the far north of Venafro, and from NW to SE in the southern part of the plain. The elevation of the water table is between 145 and 190 metres above the sea level. This water table, also considering the fundamental homogeneity of the land and the relevant permeability, shows figures of piezometric gradient that are characterized by a very reduced variability, equal to about 4.5 ‰.

DATA PROCESSING AND SINTACS INDEX CALCULATION

The entire study area was divided into Square Elementary Cells (EFQ) consisting of square grid with sides 25 meters long. Then, the appropriate score was attached to each EFQ and each

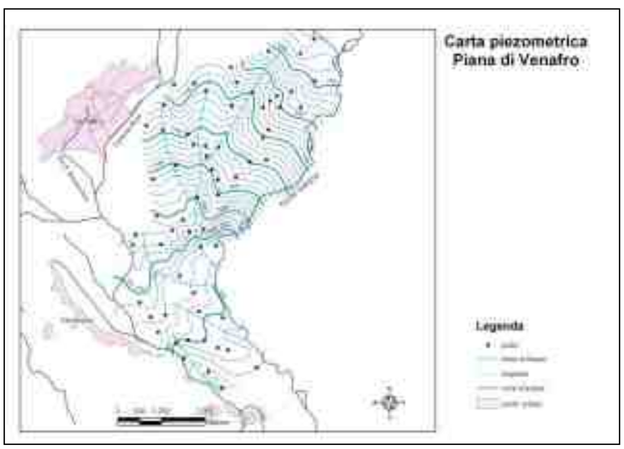

Fig. 1 – Piezometric pattern of Venefro plain.

parameter.

The parameters for the vulnerability calculation index have been recovered from the development and reorganization of a data series already available and adequately validated. The seven key parameters are the “depth of the groundwater”, “depth to the effective infiltration”, “the effect of self-purification of non-saturated”, “type of coverage”, “hydrogeological characteristics of the aquifer”, “the aquifer hydraulic conductivity”, “slope of the topographic surface”.

After generating the SINTACS data_GRID related to the seven parameters, using GIS Model_Builder it was possible to obtain the sum of the values and multiply each of them by a factor which is representative of the environmental characteristics of the area under study.

The SINTACS rating decreases according to a hyperbolic type decrease, proportionately to the increase of the depth, that is the increase of “not saturated” thickness; adopted values range between 10 and 1. In particular for the floodplains, the groundwater depth parameter, has an always high weight which is decisive in the final calculation of the SINTACS index.

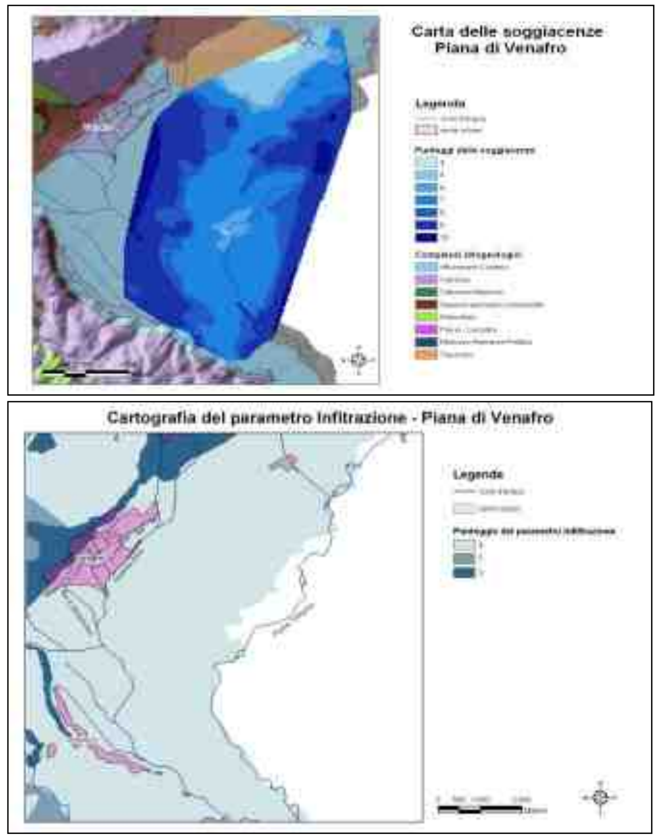

Fig. 2 – Example of GRID scores relative to the depth of the aquifer and the slope of the infiltration effective.

Low values of depth correspond to high scores that increase following the specific weight of the string, so determining a heavier impact on the vulnerability index. Similarly, an unsaturated capable of a strong mitigation action will give a low product even if the multiplier is high, while easily penetrable unsaturated will strongly increase the index of vulnerability.

The final outcoming GRID is the final map of the inherent vulnerability of the aquifer: in it each cells corresponds to a score depending on the degree of vulnerability to which the area identified by the single EFQ is exposed.

The numerical modeling carried out through the conceptual model SINTACS has allowed the drafting of the final report concerning the inherent vulnerability of the aquifer of the Plain of Venafro, expressed with a numerical index that allows a sufficiently objective evaluation.

It is thus clear that the plain of Venafro shows two degrees of vulnerability: "high" and "very high", respectively, related to areas located in its eastern and western sides, with two additional sub-zones showing a "very high" vulnerability in its NE and SW regions.

Once an intrinsic vulnerability map is obtained, it is possible to overlay on it the centers of danger that are present in the area,

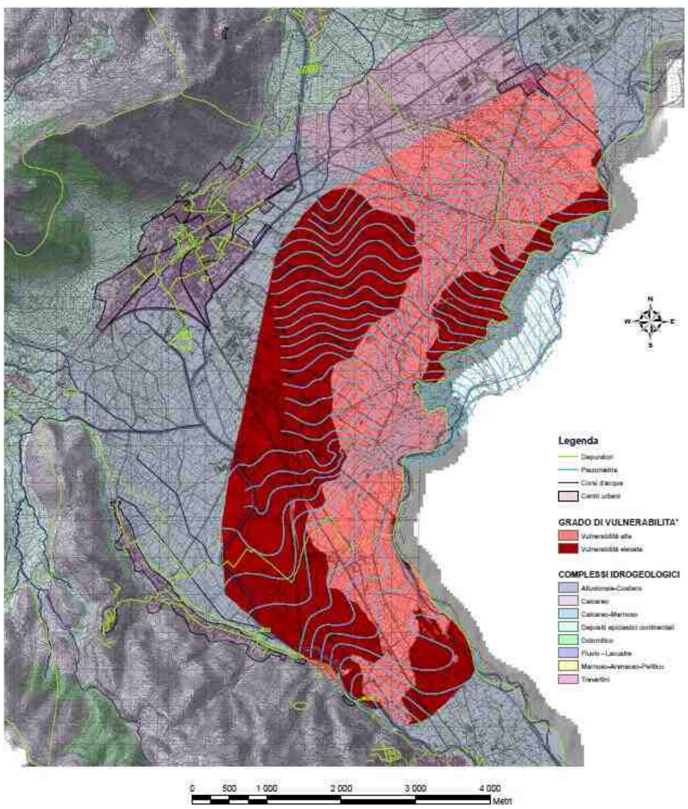

Fig. 3 – Venafro flood plain vulnerability map.

and so draw a map of the risk of pollution, that is the degree of probability that a polluting phenomenon affect the groundwater.

CONCLUSIONS

In the national environmental context the groundwater is a strategic resource both for the high quality and for the abundant availability. However, the vulnerability map provides useful information regarding possible actions for the monitoring, the prevention of pollution's episodes and the protection of groundwater, and offers also a first general assessment of the potential risk.

The main purposes of the numerical and cartographic calculations related to the intrinsic vulnerability of aquifers are to provide specific interventions for prevention and protection, which can be carried out through the existing legal system or the introduction of new constraints (General Development Plans, Plans Basin, Water Protection Plans, etc ...), and supply the planner with accurate information about the land uses and management.

The cartography of vulnerability aims, therefore, at reducing the risk of exposure of the targets like the environmental system oriented to future generations and to the directly exposed population, in connection with the monitoring of resources and the need to pursue the quality targets of the Water Bodies, as they have been established by the European and national legislation.

Relazioni tra la radioattività naturale e i lineamenti geologici nel territorio comunale di Caraffa (CZ)

FOLINO GALLO MICHELE (*), PROCOPIO SALVATORE (*)

Key words: *faglie, gas radon.*

INTRODUZIONE

Recenti studi condotti in alcune aree ad elevato potenziale sismogenetico della Calabria (Valle del Crati, Altopiano Silano ionico, Piana occidentale di Lamezia Terme), hanno dimostrato che le principali faglie attive sono caratterizzate da alti valori di concentrazione di gas radon nel suolo (TANSI *et alii*, 2005; FOLINO GALLO *et alii*, 2011).

Gli *stress* tettonici attivi in un'area possono provocare variazioni nel tempo di alcuni parametri fisici. Numerosi studi riportati in letteratura hanno suggerito che le misure della concentrazione di radon nell'acqua e nel suolo, possono essere un valido strumento per la comprensione dei fenomeni geodinamici (THOMAS, 1988; KING *et alii*, 1996). Le caratteristiche chimico-fisiche, tempo di dimezzamento e solubilità, consentono al radon di essere trasportato per notevoli distanze da liquidi trasportatori come l'anidride carbonica e l'acqua. Le faglie determinando un aumento considerevole degli indici di fratturazione delle rocce che attraversano, rappresentano una via di fuga preferenziale per i gas. Una mappa delle concentrazioni di radon nel suolo può fornire elementi utili a definire sia la geometria che il potenziale sismico delle faglie e il rischio ambientale derivante dalla maggiore probabilità di accumulo di radon negli ambienti confinati. L'approccio metodologico già sperimentato, è stato di recente riproposto per lo studio della radioattività naturale nel Comune di Caraffa. Il monitoraggio della radioattività naturale e del gas radon ha interessato l'intero territorio comunale attraverso la stima dei livelli di concentrazione di radon sia indoor che nel suolo. Il confronto tra gli elementi tettonici, i dati della sismicità e le misure di radon sembra confermare il *trend* regionale con buona correlazione tra l'andamento delle strutture tettoniche e la distribuzione delle concentrazioni più elevate di radon.

ASSETTO GEOLOGICO

Il radon, gas radioattivo che costituisce la frazione preponderante della radioattività ambientale, è naturalmente emanato dalle rocce che costituiscono la crosta terrestre. Esso deriva dal decadimento dell'Uranio-238, le cui tracce sono presenti in ogni tipo di suolo. Per tale motivo è fondamentale individuare le possibili vie di comunicazione tra il sottosuolo e la superficie (faglie e fratture). Infatti, il discreto tempo di dimezzamento (3,82 giorni) e la sua solubilità permettono al radon di essere trasportato per considerevoli distanze da gas o liquidi trasportatori, come l'anidride carbonica e l'acqua. Le faglie inducono un aumento considerevole degli indici di fratturazione delle rocce che attraversano, costituendo una via di fuga preferenziale per i gas (Fig.1).

Da un punto di vista geologico, l'Arco Calabro rappresenta un *thrust-belt* prodotto dalla sovrapposizione, attuatasi tra il Cretaceo sup. ed il Paleogene, di una serie di unità costituite da rocce cristallino-metamorfiche paleozoiche e coperture mesozoiche, derivanti dalla deformazione di domini continentali ed oceanici. Durante l'Oligocene-Miocene Inferiore, le suddette unità sono

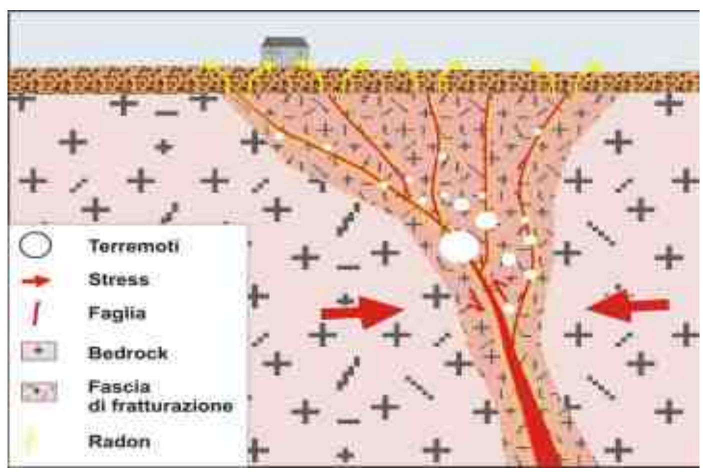

Fig. 1 – Schematizzazione della risalita del radon lungo faglie attive

sovrascorse "*in toto*" sulle unità di piattaforma appartenenti alla catena appenninica, lungo *overthrusts* che mostrano attualmente vergenza NE (AMODIO-MORELLI *et alii*, 1976; TORTORICI, 1982).

La Calabria Centrosettentrionale è attraversata da un sistema di *shear-zones* profonde (Fig. 2) che, dal Pliocene medio e fino a tempi recenti, ha disarticolato il complesso edificio a thrust che costituisce l'Arco Calabro con una tettonica di tipo prevalentemente trascorrente (VAN DIJK *et alii*, 2000; TANSI *et*

(*) ARPACal - Dipartimento Provinciale di Catanzaro.

alii, 2007; FERRANTI *et alii;* 2009, FOLINO GALLO M., 2011). In particolare, l'area di studio, corrispondente con il territorio comunale di Caraffa, si estende su un'area di circa 24,7 km² e ricade nel settore centrale del *graben* di Catanzaro.

Quest'ultimo rappresenta orograficamente una depressione morfologica allungata in direzione E-W, delimitata a Nord dal Massiccio della Sila e a Sud da quello delle Serre (Fig. 2).

Il *graben* di Catanzaro è strutturato da importanti faglie che mostrano piani sub-verticali caratterizzati da cinematismi prevalentemente normali con una componente di trascorrenza che talora può diventare predominante. In particolare, l'area di studio

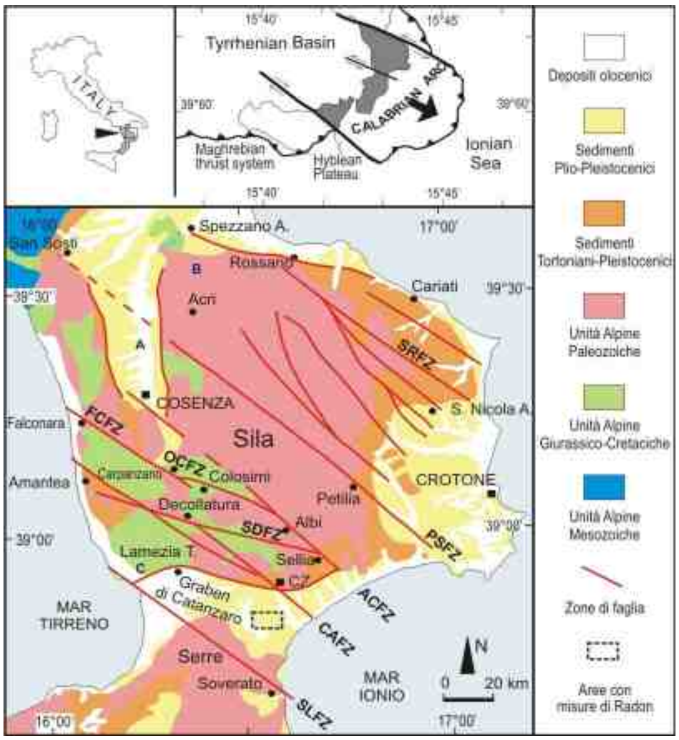

Fig.2 – Mappa schematica con i principali lineamenti tettonici della Calabria settentrionale (VAN DIJK *et alii*; 2000, modificata).

è caratterizzata da un elevato rischio sismico ricadendo nell'area macrosismica del terremoto del 28 marzo 1783 - intensità alla sorgente pari a XI MCS, magnitudo equivalente pari a 7 (BOSCHI *et alii*, 1997).

Infine, da un punto di vista litologico nell'area in esame affiorano depositi sedimentari di età Miocene-Pliocene Sup. Tali sedimenti sono rappresentati da una successione di depositi prevalentemente sabbiosi ed arenacei e una successione di depositi argillosi (Fig. 3). In questo quadro geologico articolato e assai evolutivo il radon può diffondersi più facilmente attraverso le fratture della crosta fino a raggiungere i piani interrati e seminterrati degli ambienti di vita, determinando un aumento delle concentrazioni di attività volumetrica e di conseguenza del rischio derivante dall'esposizione.

MISURE DI RADON E CONFRONTO CON I LINEAMENTI NEOTETTONICI

I dati geologico-strutturali assieme ai caratteri della sismicità strumentale e storica, sono stati confrontati con le misure di radon *indoor* e nel suolo eseguite ed i risultati ottenuti sono di seguito descritti (Fig. 3).

Per la misura della concentrazione del gas radon in aria sono stati impiegati dosimetri ad elettrete per lunga durata (*long term*), dischi di teflon carichi elettricamente montati su una camera di conteggio in plastica conduttiva tipo L. La tecnica di misura è denominata sistema E - Perm e si basa sulla rivelazione della radiazione α emessa durante il decadimento radioattivo. Dalla differenza tra il potenziale elettrico iniziale e quello finale è possibile determinare la concentrazione di attività volumetrica di radon in Bq/m^3 presente in un determinato sito sfruttando la relazione [1]:

$$[^{222}Rn] = \left\{ \frac{V_i - V_f}{C_F \cdot t_e} - C_\gamma \right\} \cdot H$$

dove [^{222}Rn] in Bq/m^3 è la concentrazione di attività di radon in aria; Vi e V_f in Volt, il potenziale superficiale iniziale e finale dell'elettrete; C_F in [(Volt m^3)/(Bq giorno)] è il coefficiente di calibrazione; t_e in giorni è il tempo di esposizione, per questa indagine un anno solare suddiviso in due semestri; in Bq/m^3 è la concentrazione di radon equivalente dovuta alla radiazione gamma; H adimensionale è il fattore correttivo per l'altitudine. Il lettore di potenziale impiegato per la lettura degli elettreti è un RadElec E-Perm.

Alla fine del periodo di esposizione con i rivelatori passivi, sono state calcolate le concentrazioni di attività degli ambienti confinati e si è proceduto con l'individuazione dei punti per la misura della concentrazione del gas radon nel suolo.

Il monitoraggio della concentrazione di radon nel suolo è stato realizzato impiegando una catena di misura formata da: un monitore tipo MR1 con un rivelatore a scintillazione, una cella di Lucas con una sensibilità di 0,0341 [cpm/(Bq/m^3)] accoppiata ad un fotomoltiplicatore e una sonda in acciaio posta ad una profondità di 60 cm dalla superficie. La misura è stata effettuata con una modalità di esecuzione attiva, aspirando il radon con la pompa di aspirazione di cui è dotato il MRI e un flusso di 0,25 l/min e realizzando su ogni punto di misura, tre campionamenti per un tempo di conteggio complessivo di 30 minuti. Le misure sono state realizzate in condizioni atmosferiche stabili.

I dati geologico-strutturali assieme ai caratteri della sismicità strumentale e storica, sono stati confrontati con le misure di radon *indoor* e nel suolo eseguite nel comune di Caraffa ed i risultati ottenuti sono di seguito descritti (Fig. 3).

L'analisi dei dati presenta un territorio in cui la concentrazione media di radon negli ambienti confinati è di 87±2 Bq/m^3, in sintonia con la media nazionale e non, con quella che annovera il territorio calabrese nell'intervallo tra 20 e 40 Bq/m^3. Il valore massimo registrato è pari a 209±27 Bq/m^3.

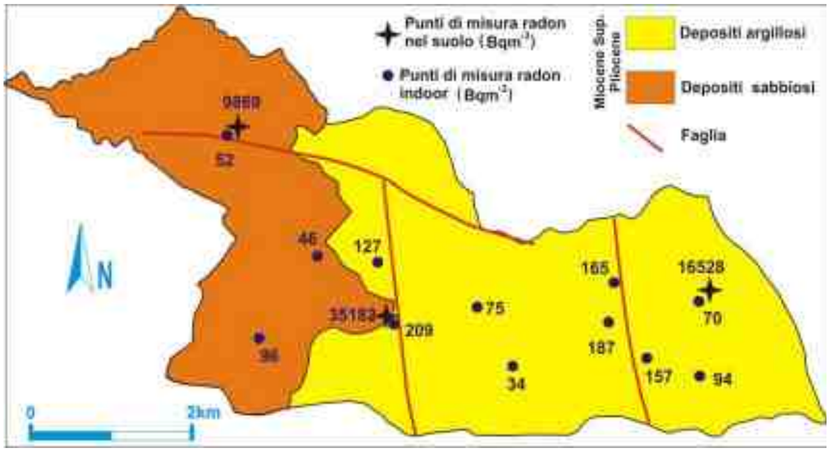

Fig. 3 – Confronto tra le misure di radon indoor e in suolo e i principali caratteri geologici del territorio comunale di Caraffa.

La concentrazione media più importante registrata di radon nel suolo è pari a 35,1±0,8 kBq/m^3, riscontrata al contatto tra le due diverse litologie affioranti.

Tale contatto è marcato da un'importante struttura crostale che si estende per molti chilometri verso sud e potrebbe essere stata riattivata dal terremoto del 28 marzo 1783.

Più in generale dal confronto tra le concentrazioni di radon misurate e la distribuzione della fagliazione quaternaria recente, si deduce, per quest'area, che i valori più elevati di radon si dispongono lungo gli allineamenti tettonici più recenti.

CONCLUSIONI

Il lavoro sperimentale ha migliorato il quadro cognitivo sugli agenti patogeni del territorio. L'analisi dei dati presenta un territorio in cui la concentrazione media di radon negli ambienti confinati è di 87±2 Bq/m3, in sintonia con la media nazionale e non, con quella che annovera il territorio calabrese nell'intervallo tra 20 e 40 Bq/m3. Le misure sperimentali hanno confermato l'andamento tipico della distribuzione lognormale della concentrazione di attività del gas radon per ambienti indoor nei piani interrati, al piano di campagna e al primo piano. I dati presentati in questo lavoro hanno confermato una forte correlazione tra l'andamento delle concentrazioni di radon e l'assetto neotettonico. L'approccio sperimentato su questo territorio è senza dubbio una buona base per applicare il modello di acquisizione e l'analisi dei dati sulla restante parte della Regione Calabria ritenuta dai promotori della campagna nazionale radon del 1990 un territorio a basso rischio radon, ignorando quasi completamente le potenzialità dell'Arco Calabro. Esiste più di qualche elemento per considerare il territorio calabrese come un'area dove non è possibile sottovalutare in alcun modo il rischio radon.

Hydrogeological and geochemical assessment of some spring waters in the municipal area of Chiaravalle Centrale (Calabria, southern Italy)

F. IETTO (*), N. CANTASANO (°), R. FROIO (°), E. INFUSINO (**), G. CALLEGARI (°) & M.G. CIPRIANI (°)

Key words: *Langelier-Ludwig diagram, ~~springs~~ discharges, variability index;*

The aim of this work is the physical and chemical water characterization of seven spontaneous springs, used for drinking purposes by local people in the municipal area of Chiaravalle Centrale (CZ, Calabria, Italy). The study of these springs, within the upstream area of Beltrame catchment, has been conducted from September 2007 to August 2008 through analyses of the main physical parameters (hydraulic discharge, pH, conductivity and temperature) on a weekly basis and through collection of water samples performed on site on a monthly basis.

The Beltrame basin (38°40'53,04" N 16° 24' 41,04" E) occupies the central-southern area of Calabrian Ionian side and it extends along the northern edge of Calabrian Serre upland. The survey area falls in the wide fan-shaped upstream area of the catchment conforming to an old lake, dating back to pleistocenic age, of which Beltrame river was its outlet (IETTO, 2000). The presence of this ancient lacustrine basin, located between 400 and 500 meters high, is strengthened by the occurrence of blanket debris not very sorted, enriched in a red earthy matrix, organized in fan deltas and covered by silty and arenaceous sediments of an obvious underwater deposit. These lithologies are typical of the basin valley in the western side of Chiaravalle Centrale's area, and show a good groundwater flow. Below the Pleistocene sediments follows, stratigraphic unconformity, the crystalline metamorphic bedrock, belonging to the Polia-Copanello Unit (TORTORICI, 1982) and formed by granulite gneisses of Paleozoic age. The related permeability is, generally, low with an increase of its value in the more fractured areas. In the eastern edge of pleistocenic lacustrine basin and, particularly, near the municipal area of Chiaravalle Centrale, outcrops the Pliocenic depositional sequence of marine origin and is constituted, from the lower to the upper levels, by: basal conglomerates, clays, fine sands with clay and silt layers, sands and sandstones with calcarenitic layers. Therefore, the relative permeability is very variable, proceeding from the low values of clays to the high values of coarse-grained sediments.

The study area has been involved in uplifting process of Serre mountain range, began in the early Pliocene and still going (GHISETTI, 1979; TORTORICI *et alii*, 1995), with subsequent development of a normal fault system. In the study area the normal fault alignments extend along a NW-SE and NE-SW directions, in accordance to (GHISETTI, 1979) and (TORTORICI *et alii,* 1995). The abundant groundwater flow, coming from the neighbouring crystalline metamorphic mountains, in the wide upstream area of the catchment, is highly conditioned by the plio-pleistocenic terrigenous sequence, variously permeable, and by the tectonic features of the site. So, in the whole area, there are a lot of springs that originally were located in old lacustrine basin. In particular, amongst the seven springs analyzed: Bovalina, Gullì, Timpa and Caria are located close to tectonic faults (NE-SW direction), while the others (Mumuriana, Buzzucoli and Via) emerge in the plio-pleistocenic terrigenous sequence.

It has been observed, by the comparative analysis of spring outflows and the rainfall data (recorded by the Chiaravalle Centrale pluviometric station), that the time lag of the related peacks varies from one to two months, particularly for the springs distinguished by greater flows as: Gullì, Buzzuccoli, Bovalina and Mumuriana. The temperature of the water samples ranges from 13.3 to 14.9 ^{0}C and show small seasonal fluctuations. A more pronounced thermic variation, of about 4 - 5 ^{0}C, is recorded, only, for Bovalina spring that shows the same trend of atmospheric temperature.

The analysis of spring discharges point out an overall homogeneity of the recession coefficients, with values $0.02<\alpha<0.0094$. The highest value of Bovalina spring (α=0.02) could show a faster discharge of the feeding aquifer and, consequently, its lower storativity. Instead, a lower value of α is found for Buzzuccoli spring (α=0.0094) and this condition could indicate a slightly lower water discharge and a relative greater storativity of the feeding aquifer. The value of variability index (Rv) measured according to (MEINZER, 1923), distinguishes the springs in two groups. The first group includes Bovalina, Gullì, Timpa and Caria springs, that show a "variable" feature corresponding to a low regulating effect of the aquifer. This model could be attributed to the localization of these springs, situated along the

(°) Istituto per i Sistemi Agricoli e Forestali del Mediterraneo I.S.A.F.O.M. U.O.S. di Rende (CS).

tectonic faults in NE-SW direction. These tectonics structures appear as underground preferential drainage with high discharge speed, supplying a dynamic behavior to the same springs. The second group includes Mumuriana, Via and Buzzuccoli springs with a "sub-variable" value of Rv, indicating a greater flow control by the aquifer. This behavior could be attributed to the geological context, because these springs outcrop in the plio-pleistocenic sequence in which some levels of lower permeability slow down and control the groundwater discharge.

The electro-conductivity measures (Eh) of spring waters show values varying from 128 μS/cm to 639 μS/cm. Compared with

TABLE 1
Chemical and physical values of springs

Springs	α (d^{-1})	Rv	E_h medium μS/cm	Hardness medium (°f)	pH
Bovalina	0,02	201	128,69	6,50	5,72
Gullì	0,018	135	147,39	7,37	5,87
Timpa	0,017	115	138,75	6,94	6,13
Caria	0,013	137	322,56	16,13	7,16
Mumuria na	0,012	89	241,34	12,07	6,13
Via-Pace	0,011	51	586,82	29,34	7,60
Buzzucoli	0,0094	84	638,84	31,94	7,15

the previous data, the values of Eh increase gradually with the decreases of recession coefficients (α) and water variability index (Rv) (tab.1). The same trend is found for the hardness values of spring waters. Therefore, the conductivity and hardness values show that the enrichment of minerals in spring waters is a consequence of groundwater persistence in the rocky substrata, as it happens for Buzzucoli spring. For the others, the values decrease gradually with the increase of recession coefficients (α) till the minimum value of electro-conductivity (Eh = 128.69 μS/cm) for Bovalina spring, marked by the maximum value of α (0.02) and the minimum value of hardness (6.5 °f).

The pH mean values are comprised in the interval 5.7-7.6 and are distributed in two groups. The first group (7.15 < pH < 7.60) includes Buzzucoli, Caria and Via springs and are marked by basic waters. The second group (5.70 < pH < 6.10), including Mumuriana, Timpa, Gullì and Bovalina springs, are marked by acid waters, exceeding the national limits fixed by D.Lgs.152/2006 and, consequently, are not drinkable. In this case, the exceeding values of acidity could be caused by a low time water-rock interactions, that causes an immaturity of the springs waters. In fact, the acidity value is higher for Bovalina spring, with high value of recession coefficients (α). For the other springs, with decreasing of recession coefficients values although the acidity is gradually decreasing, confirming higher time of water-rock interactions.

The water chemistry of ion proportions, shown on the Langelier-Ludwig quadratic diagram (fig.1), point out that the spring waters are classified in two different groups, both arranged in IV quadrant (alkaline–earthy waters with prevailing bicarbonate ions). The first group, with a marked bicarbonate prevalence, includes Buzzuccoli, Via and Caria springs, located in the plio-pleistocenic complex with low values recession coefficients (α) and high values of conductivity (E_h). The second group, including Bovalina, Gullì, Timpa and Mumuriana springs, marked out by an increase of the recession coefficients (α) and by a decrease of conductivity values (E_h), is located in the boundaries of quadrants I-IV. This water chemistry could be regarded as a mixing, in variable proportions, between these two end-members with a greater influence of the rocky-crystalline complex giving to the spring waters a prevailing chloride – alkaline feature.

CONCLUSIONS

The chemical features of water sources have enabled to discriminate two spring water groups. The first group, including Buzzuccoli, Via and Caria springs, is distinguished by basic waters (7.15 < pH < 7.60), that in Langelier-Ludwig diagram, are arranged in IV quadrant. The second group, including Bovalina, Gullì, Timpa and Mumuriana springs, is distinguished by acid waters (5.7 < pH < 6.1), that in the same diagram are located at the boundaries of quadrants I-IV. Therefore the quick feeding of the springs, coming from crystalline complex, is affected by a mixing action with the groundwater of plio-pleistocenic terrigenous sequence, characterized by low flow velocity and enriched by bicarbonates for the washing away action of the calcarenitic interbeddings.

The study of the spring outflows has enabled to assign, according to Meinzer's classification, a "variable" behavior for the springs: Bovalina, Gullì, Timpa and Caria, located along tectonic faults, in NE-SW direction, which act as preferential drainage pathways. In fact, these springs show a faster outflow of the groundwater and a lower values of electro-conductivity (E_h). The other springs with a "sub-variable" behavior are arranged in the plio-pleistocenic terrigenous complex variously permeable, indicating a greater control action by the aquifer. This behavior is confirmed, also, by related values of recession coefficients that are inclined to decrease gradually with the consequent increase of the conductivity. Finally, the spring water temperatures show more pronounced variations only for Bovalina spring, highlighting the same trend of atmospheric temperature and therefore suggesting a feeding from a water table most surface.

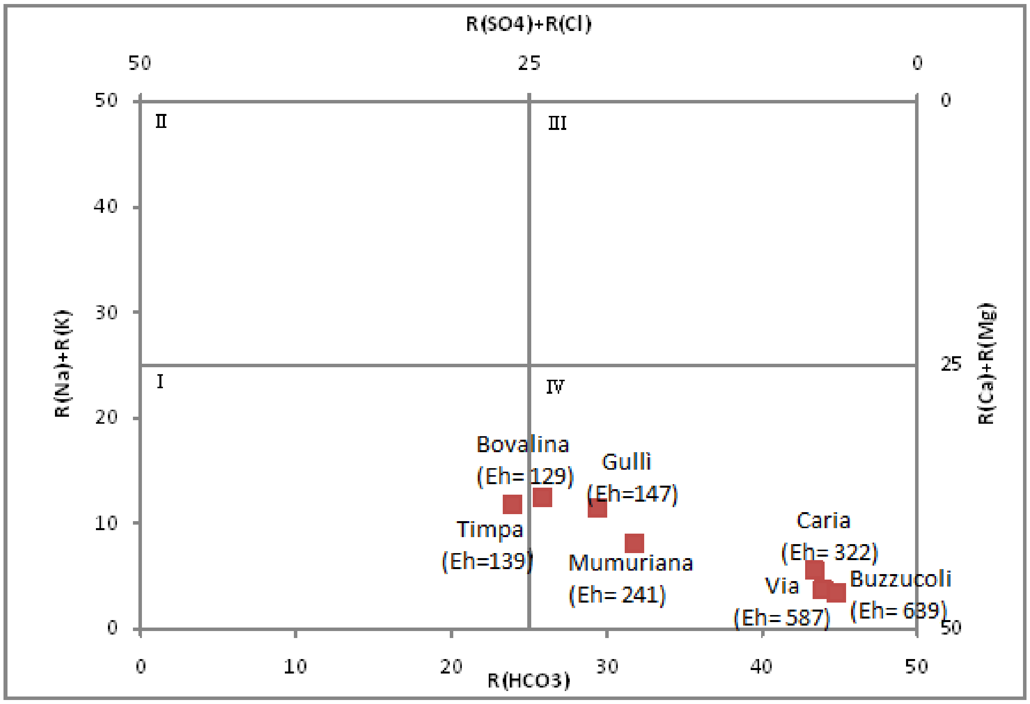

Fig. 1 – Langelier-Ludwig quadratic diagram of spring waters with values of conductivity (E_h).

Methodological approach for the assessment of natural alterations at sites used for waste disposal: the case study of Decollatura (Calabria, Southern Italy)

F. IETTO [(*)], F. TALARICO [(**)] & A. GIGLIO [(**)]

Key words: *contamination soils, heavy metals, waste disposal*.

The aims of this study were to analyze the uptake of metals from contaminated soils and compare the effects on *Carabus lefebvrei* (Coleoptera, Carabidae, Insecta) evaluating the suitability of this species for heavy metal bioindication by to measure the immune function using phenoloxidase enzyme activity.

The area evaluated in this study was a site for the disposal of municipal solid urban waste located about 1.5 km from the town of Decollatura (Fig. 1). The study area is on the Tyrrhenian side of the Calabrian Arc, central northern section, at the southern boundary of the Sila upland. The area is typified by a hilly morphology stretching along the foot of the northern edge of Monte Reventino (1410 m s.l.m.). In particular, the area used as a waste tip is at the southern boundary of a level area that forms the crest of a hilly ridge (altitude of 770 m a.s.l.), oriented NW-SE, and bordered by the River Amato on the northern side and the River Grande on the southern edge. Slope gradients are relatively low, around 15-20%, along the slope with the waste tip, whilst the northern slopes are steeper.

The lithology of the area is made up of a substrate of metamorphic rocks, belonging to the *Unità di Bagni* (AMODIO MORELLI *et alii*, 1976; ALVAREZ, 2005), consisting of grey phyllitic schists with quarzitic intercalations. It is a lithoid complex with strong resistance to erosion and a low permeability which tends to increase according to the degree of rock jointing. The lithoid substrate is covered by a substantial layer of detritic deposit, originating from weathering of the crystalline complex of the basement. In this context the soils are composed of phyllitic clasts of varying grain size in a sandy-loam matrix with a clayey component, whose thicknesses vary from moderately deep to deep. Furthermore, the sandy-loam texture, present in all horizons, gives a good value of permeability for porosity and a good drainage of the horizons. Organic matter is high which, together with the mineral fraction, gives the soils a brown colour. These characteristics designate the study area as belonging to province 13 of the Pedological Map of Calabria (ARSSA, 2003).

The rainfall regime of the area ensures a good water supply for vegetation, which is particularly lush, limiting surface water flow and consequently erosive phenomena.

This is the morphogeological context that hosts the site for the disposal of solid urban waste of the small town of Decollatura, no longer in use for about 10 years. The site, about 1.5 km in direct line from the town, was created with an excavation bordered by walls with an average height of 2.5-3.0 m, such as to contain a volume of around 46,000 m^3 according to the original project. The base of the excavation was impermeabilized by lining with a high density polyethylene geomembrane (thickness of 2 mm), so as to avoid percolate infiltration that would have contaminated underground water resources. At closure of the site the entire area was covered with a thick layer of locally obtained inert material.

At the present time the disposal site is completely lacking in tree plantation and without any controlled channelling of rainfall. As a result, free flow of surface run-off has eroded large rills, with consequent exposure of waste materials, particularly along their sidewalls. There is neither a system of collection or stocking of the percolate produced, nor any systems of reducing the biogases coming from the decomposition of the organic fraction of the wastes. In these conditions the pollution hazard is high for the area surrounding the site, with consequent possible impacts on the local ecosystem.

A study was carried out which involved sampling of soils along the downslope perimeter of the ex-site (site P in the Fig. 1). The sampling area was chosen taking into account the potential transport of pollutants from the urban waste disposal site by means of both infiltrating waters and surface flow. Further sampling was also done in an area that was above the site, used as representative of the natural contamination-free conditions (site PCTRL in the Fig.1). The sampling, carried out in April 2009, consisted of soil samples down to a depth of about 20 cm from the field surface, of which five were downslope of the disposal site (site P) and three above the site (site PCTRL).

With the aim of identifying the concentrations of trace elements in the soils sampled, a mass spectrometry analysis (ICP-MS: Inductively Coupled Plasma- Mass spectrometry) was carried out with plasma source and inductive coupling (model: Perkin Elmer SCIEX Elan DRC-e).

To investigate the effects of exposure to heavy metals on life history parameters of *C. lefebvrei*, males and females were hand-collected from P and PCTRL sites in early spring 2010 and used for enzymatic assay. In the laboratory, the beetles were reared to expose the larva and pupa to experimental treatments. To establish the toxic responses at the molecular level, metal effects on immune response was measured using phenoloxidase (PO) assay. The hemolymph was collected from pupa, larvae and adults and centrifuged at 5000g at 4 °C for 5 min. Forty

(**) Dipartimento di Ecologia, Università della Calabria (CS)

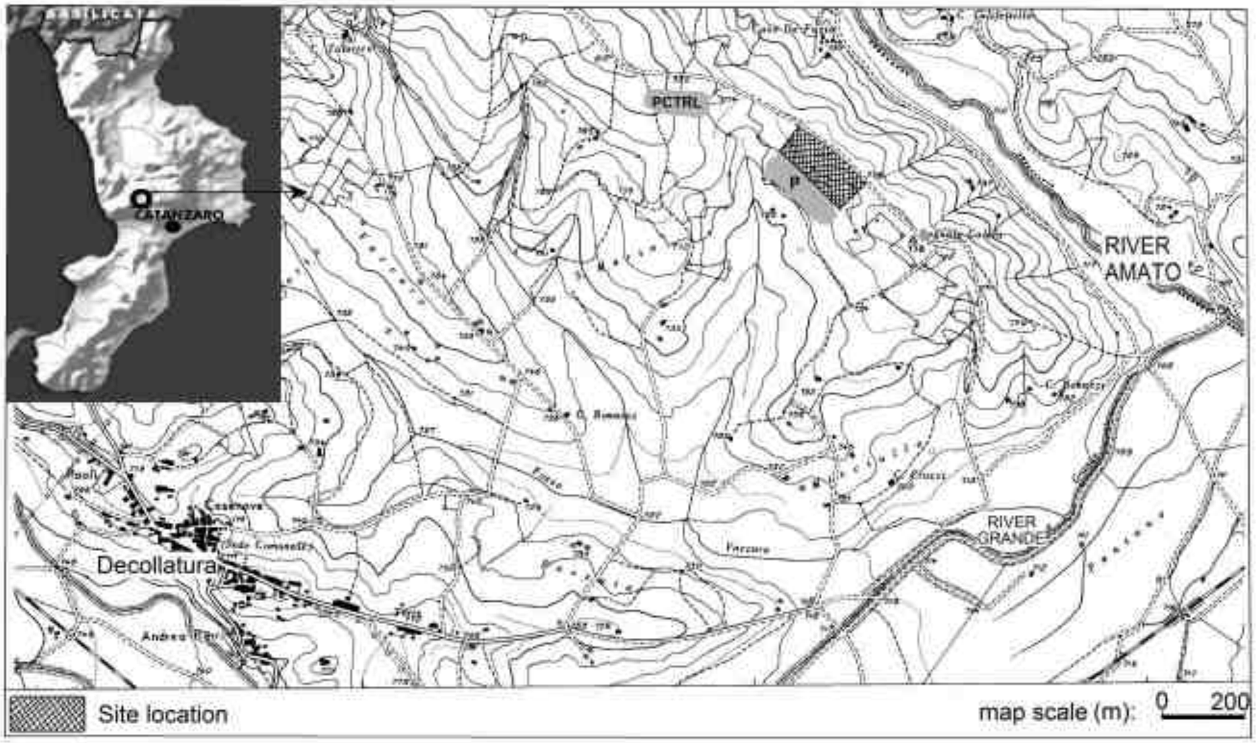

Fig. 1 – Location of waste disposal site, gray dots (P anf PCTRL) indicate soil samplings.

microliters of hemolymph-buffer supernatant is taken and mixed with 160 μL of DL-DOPA (3,4-Dihydroxy-DL-phenylalanine, Sigma) (3 mg/mL phosphate buffer) in a microtiter plate. PO activity at 25 °C was measured at 492 nm for 30min in 5min intervals using a plate reader (Sirio S, SEAC). Enzyme activity was expressed as Au/ μL The animals used for these analyses were larvae at the last (third) larval instar, 10 days old pupae and emerging adults reared on polluted and control soil.

RESULTS

The soil analysis, by means of the ICP-MS, identified 17 trace elements. The average concentrations in the P site, in ppm, were compared both with the reference sample (PCTRL) and with the limits established for public green use and industrial use as specified in the Italian decree 152/06 (tab.1). With the aim of identifying the variations in concentration between the trace elements in the P samples with the reference samples (PCTRL), was calculated their relationship and illustrated in the tab.1. This analysis indicated a mercury and zinc concentration which, in the site P, is respectively 3.01 and 1.32 times the reference limit value (PCTRL), going beyond the limits in both cases for use public green areas. The other trace elements found in the samples of P site almost always have concentrations greater than the reference samples (PCTRL) but don't exceed legal limits. The high of concentrations of some elements (vanadium, thallium, beryllium) in all P and PCTRL samples, compared with the legal limits, can however be attributed to natural values of the substrate and outcropping surface layers. On the other hand, the lack of some trace elements could be due to leaching out by percolation processes, and the same processes could explain the marked variations in concentration of some elements in the various samples.

The PO activity of animals collected in the urban waste varied significantly compared with those collected in the control site. As far the absolute activity of the PO measured as the absorbance at 15 and 30 min of incubation with DL-DOPA is concerned, the larvae collected in the urban waste presented at both times a significantly lower PO activity compared to animals collected in the control site (Wilcoxon rank sum test: $p<0.05$). The increment of PO activity after 15 and 30 min of incubations were highly significant lower in animals from the urban waste site (Wilcoxon rank sum test: $p<0.01$). The PO activity of the pupae did not show difference at the two slot , whilst the increment of PO activity after 15 and 30 min were significantly lower in samples collected in the urban waste area (Wilcoxon rank sum test: $p<0.05$). The adults collected in the polluted area presented a significantly lower PO activity and increment of PO activity at both times (Wilcoxon rank sum test: $p<0.05$).

CONCLUSIONS

The soil analysis, using the ICP-MS, showed the presence of high concentrations of mercury and zinc in samples near to disposal site (P), with mean values that are greater respectively by 3,01 and 1,32 times the reference values of samples PCTRL.

Pb	33,11±5,82	36.15±11,87	100	1000	0,9159
Bi	0,66±0,07	0.64±0,62	*	*	1,03
All values expressed in ppm			* no legal requirement		

The values recorded are greater than the permitted limits for public green use according to current legislation, whereas the limit for industrial is reached only by the mercury concentration in some samples of the P site.

The high concentration of heavy metals in the sampling area P can be attributed to a greater contribution of contaminants transported by the surface water runoff and infiltration from the disposal site. Infact, given the morphology and lack of controlled canalization, the free flow of rainwater and of infiltration, tends to flow in a concentrated manner along the southern border of the site (P site), where there has been high concentrations of heavy metals contamination.

The potential problem to assess metal pollution on ecosystem using carabid as model is the fact that the bioaccumulation and effects do not necessarily give a similar answer due to their efficient detoxification mechanisms and difference in exposure and sensitivity between developmental stages. *C. lefebvrei* can be used to valuate metal contamination in the field as non-specialized predators and 2nd order consumers in the food chain as potential biological indicators both of bioaccumulation and toxicological effect.

The lagoon of Nador (Morocco): geochemical and petrographic analysis of sediments and environmental conditions

MARIN E.(*), NACHITE D.(**), NAJIH M.(°), ANFUSO G. (°°), MARROCCHINO E. (*) & VACCARO C. (*)

Key words: *ArcGis 9.3, anthropogenic pollution, lagoon of Nador, heavy metals, XRF.*

ABSTRACT

The Nador lagoon is one of the most important ports on the coast of Morocco, and the second lagoon in North Africa by extension (1115Km^2). The lagoon is bordered to the north-west by the volcanic products of the Gourougou volcano complex (887 m asl) and south-east by the Jurassic carbonate succession of marine environment belonging to the Complex of Kebdana (932 m asl); the rest of the area around the lagoon is flat and is characterized by arenaceous-pelitic deposits linked to the Miocene and Quaternary magmatic activities.

The rocks outcropping in the hinterland are generally characterized by low concentrations of metals, and are no exception most of the volcanic rocks of the Gourougou Complex, constituted mainly by latitic tuffs and trachytes, and rare basalts and andesite of the promontory of Atalayoum that are not volumetrically significant. A natural potentially impacting source of heavy metals is located in the northwestern part of the lagoon, where outcrops skarn with magnetite mineralization, widely exploited since ancient times (EL ALAMI *et alii, 1998*; EL RHAZI & HAYASHI, *2002*; GILLA *et alii, 2004*) .

To fully describe the quality of Nador lagoon sediments, 49 samples along the banks and on the bottom of the lagoon were gathered and their distribution was analysed and compared with the patterns of water circulation in the lagoon.

The samples were subjected to petrographic and geochemical characterization by x-ray Fluorescence (XRF) by means of an ARL Advant X Spectrometer model. Furthermore, data distribution was obtained using GIS tools (ArcGis software, version 9.3) and thematic maps were created.

The data showed that, despite the prevalence of contributions from the Miocene-Quaternary sedimentary sequences, characterized by low content of heavy metals, the samples contained high quantities of heavy metals, evidencing diffuse human related pollution problems.

Since sediments are predominantly composed by quartz and carbonate, the content in metals is extremely low and the only natural source of pollution is attributable to the mobilization of metals contained in ancient iron mines dumps located along the banks of the Gourougou Complex. Such sediments are exposed to weathering and leaching processes that produce in nearby areas the largest observed concentrations of iron, in this sense enhancing the importance of the anthropogenic pollution versus the natural one. Specifically, the points with higher rates in metals are found near the town of Nador, the main urban centre in the area. High concentrations are also observed south of Nador, close to the plain of Bou Areg, densely tilled and devoted to agricultural purposes carried out using massive quantities of fertilizers and unpurified wastewater for irrigation. It is not clear however if the Promontory of Atalayoum, located in the north of the lagoon, constitutes a natural supply area of heavy metals. In this sense, further investigation should be carried out to fully understand the role of basic volcaniclastic deposits in the pollution linked to Cr, Ni, V and Co. However, it is possible to state that the main anomalies concern Cu, Fe, Pb and Zn, whose contributions are typical of human impact. Along the banks of the Nador lagoon, are also located the towns of Beni Enzar and Kariet Arkmane, characterized by a dramatic increase in population over the past 30 years, because of the opportunities offered by the business linked to the construction of summer houses, hotels, etc. as well as to the enlargement of the local port. The rapid increase in population was not accompanied by the realization of services and, most importantly, there are no appropriate treatment facilities for wastewater, with the associated environmental problems.

In addition, analyzing the obtained maps using a geochemical point of view, two distinct areas are observed and linked to water circulation patterns within the lagoon. It is possible to observe a preferential current along the banks and a secondary current that splits into two parts in the middle of the lagoon, this being related to the very specific geomorphologic characteristics of the lagoon; it may be also noticed that neither the streams that flow into the lagoon nor the inlet to the Mediterranean Sea create appreciable convective motions.

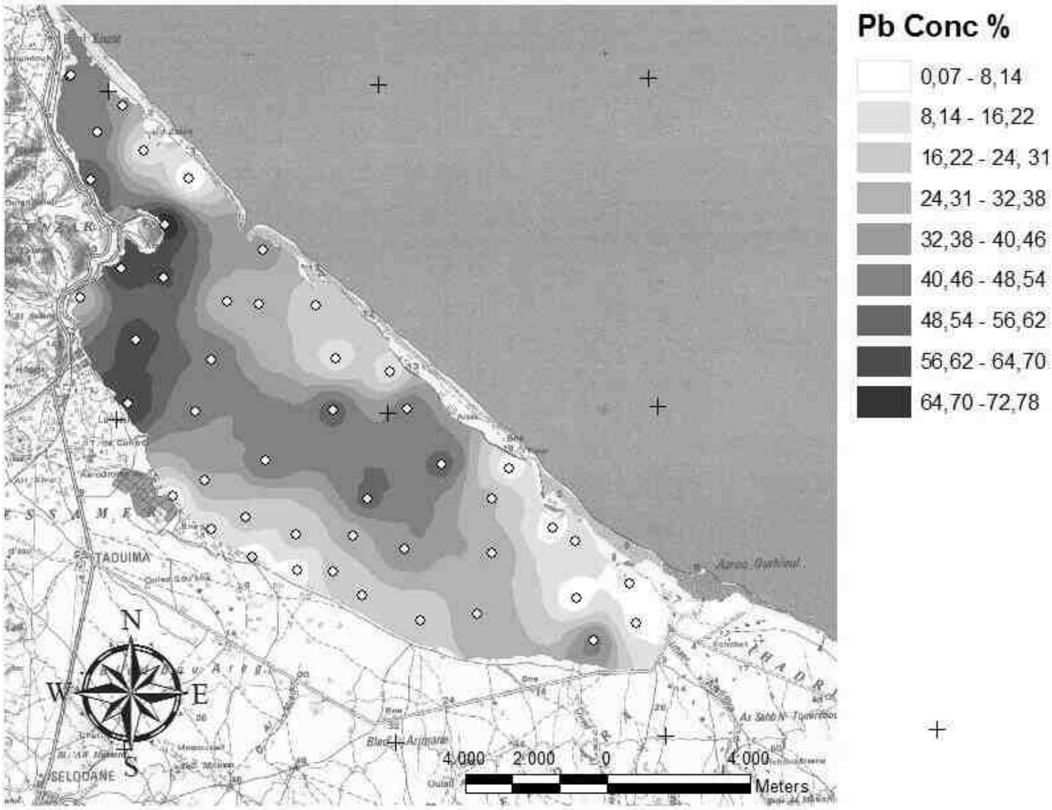

Fig. 1 – Distribution of Pb concentrations in the lagoon of Nador: map was created using IDW interpolation and software ArcGIS 9.3.

The internal flows of the lagoon have low intensity; this fact and the shallow water depths determine an insufficient water supply and oxygenation (BLOUNDI *et alii, 2008*). For this reason, in recent years, it was started the building of an artificial inlet with the Mediterranean Sea. Specifically, the main aim of the construction of the Canal is to improve the water quality of some parts of the lagoon and mitigate the environmental problems, which were confirmed by the presented investigations. It would be useful, in a near future, to carry out further researches to evaluate the effects of the new inlet on water circulation and associated environmental problems.

In conclusion, the study outlines how the quality of bottom sediments of Nador lagoon is deeply affected by the increasing anthropogenic pressure and the geochemical intrinsic characteristics of local sediments rich of heavy metals.

FIGURES

In Fig.1 example of thematic map describing the distribution of elements in the Nador lagoon: the areas characterized by a greater amount of Pb are located close to the cities of Nador and Beni Anzari and in the northern area along the banks of Gourogou Complex. Furthermore, the distribution of the presented element reflects the geomorphologic characteristics and the water current patterns in the lagoon.

Effects of climate change and anthropic activities on groundwater resources in the south-eastern Sicily

GIOVANNA PAPPALARDO (*)

Key words: *Anthropic activities, climate, shallow and deep aquifers, groundwater resources, south-eastern Sicily*

INTRODUCTION

The availability and the chemistry of groundwater resources are influenced by several factors such climate change and human activity. The desertification process, defined as the irreversible reduction of the soil's ability to produce resources and services (FAO-UNEP-UNESCO, 1979), according to the second United Nation Convention Combact Desertification (UNCCD, 1996, 2003) is also favored by these factors. The third IPCC Intergovernmental Panel Climate Change (2001), states among the major human causes of desertification, the role of unsustainable agricultural practices. Starting from these general statements, the paper deals how these factors locally threaten the groundwater resources particularly in the south-eastern Sicily. The "Map of vulnerable areas to desertification in Sicily" at the scale 1:250,000 (CARNEMOLLA *et alii*, 2002) classifies the south-eastern Sicily to medium high risks. In the ambit of the Italian context, Sicily is the most exposed region to Land Degradation by agricultural activities (PERINI *et alii*, 2007).

Most of the Sicilian farms (44.8%) concentrate in the eastern sector of the region (ISTAT, 2001). Horticulture is classified at the second place of the productive activities engaging area in Sicily and it represents one of the most receipts in the agriculture context (PAPPALARDO G., RAPISARDA F., 2008).

The study area is located along the south-eastern coast of Sicily belonging, from a geological point of view, to the Hyblean Plateau. This is a flat area formed by Quaternary marine sediments (sands, clays and calcarenites) overlaying a thick sequence of Miocene carbonates. This geological setting controls the groundwater flow that is characterized by a shallow aquifer and a deep aquifer.

The shallow aquifer, is constituted by Pleistocene sands and calcarenites, by coastal dunes and marine terraces resting on impermeable Miocene clayey marl.

The variability of the spatial distribution between very permeable loose sediments and less permeable consolidated levels, determine the anisotropy of the aquifer. Despite the differences of permeability existing between the different rocks that constitute the aquifer, it shows a continuous circulation of water for the whole thickness (FERRARA V., PAPPALARDO G. 2003). This aquifer has played an important role in the economic development area, constituting the main source of water supply easily exploitable for the modest depth from ground level. This has, however, favored the deterioration of groundwater due to the sea intrusion and, both agricultural and urban pollution, as evidenced by hydrochemical data analyzed in this paper.

The deep aquifer, consisting of carbonate rocks having high permeability due to fracturing and karstification is confined at the top by marly deposits belonging to different Oligocene-Miocene formations. The main directions of groundwater flow overlap the main tectonic trends (FERRARA V., PAPPALARDO G. 2004).

To check the status of groundwater resources and to identify the factors driving the change, were compared two different measurement campaigns (October 1996 and October 2006) on wells distinguished on the basis of the aquifer they exploit. The measurements regarded the main physyc-chemic parameters and the groundwater level. The comparison of data shows that along the coast between Marina di Ragusa and the course of the River Ippari, the fault systems of Marina di Ragusa (NNE-SSW) and Scicli (NE-SW) control the movement both of the superficial aquifer water that of the deep one. This trend is complicated by the effect of continuous pumping wells exploiting the deep aquifer that lead to a strong depression of the water table evidenced by the isophreatic map.

The conductivity of the water shows a widespread deterioration of their quality which is particularly evident in the shallow aquifer where it is >20.000 μS/cm typical of poor water from a qualitative point of view (PAPPALARDO G., RAPISARDA F., 2008a). In the deep aquifer the increasing of conductivity proceeds from the hinterland towards the coast, here the average values of conductivity is 1.000 μS/cm cm but locally it can reach peaks of 5000 μS/cm.

The development of the characteristic relationships between the major ions showed the influence of the sea intrusion of the human activities on groundwater. The most significant data concerning the relationship between HCO3 -/Cl, the ratio is always less than 0.0010, and between SO4 - / Cl - <1, near the coast. These values reports the effects of pollution induces by agricultural activity that in these areas is very intense. The hydrological and hydrochemical results were related to local climate (temperature and precipitation) collected by thermo-pluviometric stations located in the area, to assess possible relationships. The calculations have revealed, for the area under consideration, a rainy period between October and February and a dry period, between March and September, with a minimum during the months of June, July and August. The mean values of annual precipitation of the last 50 years, showed the changes of rainfall distribution occurring in the area. It was also calculated the aridity index to define the annual drought period; to point out how it evolved over time and as an prolongation of this period may have an impact on groundwater. The result agrees with the weather forecast measures for the period 1965-1994 conducted by the Department of Agriculture and Forestry of the Sicilian Region (Climatology of Sicily, 2002). These indicate to the south east of Sicily, especially along the coastal areas, medium - high desertification risk characterized by the highest values registered in the Island of average evapotranspiration (800-1000 mm) and temperature (16-19° C) (PAPPALARDO G., RAPISARDA F., 2008a).

Geochemical and hydrogeological characterization of the metamorphic-serpentinitic multi-aquifer of the Scala catchment, Amantea (Calabria, south Italy)

GIOVANNI VESPASIANO (*), CARMINE APOLLARO (*), FRANCESCO MUTO (*) & ROSANNA DE ROSA (*)

Key words: *Aquifer, hydrogeochemistry, metamorphic-serpentinitic.*

INTRODUCTION

The work focuses on the characterization of the groundwater in the Scala Basin (Amantea, CS) through the use of a comprehensive geochemical, hydrogeological and geological approach.

The considered aquifer is located in the northern sector of Calabria, in an area comprising Coreca, the Oliva river, the Scala river and the southern part of Amantea.

In the studied area rocks belonging to metamorphic and sedimentary units outcropping in tectonic window. Basal unit is constituted of Triassic dolostone and limestone overthrusted by ophiolitic sequence of Frido and Gimigliano units (AMODIO MORELLI *et alii*, 1976). The latter mainly consists of metapelites and slates. Metamorphic units are sealed by Late Miocene sedimentary sequences consisting in calcarenites, clays, marls, Messinian limestones on the upper part. Pleistocene terraced deposits rest on the top of terraced surfaces (MUTO & PERRI 2002). The Main acquifer of the Scala catchment consists essentially of serpentinites, metabasalts, phyllites and carbonates.

Structural features suggests the presence of a metamorphic aquifer represented by the ophiolitic rocks, suspended by slates of the Frido Unit. Another aquifer consists of Miocene carbonate rocks and results isolated from the metamorphic aquifer by high angle faults.

Groundwater geochemistry was investigated through sampling and analysis of a significant number of, springs and wells. Some groundwater parameters such as pH, Eh, temperature, alkalinity and specific electrical conductivity, were measured in the field. Groundwater samples were filtered in situ through a 0.4 µm pore-size membrane filter and acidified with suprapure nitric acid.

The concentrations of Cl^-, Br^-, SO_4^{2-}, F^-, NO_3^-, and PO_4^{3-} were determined by HPLC, whereas Ca^{2+}, Mg^{2+}, Na^+, K^+, SiO_2 and some trace elements, were analysed by a quadrupole ICP-MS. Data quality for major components was evaluated by charge balance. Precision and accuracy for minor and trace elements was evaluated against two different standard reference samples.

The waters were further classified according to the classical geochemical methods (APPELO C. *et alii*, 1996).

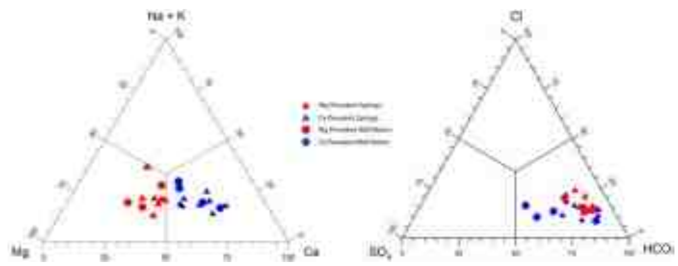

Fig. 1 – Ca-Mg-Na+K and Cl-SO_4-HCO_3 diagrams (LANGELIER, W. F., & H. F. LUDWIG 1942).

Preliminary results allowed to identify the groundwaters characteristics in the basin and to reconstruct the hydrogeochemical model of the area. Two groups of waters can be identified: the first one falling in the Ca^{2+} field, suggests that the chemical composition of these springs is controlled by the dissolution of Ca-rich phases present in the metabasalts and in Miocene cover; while an interaction of meteoric water with serpentinitic rocks may explain the second group of Mg-HCO_3 groundwaters (fig. 1). Geological, hydrogeological (CELICO P., 1986) and geochemical data confirm the existence of two distinct aquifer in the Scala catchment.

The trace elements have shown abnormal concentrations of Fe.

The high Fe concentrations are probably due to interaction with slates and Miocene deposits that characterize the area.

In Figure 2 is represented a geological cross section with the main lithologies and the groundwater circulation (Fig. 2).

Synergic application of different methodologies for the characterization of aquifers in carbonate rocks

BARTOLOMEO VIGNA (*), ADRIANO FIORUCCI (*), FEDERICO MARCHIONATTI (*), CINZIA BANZATO (*), BARBARA MOITRE (*)

Key words: *karst aquifer, monitoring, radon, tracer test, rare earth elements (REE).*

INTRODUCTION

In the study of aquifers in carbonate rocks, the application of different methodologies in synergy leads to a better understanding of the functioning of an aquifer.

In this paper we examine the results obtained from the use of several approaches conducted in aquifers of the Piedmont region with hydrodynamic and geochemical characteristics very different from each other.

In particular we highlight the different responses to the input by monitoring flowrate, temperature and electric conductivity of spring water (BAKALOWICZ M. - 1987, MUDRY J., *et alii* - 2008) was performed for multi-year periods, allowing distinguish different aquifers according to the three conceptual models: dispersed circulation systems, interconnected conduit systems and dominant conduit system (GALLEANI L., *et alii* - 2010; VIGNA B. - 2002).

Corresponding to some aquifers, artificial tracers tests were performed to reconstruct in detail the arrival curve of the dye to the spring, which clearly shows the different types of aquifer system.

Further investigation through measurements of the concentration of main ions and rare earth elements in the water in different hydrodynamic conditions, allowed to obtain more information on the functioning of aquifer systems (HERSHEY RL *et alii* – 2010; BIDDAU R., *et alii* - 2009).

Finally, in the karst system Bossea was experienced a data-logger of radon concentration in water that has allowed to collect more useful information on the variation of this parameter in connection with the main collector flowrate and some minor contributions.

TEST SITE

In the area of the southern Piedmont, a series of springs, fed by carbonate rocks aquifers with different intensity of fracturing and karsting, were equipped with flowrate, temperature and electric conductivity data-logger.

These springs may be representative of different carbonate systems present in the Mediterranean area, from highly karst circuits such as those of the Trieste Karst (Timavo system) to predominantly fractured systems such as those of Apennines (Peschiera, Gari, Fibreno, Caposele).

The Pesio and Fuse springs (not captured) are fed by highly karst and reduced fracturing aquifers, with very visible epigeal and hypogeal phenomena and important cave that constitute the main drainage pathways. These aquifers are characterized by a circulation to "dominant conduit" with significant low flow in the absence of precipitation and flood with rapid increases and decreases in flowrate. The snow-melting floods continue to exist for long periods with showy daily flowrate fluctuations, conditioned by the processes of snow-melting that occur predominantly in the central hours of the day. The electric conductivity and the temperature of water present showy changes during main floods with prevailing replacement phenomena (GALLEANI L., *et alii* - 2010) marked by rapid decrease of the values during the full peak for the arrival of newly infiltrated waters to the source. The tests with artificial tracers show very rapid flow velocity (greater than 120 m/h) and breakthrough curves to pulse with increase and decrease of the tracer concentration values of the duration about a tens of hours.

Chemical analyzes reveal shallow mineralization with average electrical conductivity values around 200 μS/cm, maximum values around 270 μS/cm (during periods of low flow) and minimum around 120 μS/cm during floods. These values are affected by reduced time of water-rock contact and high speed flow typical of a dominant conduit system. The chemical *facies* are bicarbonate calcium-magnesium for Fuse Spring and bicarbonate calcium with sulfate-magnesium *sub-facies* for Pesio Spring, due to the presence of carniole horizons.

The Dragonera and Tenda springs (captured for drinking water) and secondary contributions in the Bossea system show the operation of “interconnected conduit systems” that take place

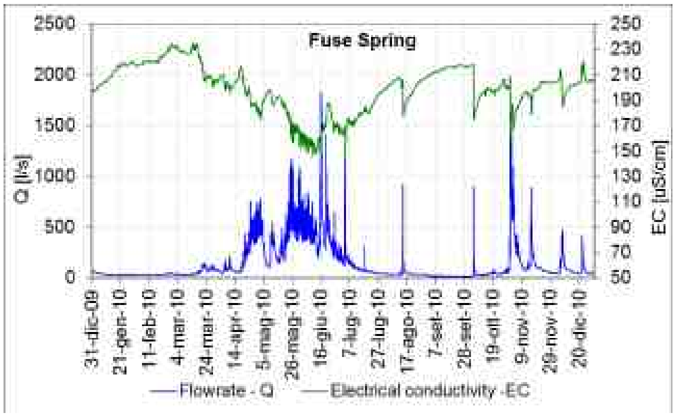

Fig 1- Annual trend of flow rate and EC (Fuse spring)

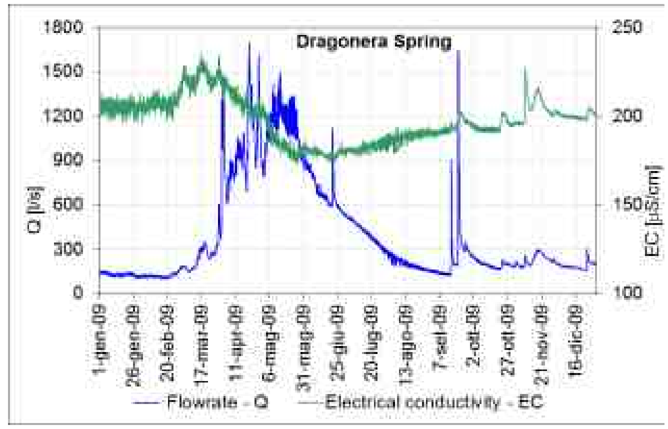

Fig. 2 – Annual trend of flow rate and EC (Dragonera spring)

in quite low karstification and medium-high fracturing rocks. In Dragonera and secondary contributions of Bossea systems significant increases in flowrate are evident, mainly due to piston phenomena, while in the Tenda system slower and less pronounced responses are recorded at infiltrative input. In the Dragonera system, the melting-snow floods show mild daily changes of flowrate, while in the Tenda system these small fluctuations are not recorded.

Electrical conductivity and water temperature show obvious phenomena of piston effect (GALLEANI L., *et alii* – 2010; VIGNA B. - 2002) in increments of values as a result of major flooding (Dragonera and Bossea secondary contributions) or with marked fluctuations in the electrical conductivity, due to phenomena of piston effect, but conditioned by the different contributions of the carbonate structure (Tenda Spring)

The temperature of Tenda Spring remains very constant (annual oscillation between 0.2 °C and 0.3 °C) even after the contributions from melting snow.

In such systems were performed some tracers test which have given negative results probably due to the slow circulation in the cluster predominantly fractured. Only on the secondary system of Bossea, where the distances between the point of release of the tracer and the point of detection of the same is very small, the tests have given positive results with flow rate of between 0.2 m/h and 3 m/h. Breakthrough curves were very prolonged in time due to significant diffusion and dispersion of the dye in the aquifer.

The water in these systems have a rather different mineralization due to the presence of layers of plaster and carniole the base of the carbonate succession in the Tenda system.

This system has a mineralization averaging around 430 µS/cm with peaks up to 530 µS/cm during the growth phases of the floods (piston effect) and minimum of 270 µS/cm.

In particular, during periods of low water they contain a calcium sulfate-bicarbonate *facies* and calcium bicarbonate facies with calcium sulfate sub facies in times of ordinary flow.

The waters of Dragonera source have a lower mineralization with an average around 205 µS/cm and maximum values of 245 µS/cm during the periods of high flow (piston effect). The minimum values around 175 µS/cm occur at the end of high flow periods.

The waters have a calcium bicarbonate *facies* regardless of hydrodynamic conditions, there is only variation (0,048 in spring samples and 0,125 in autumn samples) in the value of the Mg^{2+}/Ca^{2+} ratio.

The contributions of the Bossea secondary system have a mineralization around 260 µS/cm, with maximum values of more than 360 µS/cm during floods (piston effect) and minimum values of 220 µS/cm during the lean periods. The chemical *facies* of the water is calcium bicarbonate.

The Ray Spring (collected to use drinking water) is fed by an aquifer set in carbonate rocks characterized by intense micro-fracturing and by the absence of karstification (movement with dispersive network).

The courses have soft annual oscillations unrelated to the daily rainfall. The electrical conductivity and the temperature of the water are very constant over time with variations of less than 0.2 °C and 10 µS/cm highlighting a typical "prevailing homogenization" response.

There are decreases in water mineralization after heavy rains of shirt duration due to infiltration directly into the cargo tanks of the catchment.

Given the type of the aquifer and the absence of zones of direct infiltration, no tracers tests were performed.

The chemistry of the waters of the Ray Spring is stable with relatively high values of mineralization, related to the contact water/rock and to the slow speed of groundwater flow. The value of the specific electrical conductivity is very constant and around 380 µS/cm. The *facies* is calcium-magnesium bicarbonate.

Simultaneously with the determination of major ions it was also analyzed rare earth elements of spring water sampled during

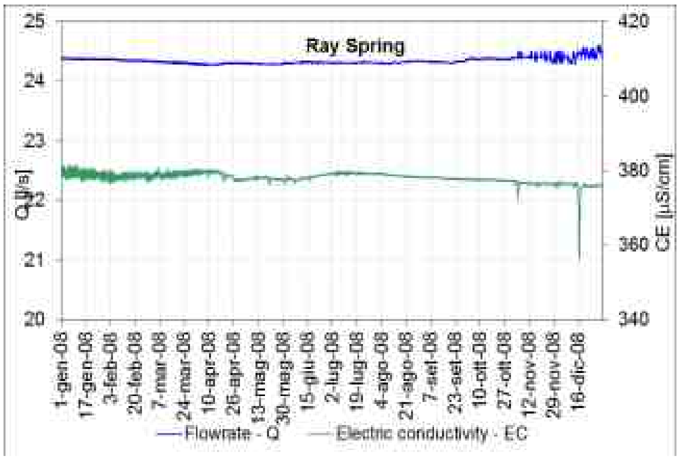

Fig. 3 – Annual trend of flow rate and EC (Ray spring)

low flow and flood periods. From their comparison, we observe a rather similar trend due to the fact that the different system are made of the same lithotype (carbonate rocks).

The concentration of the rare earth elements (REE) in groundwater normalized to the corresponding concentration in the Post-Archean Australian Shale PASS, under high and low flow condition.

The most striking features in this pattern are the marked positive Eu anomaly and then the negative Ce anomaly.

The interconnected conduit systems (Tenda and Dragonera) have higher values during periods of flood. The dominant conduit systems (Fuse), during periods of high folw, have greater values only for HREE (high rare earth elements).

For Ray the source data are not yet available.

Continuous radon concentration measurements in water provide a powerful method to confirm the general hypothesis on radon exchange dynamics between bedrock, cave waters and indoor underground atmosphere in the Bossea karst system (PEANO *et alii* - 2011).

In the main collector is possible to note the close relationship between the flow and the variations of radon that has large increases closely correlated with major floods.

CONCLUSIONS

The data obtained in this study show significant differences between the different karst systems of the southern Piedmont.

The monitoring data relating to flow rate, to the temperature and to the specific electrical conductivity, the tests with tracers and chemical data provide information with each other in agreement. A single type of data is not sufficient to understand the hydrological functioning of a given system. While the synergy of the different approaches can achieve a more complete understanding of the system.

The dominant drainage systems (Fuse and Pesio) are characterized by considerable variations of the capacity, high speed of flow and reduced mineralization. The chemical-physical response has been called "prevailing replacement".

The interconnected drainage systems (Dragonera, Tenda and secondary contributions of Bossea) can have high variations in flow (related to individual events infiltrative) or lower seasonal trends (related to the melting snow levels). The chemical response has been called "prevailing piston effect".

The systems with circulation dispersive (Ray) are characterized by values of the flows fairly constant and not correlated with the input infiltrative. The chemical response has been called "prevailing homogenization".

The lanthanides data appear to highlight differences between the different systems, but needs further confirmation.

Southern Adriatic Sea: a potential site for CO_2 geological storage

VOLPI V. (*), FORLIN E. (*) SAULI C. (*), DONDA F. (*), FACCHIN L. (*), CIVILE D. (*), MERSON B. (*), ZECCHIN M. (*)

The Southern Adriatic Sea is one of the five prospective areas for CO_2 storage, being evaluated under the three-year European SiteChar project dedicated to the characterisation of European CO_2 storage sites (FP7). Among two onshore projects, a gas reservoir in Poland and a sandstone aquifer in Denmark, and two offshore projects in the UK North Sea and Mid Norway, the Southern Adriatic Sea is probably one of the most challenging site in the SiteChar project, due to the fact that the potential reservoir is represented by a carbonate formation. The main objective of this study is to build a structural model of potential reservoir-caprock systems in carbonate formations , suitable for CO_2 storage in the Southern Adriatic Sea. The building of the 3D geological model plays a key role since it represents the starting point for further evaluation in the application of the CO_2 Carbon Capture and Storage (CCS) techniques in this area.

Key words: SiteChar, *Southern Adriatic*, *CO_2 geological storage*, .

INTRODUZIONE

Carbon Dioxide (CO_2) release to the atmosphere is increasing as our modern industrial society continues to develop.

Growing of CO_2 concentration in the atmosphere causes global warming, which impacts on climate change.

The European Union has been identifying ways to reduce CO_2 concentrations in the atmosphere through different specialized projects. The SiteChar project (FP7) dedicated to improving the characterization of sites for the geological storage of CO_2 has been launched in January 2011. The project's objective is to to provide a methodology for assessing potential storage sites. SiteChar will provide a valuable tool for the roll-out of geological storage on industrial scale in Europe. Led by IFP Energies Nouvelles, the project brings together another sixteen partners from research and industry, as well as the consultancy sector, from ten EU countries: AGH, ECN, ENEL, GEUS, GFZ, IMPERIAL, NERC, OGS, PGNiG, Statoil, TNO, SINTEF-PR, UniRoma1-CERI, UfU, Vattenfall and the Scottish Government.

Five European potential storage sites have been selected as test sites for the research work because they are representative of various geological contexts: a North Sea offshore multistorage site (gas field and aquifer) in the United Kingdom, an onshore

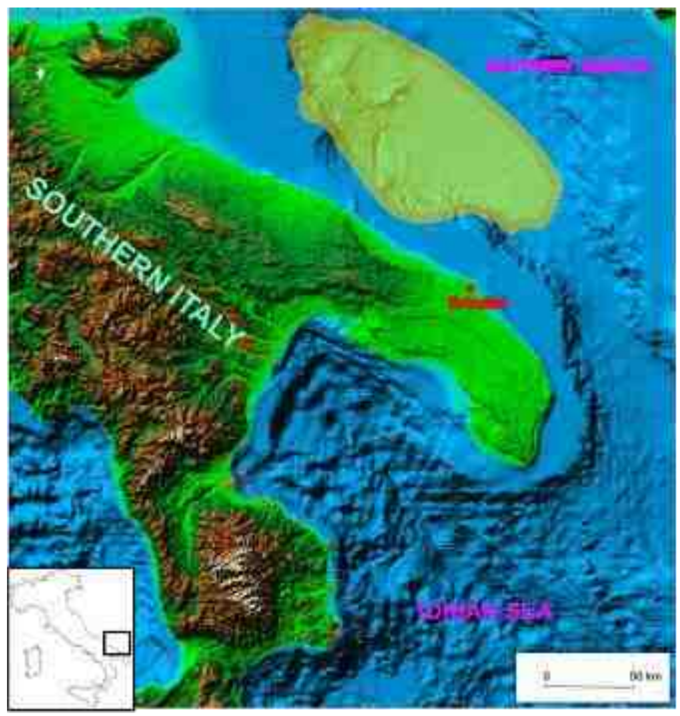

Fig. 1 – Location map of the study area

aquifer in Denmark, an onshore gas field in Poland, an offshore aquifer in Norway and, finally, a carbonate aquifer in the Southern Adriatic Sea. The Italian Southern Adriatic Sea is an area with minor oil and gas industrial activity. Carbonates are the main formations that were targeted during the limited hydrocarbons exploration in the region. This study looks at

the geological characterization of potential structures suitable for CO_2 injection, lying offshore the South Adriatic Sea (Fig.1).

The Southern Adriatic Sea is a tectonically stable area representing the foreland of both the Apennines and the mountain chain which runs through Montenegro, Albania and Greece. This area belongs to the Adria plate, or more precisely, Apulian platform. The Adria Plate constitutes the

(*)Istituto Nazionale di Oceanografia e di Geofisica Sperimentale OGS Borgo Grotta Gigante 42/c 34010 Sgonico (Trieste)

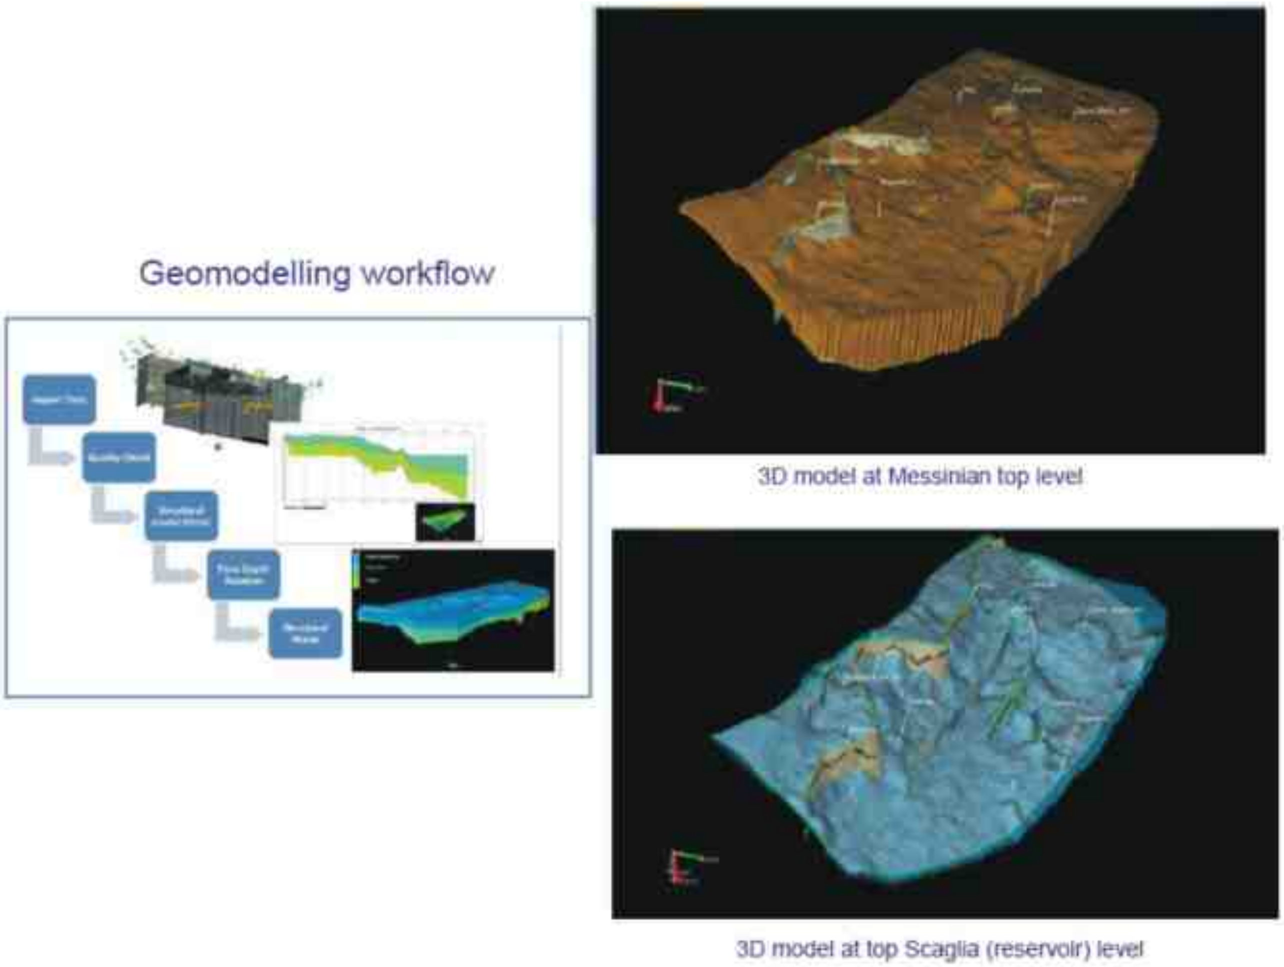

Fig. 2 – Geomodelling workflow and 3D view of the structural assessment of reservoir top and caprock top.

foredeep and foreland area with respect to the circum-Adriatic belt system. This comprises the Apennines, Southern Alps, Dinarides and Hellenides.

From the CCS point of view, the sequence that would be idoneous to potentially contain the injected CO_2 is the Scaglia Formation (middle upper Cretaceous). It has an average thickness of 50 m, hosting a and wackstone and mudstone saline aquifer. The caprock is represented by the marls of the Oligo-Miocene formations and by the Plio-Pleistocene clay.

In some parts, the aquifers show oil or gas mineralizations. A wide range of storage structures were identified within this analysis (e.g. continuous layers, anticlines and fault systems). These features required specific studies, since the CO_2 behaviour may vary within each structure.

The seismo-stratigraphic and structural analysis of multichannel seismic profiles, through the correlation of boreholes drilled in the area, led to the building of 3D geological model of the whole study area and the petrophysical characterization of the identified structures suitable for CO_2 injection (Fig.2).

Aknowledgments

This work has been funded by European SiteChar project (FP7), led by IFPEN (dr. Florence Delprat –Jannaud).

The pyroclastic level of Amantea Basin (Coastal Chain, north-western Calabria)

CANNATA C. B. (*), DE ROSA R. (*), MUTO F. (*) & DAVI' M.

Key words: *Amantea Basin, Pyroclastites, Tephra.*

INTRODUCTION

The Amantea basin is one of many Neogene basins along the Tyrrhenian margin of Calabria (DI NOCERA *et alii*, 1974; ORTOLANI *et alii*,1979; COLELLA, 1995; MATTEI *et alii*,1999). The sedimentary infill is characterized by five main depositional units (Fig. 1), bounded by stratigraphic disconuities (MUTO & PERRI, 2002). The onset of the basin started during the early Tortonian, in response to tectonic subsidence induced by extensional faulting. The first unit shows a time-transgressive sedimentary evolution for the basin, with facies associations varying from alluvial fan to submarine fan deltas. In the second unit an alluvial fan overlain by a carbonate platform depositional system is present. It overlies the first unit with an angular unconformity, due to the fall of the sea level and synsedimentary tectonic activity. During the deposition of the upper part of the second unit (late Tortonian), the basin was subjected to contractional deformation. It strongly influenced the development of the sedimentary sequence, producing numerous unconformities in response to the growth of transpressional structures. At this time a new rise of sea level occurred. It caused transgression over adjacent continental zones. The third unit records these phenomenas. Local emergence of basin-fill produced intrabasinal sediments and the deposition of coarse-grained fan at the base of the unit. A successive drop of the sea level brought to the development of a thin evaporitic succession which characterizes the fourth unit. It starts with an angular unconformity on sediments and bedrock dated back to late Messinian. The fifth unit is characterized by marine sediments lying at varied topographic levels, testifying the uplift of the basin that continued through the Pleistocene. The basin experienced transtensional and transpressional phases during the Pliocene. The last deformation phase was characterized by extensional fault systems, dipping toward Tyrrhenian Sea, ending

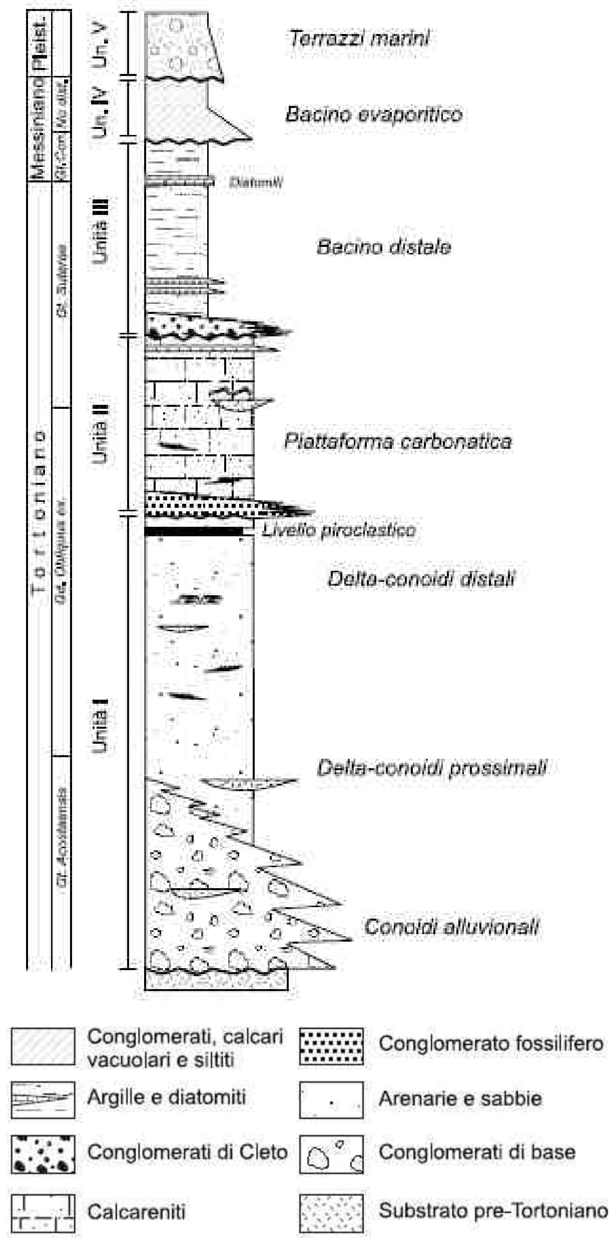

Fig. 1 – Schematic stratigraphic column of the sedimentary sequence of the Amantea basin (Muto & Perri, 2002)

(*) Department of Earth Science, University of Calabria (Arcavacata di Rende, CS)

the basin emergence.

The volcanic level object of this study has been recognized within the first depositional unit of nineteen outcrops.

Field observations and also petrographic and geochemical analyses revealed that the pyroclastites belong to a sub-areal, explosive volcanism of rhyolitic composition, which suffered a primary transport via aereal or flows. On the field, the volcaniclastic level shows centimeter thick-plane parallel layers, light brownish to dark grey, yellow or deep yellow, with grain size varying from silt to coarse-grained sand. On the top the raising of thickness is associated with a decreasing of the grainsize of deposit. Coarser layers are massive or bended, while the thinner are laminate bended. Each flow unit of the deposit shows a clear gradation with rhythmic alternation which is associated to sedimentary structures. It gives inferences for a turbidity current origin. Therefore we propose the idea that the volcaniclastic level of Amantea Basin takes origin from secondary sedimentation by turbiditic flows, mixing with sedimentary silico-clastic materials in marine environments. The rhyolitic composition induced to think for the late stadies of Sardinia magmatic activity.

Architectural style and facies distribution of channel and channel-lobe transition zone in the Lower Messinian turbidite systems of Laga Basin (central Apennines, Italy)

DOMENICO CANNATA (*), SALVATORE MILLI (*) & MASSIMILIANO MOSCATELLI (**)

Key words: *Lower Messinian turbidite systems, facies association, architectural style, channel, channel-lobe transition deposits, Laga Basin, central Apennine.*

INTRODUCTION AND GEOLOGICAL SETTING

Turbidite channels represent the main ways through which gravity flows transport large volumes of sand and mud in deep-water basins. Most of researchers carried out in the last years have been addressed to define mechanisms of formation and filling of sinuous channels typical of fine-grained mud-rich turbidite systems, while little is known about mode of formation and filling of the channels developed in coarse-grained sand-rich turbidite systems. The data presented here want to contribute to better define the main features of the channels developed in coarse-grained sand-rich turbidite systems as those occurring within the Laga Basin (central Apennine, Italy). Our analysis is based on field data and on the measure of several stratigraphic-sedimentological sections for a total thickness of about 13,000 m. The aim is to describe the channelform geometry and the channel hierarchy, the mode of their formation and filling, and how the features of channel deposits vary from up- to downstream along the depositional profile. The lower Messinian Laga turbidite basin developed since the late Tortonian, when the ensuing propagation of the Apennine compressive thrust-front led to the progressive fragmentation, reorganization and closure of the Marnoso-arenacea foreland basin system. Causing this the Laga Basin shows the typical features of a confined basin where thrust propagation controlled shape, dimension, and topography of the basin as well as the geometry of the deposits and resulting facies.

STRATIGRAPHIC AND SEDIMENTOLOGICAL DATA

The turbidite deposits of Laga Basin constitute a turbidite complex forming a third-order composite depositional sequence (Laga Depositional Sequence, LDS) made up of several turbidite systems in which it is possible to recognize, from up to down current (i.e., from NW to SE) a channel complex zone, a channel-lobe transition zone, and a lobe zone. Facies analysis allowed to construct two possible facies tracts showing the genetic relationships among channel, channel-lobe transition, and lobe zones. These facies tracts highlight the close physical relationships among these three zones and allow, together with others stratigraphic and sedimentological considerations, to attribute the turbidite depositional systems of LDS to type II systems by MUTTI (1992).

Channelized deposits of LDS form a complex hierarchy of sandstone bodies reflecting deposition of turbidity currents at different spatial and temporal scales. Field analysis based on the measure of several stratigraphic-sedimentological sections and detailed correlation panels, allowed to recognize several facies and a channelform hierarchy ranging from single channels, composite channels, and channel complexes. The surfaces bounding the single channels represent diachronous surfaces forming through the passage of several turbidite currents. On the other hand, surfaces bounding composite channels and channel complexes represent the envelopment of several erosional surfaces formed by the migration of single channels. Single channel exhibit facies change from channel axis to channel margin, and a vertical stack of often amalgamated bedsets formed through the migration of 3D bedforms. Ripples and dunes document the movement of sediment bedload and constitute the building blocks of compound and composite dune, approximately from 1 to 3-4 meters thick and several tens of meters long. The life of a single channel is mainly dependent on its stability in a given sector of the fan, a factor that is strongly influenced by the interaction between flows and topography. This interaction can lead to avulsion processes enabling migration of the single channels and the formation of composite channels. Finally, channel complexes represent the channelized sectors of the turbidite systems and are internally characterized by a hierarchy of channel bodies reflecting i) the lateral migration of composite channels driven by avulsion, and ii) the back-filling processes of the system. Unlike for single and composite channels, such mechanisms are under the control of allocyclic factors, such as climate and tectonics, which in turn control the variations in sediment supply. The plan geometry reconstruction of single channels indicates for these architectural elements a funnel-shape geometry, having a narrower section upstream and a wider section downstream, a

(**) Istituto di Geologia Ambientale e Geoingegneria, CNR, massimiliano.moscatelli@igag.cnr.it.

sector this latter that in part coincides with the channel-lobe transition zone. Coherent with this channel shape are also the dimensions and the geometry of the bedforms showing, from up to down-profile, a reduction of their height, an increase of their lateral extension and locally the passage from 3D to 2D geometry. The down-profile widening of the channel also promoted overbank deposition and the formation of thick fine to very-fine grained sandstone bodies with well-developed climbing ripples. The interaction between the gradient of depositional profile, volume of flows and concentration of coarser fraction (i.e., sand), and topography (either related to substrate or depositional relief) is considered responsible for this plan shape of channels. In the Laga Basin such relationships suggest also that the persistence of a single channels in a certain position controls the stacking pattern of lobes at the level of lobe stack. Avulsion processes of the channel appear to control, instead, the stacking pattern of lobes at level of lobe sets and lobe complexes.

High-resolution sequence stratigraphy of clastic systems: autocyclic and allocyclic controls, and implications to the concept of sequence

OCTAVIAN CATUNEANU (*) & MASSIMO ZECCHIN (**)

Key words: *allocyclicity, autocyclicity, clastic systems, high-resolution sequence stratigraphy*.

Outcrop- and core-based studies are aimed to recognize features that are well below the seismic resolution, and represent the basis for high-resolution sequence stratigraphy. Such studies adopt the most practical ways to subdivide the stratigraphic record, and take into account stratigraphic surfaces with physical attributes that may only be detectable at outcrop scale. The resolution offered by exposed strata typically allows the identification of a wider array of surfaces as compared to those recognizable at the seismic scale, which permits an accurate and more detailed description of cyclic successions in the rock record (ZECCHIN, 2007) (Fig. 1). These surfaces can be classified as 'sequence stratigraphic', if they serve as systems tract boundaries, or as facies contacts, if they develop within systems tracts (CATUNEANU, 2006) (Fig. 1). The sequence boundaries that may be employed in high-resolution sequence stratigraphy are represented by the same types of surfaces that are used traditionally in larger scale studies, but at a correspondingly lower hierarchical level.

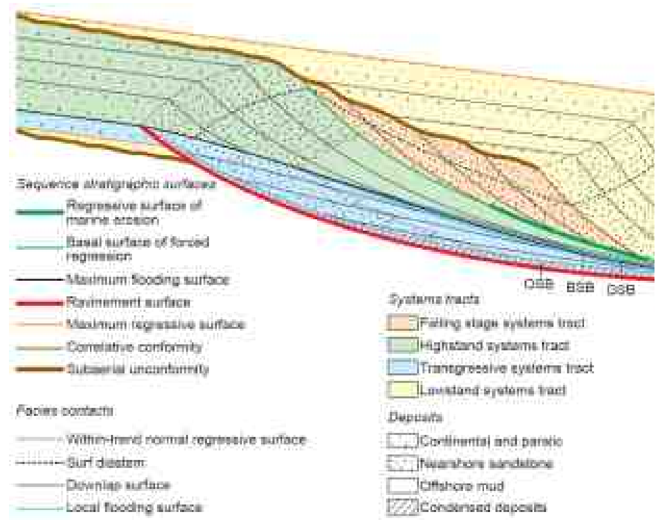

Fig. 1 – Sequence stratigraphic surfaces, facies contacts, condensed shell beds and systems tracts developed during a full cycle of base-level change in a clastic shelf/ramp setting. BSB – backlap shell bed; DSB – downlap shell bed; OSB – onlap shell bed.

Both allogenic and autogenic processes may contribute to the formation of sequence stratigraphic surfaces, particularly at the scale of fourth-order and lower rank cycles. This is the case with all surfaces that are associated with transgression, which include the maximum regressive surface, the transgressive ravinement surfaces and the maximum flooding surface, and, under particular circumstances, the subaerial unconformity as well (Fig. 2). Not all autocyclic processes play a role in the formation of sequence stratigraphic surfaces, but only those that can influence shoreline shifts. Any changes in shoreline trajectory, whether auto- or allocyclic in origin, influence the stratal stacking patterns in the rock record which sequence stratigraphic interpretations are based upon.

The discrimination between allo- and autocyclic processes that control changes in shoreline trajectory is a matter of interpretation and is tentative at best in many instances. For this reason, the definition and nomenclature of units and bounding surfaces need to be based on the observation of stratal features and stacking patterns rather than the interpretation of the controlling mechanisms. In this light, we extend the sequence concept to include all cycles bounded by recurring surfaces of sequence stratigraphic significance, irrespective of the origin of these surfaces (Fig. 3). The updated sequence concept promotes a

Sequence stratigraphic surface	Control	
	Allogenic	Autogenic
Subaerial unconformity	√	√
Maximum regressive surface	√	√
Maximum flooding surface	√	√
Transgressive ravinement surface	√	√
Basal surface of forced regression	√	
Regressive surface of marine erosion	√	
Correlative conformity	√	

Fig. 2 – Controls on the development of sequence stratigraphic surfaces. With the exception of the three subaqueous surfaces that form specifically in relation to forced regression, all other sequence stratigraphic surfaces may have an autogenic origin.

Sedimentary cycles	Origin of cycles	Subdivisions	Bounding surfaces
Stratigraphic: sequences	Allocycles or autocycles, related to shoreline shifts	Systems tracts	Sequence stratigraphic
Sedimentologic: bedsets	Autocycles, independent of shoreline shifts	Beds, bedsets	Facies contacts

Fig. 3 – Classification of sedimentary cycles into (1) stratigraphic, with applications for correlation, and (2) sedimentologic, with applications for facies analysis. Sequences are defined by the recurrence of the same types of sequence stratigraphic surface in the geological record, irrespective of the origin (i.e., allo- versus autogenic) of these surfaces.

separation between the objective observation of field criteria and the subsequent interpretation of controlling parameters, and stresses that a sequence stratigraphic unit is defined by its bounding surfaces and not by its interpreted origin.

Following these considerations, the use of high-frequency sequences eliminates the need to employ the concepts of parasequence or small-scale cycle in high-resolution studies, and simplifies the sequence stratigraphic methodology and the nomenclature.

Characters and significance of the coarse-chaotic deposits within the deep-sea turbidite systems of the Northern Apennines (Oligocene-Miocene, Macigno Fm.)

GIANLUCA CORNAMUSINI (*)

Key words: *coarse-chaotic deposits, turbidite systems, provenance, Oligocene-Miocene, Northern Apennines.*

INTRODUCTION

Coarse-disorganised and chaotic deposits (clasts > 5 cm) are generally produced by mass-flows like debris flows. They reveal a great importance when included in deep-sea turbidite systems, because they represent particular flow events. They generally occur inside very proximal turbidite systems, whereas are unusual for distal and high-efficiency ones. The significance and importance of the coarse-disorganised and chaotic deposits associated with the turbidite systems have been often undervalued, also due to their subordinate recurrence. Based on their sedimentological features, stratigraphy and composition, they can furnish a lot of relevant informations about: triggering mechanisms and events, transport and depositional processes, flow-transformation processes, palaeogeography and composition of the sourcing and feeding systems, features of the shallower basin, of the depositional systems and of the slope, physiography of the deep-sea basin, efficiency of the turbidite system, etc. To the regard, the diachronous foredeep turbidite systems of the Late Oligocene-Early Miocene of the Northern Apennines, represent a good chance to observe such deposits and to consider their significance. Moreover it is some more intriguer due to the role that these deposits can play about the palaeogeographic/geodynamic reconstruction of such still enigmatic sector of the Northern Apennines. The turbidite systems objects of this research are the so-called "Macigno costiero" and "Macigno del Chianti" of the Southern Tuscany, ranging in thickness respectively about 600 meters and 1500-2000 meters. They are represented by several facies associations, with the occurrence of rare coarse-disorganised levels. These turbidite successions include thick olistostromes (submarine slides coming from the orogenic units stack) and coarse-disorganised deposits, these latter subject of this work. The restricted areas where such deposits crop out are (from the west, Fig. 1): La Spezia-Cinque Terre, Baratti-Piombino, Calafuria and Punta Ala along the Tyrrhenian coast ("Macigno costiero"), Chianni, Val d'Orcia and Chianti Mts in the tuscan inland ("Macigno del Chianti"). Some of these have been studied by sedimentological or compositional point of views by a few researchers (i.e. PATACCA, 1973; FERRINI & PANDELI, 1983; CORNAMUSINI *et alii*, 2002).

commonly disorganised/chaotic, poorly sorted, with intrabasinal or extrabasinal clasts (pebbles and cobbles) dispersed inside a muddy matrix and with none or very poor organisation, sometimes with a slight orientation of the clasts. These last are well-rounded with spherical or bladed shapes.

Mass flow deposits contained into the Macigno turbidite systems can be classified in three types, based on their sedimentological and compositional features (Tab. 1). Type A - mainly intrabasinal coarse disorganised-chaotic deposits, subdivided into three portions, upward (Fig. 2): - basal lenticular graded pebbly sandstones with extrabasinal clasts (facies C); - pebbly mudstone with muddy-silty matrix containing dispersed intrabasinal carbonate clasts, fossils and floating muddy-silty slides (facies B'); - similar to facies B', but dominated by muddy-silty slide/slump floating blocks (facies A'). Type B - mainly extrabasinal coarse disorganised-chaotic deposits. They are characterised by a muddy-sandy matrix with dispersed well-rounded extrabasinal clasts (facies B'''). Sometimes vertical facies changes can be present, with a matrix-poor conglomerate (pebbles) (facies B'') at the bottom and not-rounded sandstone cobbles/boulders (intrabasinal) and floating slumped silty-muddy blocks (facies A) at the top. Type C - chaotic huge bodies of allochthonous slides (olistostromes and olistoliths), very diffused in the Macigno systems, not considered here.

DISCUSSION

The features of the coarse-disorganised deposits, both Type A and Type B, agree with very flow-immature deposits, sedimented in proximal sites with respect to the sources of the flows, so to exclude long transport pathways. They allow to interpret them as produced by submarine cohesive debris flows, interacting with deep-sea turbidite fans. The composition of the clasts is relative to basement crystalline rocks and subordinately to volcanic and sedimentary rocks. It is well comparable with the composition of the closed turbidite sandstone beds, so to reveal the same or similar provenance. So, the debris flows were the products of the reworking of more proximal sedimentary systems (e.g. fan-deltas or beach), relative to extrabasinal clastic drainage. Finally, the joining of sedimentological and compositional characters of the coarse-disorganised deposits and of the interlayered sandstones represents a powerful tool to reconstruct the source vs basin infilling history and to interpret the regional-geodynamic

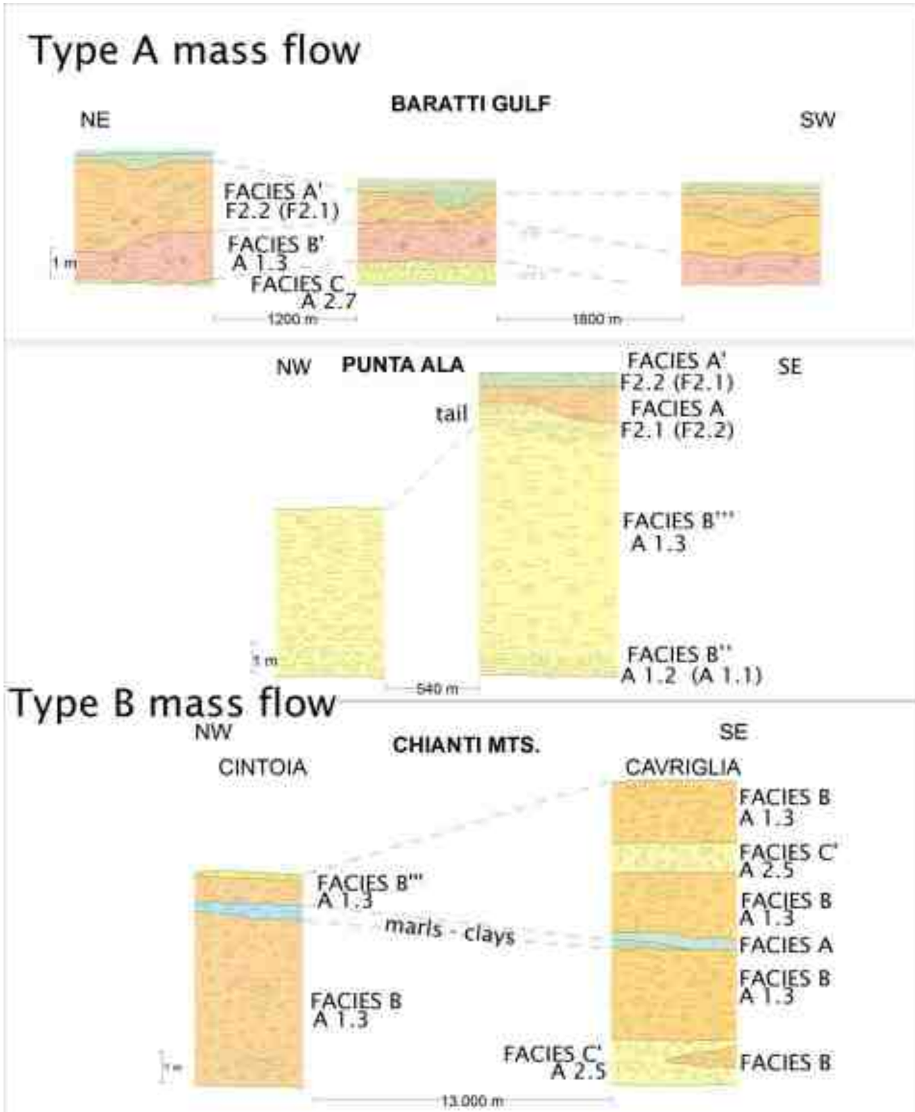

Fig. 2 – Stratigraphic and sedimentological features of the Type A and Type B mass flow deposits for the Macigno Fm. of Tuscany, with facies and subfacies distribution. These derive by this research and by the scheme of Pickering et alii (1989).

framework. To the regard, the results allow to suggest that the sources of the mass flows have to be located in the inner hinterland of the foredeep, as the Corsica-Sardinia Massif, part of the European basement. So the feeding of the debris flows was transversal to the inner foredeep, from narrow shallower basin located on top of the thrust wedge and close to the palaeoeuropean margin. Moreover, such deposits should also represent the sedimentary records of the main thrust propagation events. These considerations should also allow a reconsideration about the sourcing of the whole Upper Oligocene – Lower Miocene foredeep turbidite systems of the Northern Apennines, that are already revisited by few authors for the innermost and oldest system (Macigno costiero), but are not quite understand for the outer systems (Macigno del Chianti).

The Pleistocenic volcaniclastic layers outcropping along the Southern Tyrrhenian coast

MARCO CROCITTI (*), ROSANNA DE ROSA (**)

Key words: *Campanian volcanism, Continental tephro-stratigraphy, Volcaniclastic layers.*

PREVIOUS WORKS

In this work we studied a volcaniclastic layer widely outcropping along the Tyrrhenian coast, between northern Cilento and the southern part of Calabrian Coastal Chain. This tephra layer is well known in scientific literature and was firstly described by MIRIGLIANO (1949) who observed it at Cala Bianca and Marina di Camerota (Salerno). A very similar deposit, with a thickness ranging between 40 cm and one meter, was found by SCANDONE & LIRER (1966) near Palinuro. Here the volcaniclastic layer is interbedded in the sands of a dunal formation related to the post-Tyrrhenian marine regression. Afterwards, on the basis of lithic industry found both at the base and top of the volcaniclastites, the Authors related this deposit to the epi-Würm II (<60 ka) (LIRER *et alii*, 1967). They also supposed a provenance from a submarine volcano situated in the southern Tyrrhenian Sea (SCANDONE & LIRER, 1966; LIRER *et alii*, 1967).

Outcrops of a very similar level, in the same stratigraphic position, are also reported by AMELIO *et alii* (1997) near Maratea; Authors attribute it to campanian volcanoes. A similar provenance has been proposed by SCARCIGLIA *et alii* (2006) for a tephra layer found in Scalea which can be correlated with those previously described.

Due to the uncertainty in the attribution of this level to a precise volcanic source, we decide to do a detailed petrographic and geochemical study, comparing the results with those of proximal and distal products of Southern Italy's volcanoes.

SAMPLING AND ANALYTICAL METHODS

The studied pyroclastic level outcrops with a good continuity all along the Southern Tyrrhenian Coast. In this work we collected and studied the deposits outcropping in three sectors: 1) Cilento coast (Punta Licosa and Palinuro); 2) Maratea valley (Cersuta- Capo La Nave, Curzo and Maratea); 3) Calabrian Coastal Chain (Diamante, Belvedere, Sangineto, Coreca) (Fig. 1). Here the volcaniclastic layer has a thickness ranging between 0.4 and 2.2 meters and is interbedded with continental or shallow-sea Pleistoicenic deposits.

As a whole 25 samples have been investigated. A petrographic and geochemical analysis was carried out on whole rock samples. Moreover, we conducted a microanalytical study by SEM-EDX on selected samples to infer the composition of minerals and glass fragments. Finally, we made a granulometric study on feldspar crystals by image analysis with the purpose of evidencing variations in the maximum size of minerals which could give information about the provenance of volcanic material.

PETROGRAPHY AND MINERAL CHEMISTRY

The volcaniclastic layers sampled in the different localities show very similar petrographic features, with the exception of the amount of non-volcanic material, that can reach a maximum of 20% in volume, and of weathering degree, which is rather variable. Another difference consists in the grain size of the deposits, which decreases from North (Cilento Coast) towards South (Coastal Chain).

The non-volcanic component is represented by lithics of different nature and quartz crystals. The matrix is made up of fine ash and glass shards, often cuspate. Volcanic component is

Fig. 1 – Sampling map.

(*) Dipartimento di Scienze della Terra e Geoambientali, Università di Bari
(**) Dipartimento di Scienze della Terra, Università della Calabria

represented by vesiculated pumices, accretionary lapilli, lava fragments and loose crystals. The most abundant phase is sanidine (Ab_{13-20} Or_{77-86}), followed by plagioclase, clinopyroxene and biotite. Leucite is always present as microphenocrysts and sometimes weathered in analcime; amphibole and opaque minerals are rare.

Plagioclase are mainly andesinic with rare An-rich crystals, bytownitic in composition.

Two different clinopyroxenes are present: one is colorless and has a Ferrosilite content less than 10% (diopside) while the other is green, more Fe-rich and can be classified as salite.

Biotite has an Mg# comprised between 66 and 75.

GEOCHEMISTRY

Due to the high weathering degree of the deposits and the presence of a non-volcaniclastic fraction, we preferred to use glass compositions obtained by SEM-EDX microanalysis for classification, rather than whole rock (Fig. 2). Glasses of all samples can be classified as trachytes in the TAS (Total Alkalies vs Silica) diagram. K_2O contents range between 5 and 10 wt% and the K_2O/Na_2O ratio is always >1.

Spider diagrams on whole rock show negative peaks in Sr and K, which can be interpreted as the result of the crystallization of feldspar, and in HFSE (High Field Strength Elements), particularly in P and Ti. This features probably reflects the composition of mafic parental magmas and clearly indicate a source from subduction- related magmatism.

PROVENANCE OF TEPHRA LAYERS

The high potassium content, the abundance of sanidine and the presence of feldspathoids as microphenocrysts indicate a provenance from the Campanian province. This is also confirmed by the alkalies ratio vs total alkalies classificative diagram proposed by PATERNE *et alii* (1988). A provenance from a volcanic province located North of the sampling area is also suggested by the decreasing granulometry of the whole deposit and of feldspar crystals in the southernmost outcrops. Therefore, on these bases, the hypothesis of a provenance from a submarine volcano of the Aeolian Archipelago proposed by LIRER *et alii* (1967) can be ruled out.

The age of the deposits is likely comprised between 60 and 10 ka. In the Campanian area both the Phlegraean Fields and Vesuvius were active in this period. A comparison with the glass of proximal deposits of Vesuvius (SANTACROCE *et alii*, 2008) shows a good correspondence with the products of the slightly SiO_2 undersaturated rocks, which were erupted at Vesuvius

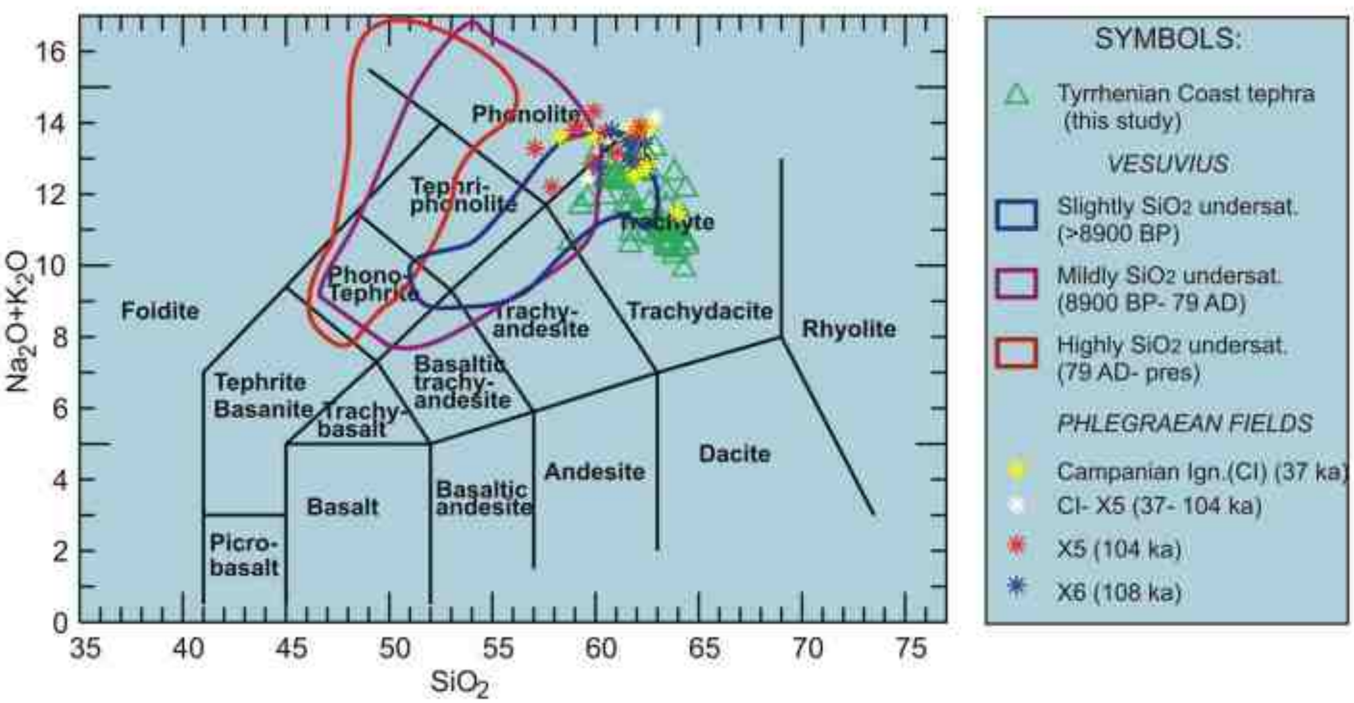

Fig. 2 – TAS (Total Alkalies vs Silica, LE BAS *et alii*, 1986) diagram for the glass of the volcaniclastic deposits outcropping along the Southern Tyrrhenian coast. Glass from Vesuvius products and for tephra layers related to Phlegraean Fields activity are plotted for comparison. Data for Vesuvius glass from SANTACROCE *et alii* (2008); data for Phlegraean Fields tephra layers from CALANCHI *et alii* (2008), KELLER *et alii* (1978), MUNNO *et alii* (2007), NARCISI *et alii* (1996), PATERNE *et alii* (1988;2008), TON-THAT *et alii* (2001), WULF *et alii* (2006).

before 10 ka BP (Fig. 2). At least five plinian or subplinian eruptions occurred during this phase; among these, Greenish Pumice (17,5 ka) and Pomici di Base (19.3 ka) glasses are more alkalies- rich than the deposits outcropping along the Southern Tyrrhenian coast, while the glasses of Codola (26,8 ka) products is less SiO_2- rich. On the whole, it seems that a provenance from Vesuvius activity can be ruled out, even if further data on mineral chemistry are necessary to confirm this hypothesis.

The most violent eruption of Phlegraean Fields is that of Campanian Ignimbrite (CI) (37 ka). The products of this eruption are very similar to those of our study from both petrographic and chemical point of view. The finding of both salitic and diopsidic clinopyroxene and of leucite microphenocrysts (beside sanidine, plagioclase, biotite and amphibole) in the products of CI strongly suggests that the studied deposits are related to this eruption. Tephra layers referred to Campanian Ignimbrite were found in different cores in the Mediterranean Sea (Fig. 2) and their composition is comparable with the glass of our samples.

In Fig. 2 other tephra layers attributed to the activity of Phlegraean Fields are plotted, including the so-called X5 and X6 layers (104 and 107 ka respectively, Keller *et alii*, 1978). Their composition is similar to that of our samples, but the lack of data about their mineralogy does not allow an undoubted correlation.

Key words: *marine tephra, SEM-EDX analyse, Southern Italy volcanism.*

INTRODUCTION

In this work we present petrographic and geochemical data on tephra layers found in the cores sampled in the sedimentary succession of the Paola Basin during an oceanographic survey carried out in 1991 by the Bologna Institute of Marine Geology.

THE PAOLA BASIN SYSTEM (PBS)

The Paola Basin is an elongated trough bounded by the Calabrian Arc terranes to the east, while to west it is separated by the Tyrrhenian abyssal plain by several submarine reliefs. The northern and southern limits are represented by the Sangineto line and by the Angitola canyon, respectively.

In the Paola Basin the post- Miocene sedimentary sequence reaches 5 km of thickness; the uppermost part of the sequence, Quaternary in age, is referred to the Paola Basin System (PBS) and partially fills a present day physiographic slope basin (TRINCARDI *et alii*, 1995).

The source area of the sediment filling the basin is represented by the Calabrian Coastal Range, mainly composed of Mesozoic ophiolites and Paleozoic basement nappes (phyllite, schist, gneiss and plutonics) thrust over the Triassic to Paleogene Apenninic sedimentary units (dolostone, limestone and clastic rocks) (AMODIO MORELLI *et alii*, 1976; CARRARA AND ZUFFA, 1976; DIETRICH, 1988).

The quick uplift of the Calabrian Coastal Range (up to 1+-0.1 mm/yr, WESTAWAY, 1993) determined high sedimentation rates in the shelf area. As a consequence, sediment was often supplied to the basin by mass failure from the shelf (TRINCARDI *et alii*, 1995).

The PBS sequence is marked, at the base, by a pronounced unconformity and is divided in three major turbidite stages, identified on the base of correlation of drape deposits; these represent pelagic sedimentation related to periods of decreased sediment supply and separate turbiditic sequences (TRINCARDI *et alii*, 1995 and references therein). The lowermost drape deposit is the so-called "Green Drape" and reaches 30 meters of thickness; the second, named "Red Drape", was emplaced during sea-level rise that led to the high stand of oxygen isotope Stage 5e; finally, the uppermost "L-Q Drape" (Late Quaternary) has been related to the Late Pleistocene- Holocene rise and highstand of sea level. The base of this deposit can be therefore dated at about 12 ka (TRINCARDI *et alii*, 1995).

THE TEPHRA LAYERS

In all the cores, at a depth of about 20 cms, a tephra layer has been found interbedded with the deposits of the LQ Drape and referred to the A.D. 79 eruption of Vesuvius (TRINCARDI *et alii*, 1995). The layer is few cms thick and is entirely composed of white and grey pumices, shards and few loose crystals.

A second volcaniclastic layer has been found in the turbiditic sequence comprised between the Red Drape and the Green Drape, just above a plane which has been dated at 20 ka (CRITELLI *et alii*, 1995).

Petrography

White and grey pumices from the upper level are highly vesicular and contain phenocrysts of biotite, clinopyroxene, sanidine, bytownitic plagioclase and several microlites of feldspatoids. In the lower level veiculated pumices and rare unvesiculated fragments are present. Phenocrysts are represented by plagioclase, clinopyroxene, biotite and few oxides.

Geochemistry

In the TAS diagram (Fig 1) the composition of glasses from the upper level obtained by SEM-EDX analyses falls in the field of the phonolites. The lowermost level has a dacitic- rhyolitic composition and a High Potassium calc-alkaline affinity (HKCA).

(*) Dipartimento di Scienze della Terra, Università della Calabria

(**) Ismar, Geologia Marina, Cnr, Bologna, Italy

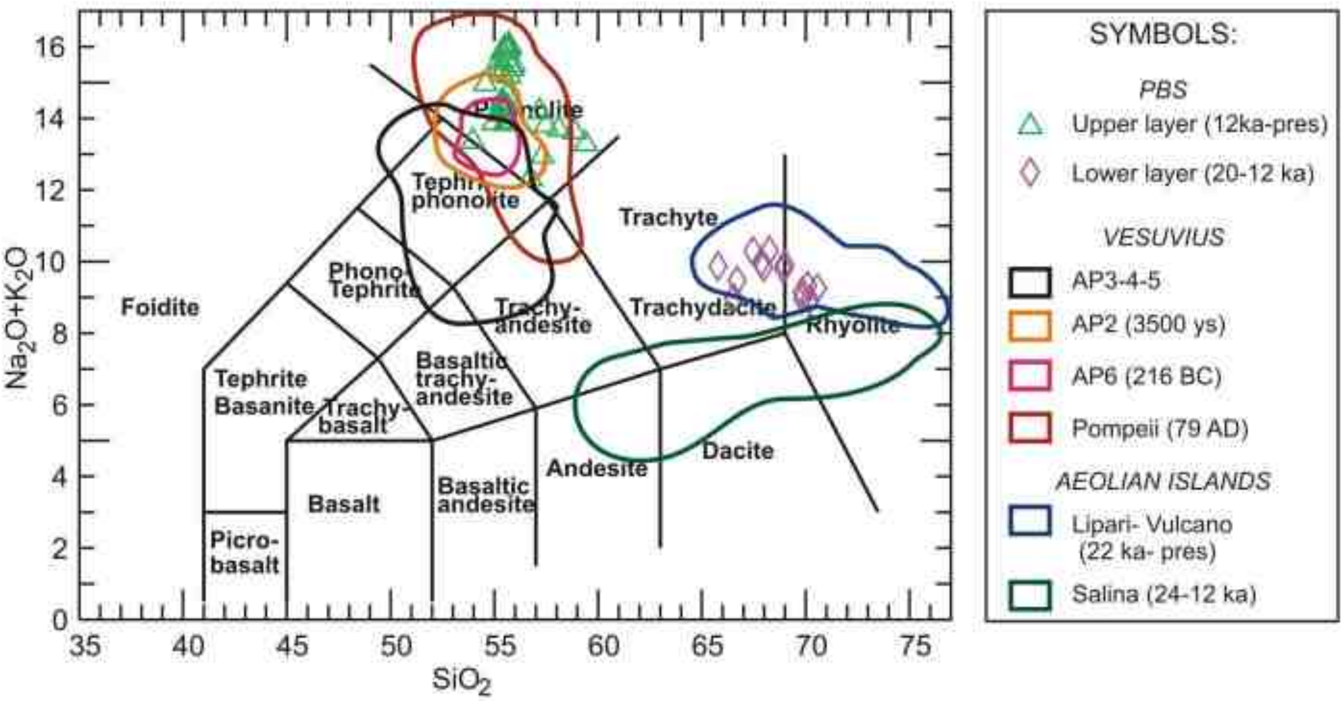

Fig. 1 – TAS (Total alkalies *vs*. Silica, LE BAS *et alii*, 1986) diagram for the glass of the two tephra layers of the Paola Basin. Contours represent glass composition of the proximal products of Vesuvius and Aeolian Islands of the last 20 ka. See the text for discussion.

The whole rock compositions (obtained by XRF) are less Silica and alkalis- rich than the glasses. The spider of incompatible elements show for samples of both levels the negative peaks in High Field Strength Elements which are characteristic of arc-related magmas.

PROVENANCE OF TEPHRA LAYERS

Upper layer

The absence of non-volcanic detritus suggests that this tephra layer deposited sin-eruptively. Information about the age (younger than 12 ka), its phonolitic composition and the presence of abundant feldspathoids in the groundmass clearly indicate a provenance from the Vesuvius volcano. An origin from the Campanian province is also confirmed by the alkali ratio vs. total alkali diagram proposed by PATERNE *et alii* (1988) to distinguish the tephra layers of Mediterranean region (Fig. 2).

Specifically, the phonolitic composition of the glasses clearly resembles that of the products of the "mildly silica-undersaturated" magmas, erupted between 8900 yr BP and A.D. 79 (SANTACROCE *et alii*, 2008). The products of three plinian eruptions (A.D. 79 "Pompeii", 4300 yr BP "Avellino" and 8900 yr BP "Mercato"), and at least six sub-plinian events (AP1-6) belong to this group. Among these, Avellino and Mercato can be excluded as sources of the volcaniclastic layer for the absence of feldspar in their mineralogical assemblage; moreover, their products were mainly dispersed toward East. The comparison with glasses of single eruptions also allows to exclude eruptions AP3, 4 and 5, whose products are tephriphonolitic rather than phonolitic. Therefore, it seems to be confirmed that the uppermost layer is related to the Pompeii eruption (AD79); however a provenance from the AP2 (3.5±0.04 ka BP) or AP6 (217-216 BC) cannot be ruled out.

A tephra level attributed to AP2, whose chemical composition is very similar to that of the Paola basin, has also been recognized in the Monticchio lake sequence (WULF *et alii*, 2004).

Lower layer

The HK calc-alkaline affinity of the glasses, their position in the alkali ratio vs. total alkali diagram (Fig. 2) and the characteristic spider diagrams of incompatible elements clearly point to Aeolian Archipelago as the source of this layer.

Among the islands of the Aeolian Arc Stromboli is the nearest to the deposition area; however the composition of erupted products is always more mafic than that of the lower layer of PBS.

Rhyolites were erupted in the last 20 ka in the islands of Salina, Lipari and Vulcano. The products of Salina (Upper and Lower Pollara) are less K-rich and show a calc-alkaline affinity, while those of Lipari and Vulcano have a composition very similar to the lower level of PBS. As most of the recent rhyolitic products from Lipari are sub-aphiric the most probable source for the lowermost volcaniclastic layer could be from Vulcano island.

The comparison with data of ash levels found in the Mediterranean area data show a strict similarity with a level dated by PATERNE *et alii* (1998) at 11.9 ka, even if, due to its stratigraphic position (just above the plane dated at 20 ka) it seems more probable an older age. Moreover, among the possible sources it is not possible to exclude the submarine volcanoes of the Aeolian Arc, for whose products very few compositional data are available.

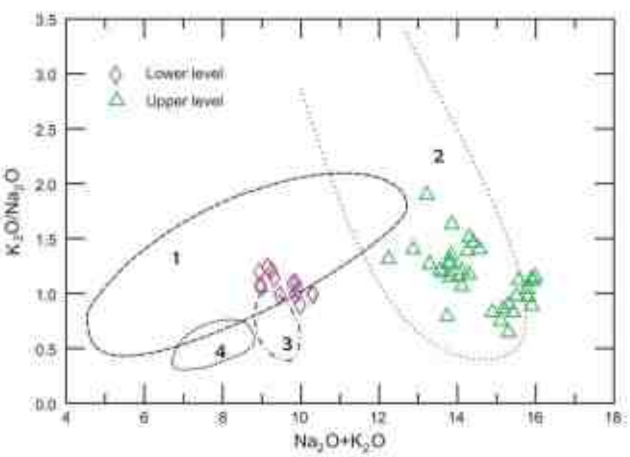

Fig. 2 – Grouping of ash layers on the basis of alkalies. 1: Aeolian Islands; 2: Campanian Province; 3: Pantelleria; 4: Etna. From PATERNE *et alii* (1988)

Unconformity-bounded stratigraphic units approach to a siliciclastic turbidite basin: the eastern part of Miocene Gorgoglione Flysch (Southern Apennines, Italy)

PAOLO GIANNANDREA (*), FRANCESCO LOIACONO (**), PATRIZIA MAIORANO (**), FABRIZIO LIRER (***) & DIEGO PUGLISI (°)

Key words: *Southern Apennines, Gorgoglione Flysch, unconformity-bounded stratigraphic units, integrated facies analysis, basin evolution.*

INTRODUCTION AND STRATIGRAPHY

The criteria of the unconformity-bounded stratigraphic units (UBSU), usually applied to continental successions, have recently been used also in the geological cartography of Quaternary volcanic areas and alluvial terraces, as well as in fluvial and shallow marine successions of Pliocene-Quaternary small basins located in foredeep or intramontane domains. These works show that the application of the UBSU criteria improves the interpretation of tectonic and sedimentary evolution of the examined areas.

Southern Apennine Chain is composed by tectono-stratigraphic units made up by several Miocene siliciclastic turbidite formations, mapped in the current geological cartography as indistinct formations. These formations testify an active deep marine clastic sedimentation in a Miocene foredeep basin area. The depositional features of these units seem to have been controlled by the structural evolution of the Apennine chain and by the eastward migration of the orogenic front. Stratigraphic, sedimentological and petrographic studies, carried out on the Middle-Upper Miocene turbidite successions, allowed to suppose the existence of a foredeep domain (Irpinian Basin, COCCO *et alii*, 1972), characterized by three progressive growing depocenters from W to E (Gorgoglione Flysch, Serra Palazzo Formation and Faeto Flysch). In this paper we propose the results of a recent stratigraphic research performed on the Gorgoglione turbidite succession, in the eastern sector of the basin (Castelmezzano, Cirgliano, Gorgoglione and Montagna del Caperino area; Fig. 1). This study shows that detailed mapping, joined with sedimentological and calcareous plankton biostratigraphic analysis, as well as clear setting of the stratigraphic boundaries can help to assess changes in turbidite systems and structural development of the basin during Langhian and Serravallian times. Well exposed outcrops on the northeastern margin of the study area allowed the recognition and assessment of four unconformities in the Pietrapertosa area. Two of these unconformities, B2 and B3 (Fig. 1), pass to paraconformities southeastward (Cirigliano-Gorgoglione area).

TABLE 1

Stratigraphic nomenclature of Gorgoglione Flysch.

		SYNTHEM (Stage)	SUBSYNTHEM (Biozone)
Gorgoglione Flysch	Gorgoglione Supersynthem	Castelmezzano (*Langhian-Serravallian*)	(MNN5b, 6a and 6b/7 of FORNACIARI *et alii*, 1996; MMi7a and 7b of SPROVIERI *et alii*, 2002)
		Cirigliano (*Langhian*)	Pietra del Corvo (MNN5a of FORNACIARI *et alii*, 1996)
			Pozzo del Pellegrino (MNN4b and 5a of FORNACIARI *et alii*, 1996)
			Ponte della Vecchia (MNN4a of FORNACIARI *et alii*, 1996)
	Val Miletta Formation		
Numidian Flysch			

The stratigraphic data suggest to divide the "Gorgoglione Flysch" into different informal units: Val Miletta Formation and Gorgoglione Supersynthem, which in turn can be subdivided into two synthems. Besides the older one (Cirigliano synthem) is divided into three subsynthems (Tab. 1). The lowermost boundary of the Gorgoglione Flysch on the eastern sectors, corresponds to a locally complex unit (Val Miletta Formation) including the Numidian-like quartzarenites and Gorgoglione-like feldspathic litharenites.

The stratigraphic analyses and the biostratigraphic results improve the reconstruction of the geometries of the sedimentary bodies and the time-space facies evolution of the synthems. Particularly sedimentologic and petrographic

characters of the upper part of the synthem point out a clear fining and thinning upward trend. Medium- and fine-grained arenites, vary in composition from quartzose sandstones to siltstones and shales, locally marked by abundant planktonic foraminifera. A very common character of the contourites (STOW *et alii*, 2002; HE *et alii*, 2008) is the frequent biogenic/terrigenous rhythmic composition (PUDSEY & HOWE, 2002). The analyzed sandy contourites are often organized in

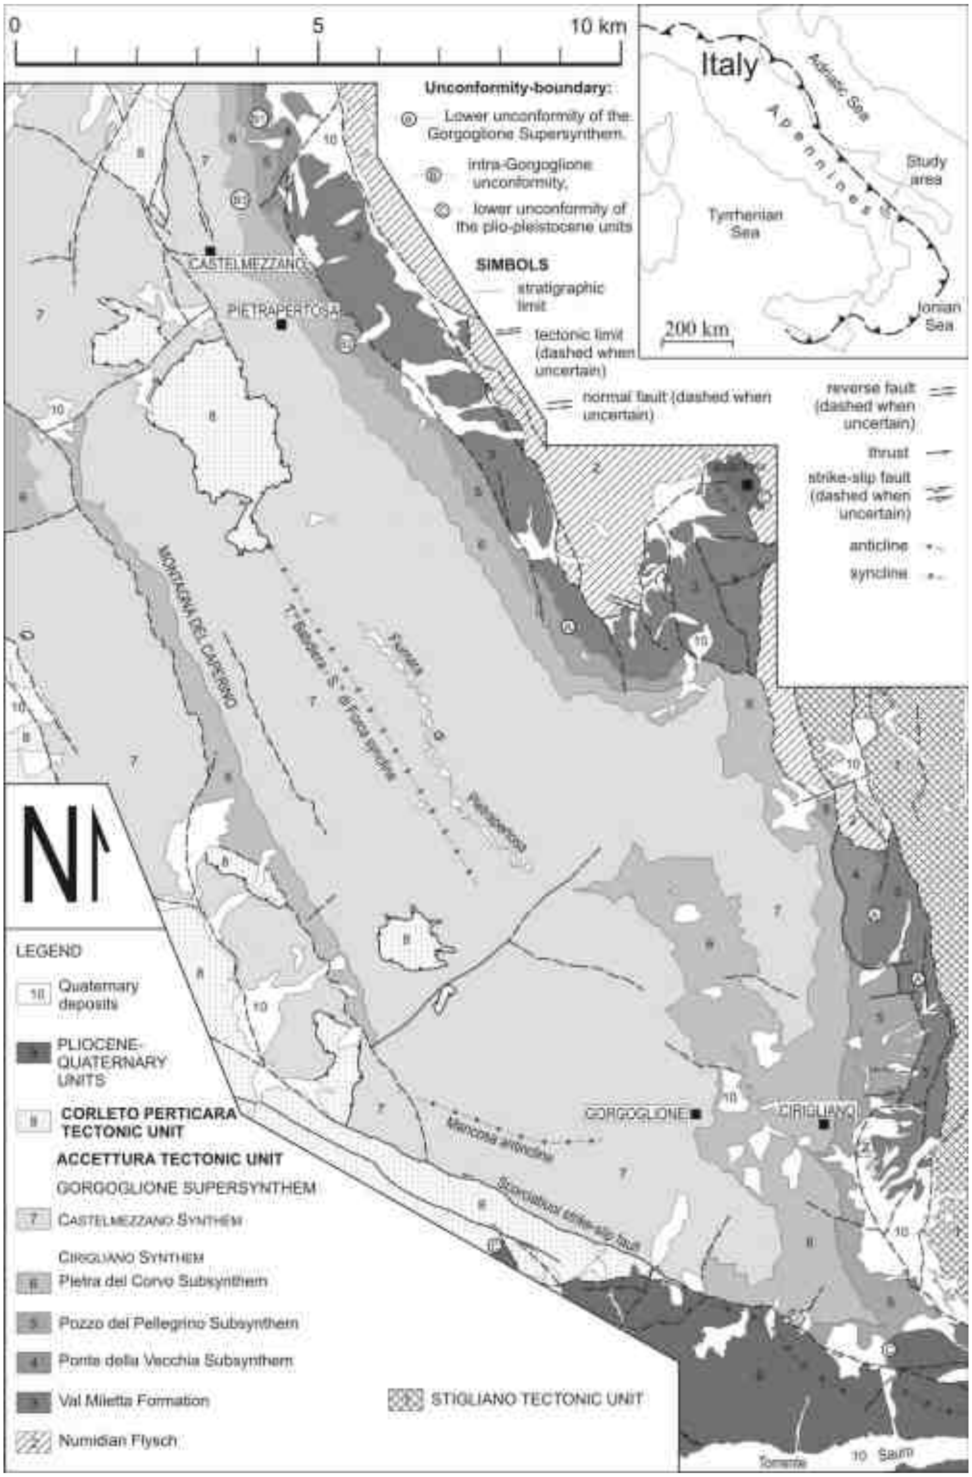

Fig. 1 – Schematic geological map of the Gorgoglione Flysch in the oriental sector of the basin.

well-marked mm-thick plane-parallel laminae, where the siliciclastic fraction alternate with biogenic horizons, very rich in planktonic foraminifers. The quartz is the most abundant mineral in the siliciclastic fraction of all the sandy contourites analyzed. It is mainly present as sub-angular to sub-rounded monocrystalline grains with high undulosity and, subordinately, as polycrystalline grains with many subgrains. Feldspars, mainly plagioclases, and little amounts of fine-grained rock fragments and carbonate clasts form the rest of the detrital framework of these rocks, whose textural maturity is usually not very high, due to the sporadic presence of a carbonate matrix.

Moreover, the relationships between tectonics and sedimentation are analyzed. The data have been finally used to propose a scheme of the tectono-stratigrafiphic evolution of the eastern sector of the basin.

Mineral phases as a tool for robust correlation of proximal-distal ash deposits in the Central Mediterranean area

GIORDANO R. (*), SULPIZIO R. (**) & CAGGIANELLI A. (***)

Key words: *Central Mediterranean area, distal and proximal tephras, mineral phases, tool for correlation.*

Tephra layers and Quaternary sedimentary archives constitute a mutual and integrative system capable of providing relevant information for both volcanological (i.e. hazard assessment) and Quaternary science research (i.e. paleoecology , paleoclimatology).

Comparative analysis of glass from proximal and distal deposits sometimes fails in providing a reliable criterion to recognise the source of a tephra (or the related eruption), owing to very similar major element compositions that makes difficult discrimination on a chemical basis. This is particularly critical for both the Campanian trachytic products (i.e. those erupted from Campi Flegrei, Somma-Vesuvius and the Ischia island volcanoes) and for the calc-alkaline rhyolitic products of the Aeolian Islands. To solve this problem, the evaluation of both the mineralogical association, and the chemical composition of the mineral phases included in the proximal tephras is required. With this approach some distinguishing features can be revealed and, if recognisable also in the distal counterpart, would represent a valid tool for correlation. Some successful examples for ther application of the method are (i) the products of Colli Albani containing both leucite and nepheline and not feldspar, or (ii) the Agnano-Monte Spina eruption ascribed to the Campi Flegrei on the basis of biotite absence.

Therefore, creation of a data-base containing compositional data of mineral phases from the proximal deposits, would make microanalysis of mineral phases from distal tephra an important tool to improve the tephro-stratigraphic correlations in the Central Mediterranean area.

Facies and processes from the confined Salto-Tagliacozzo Basin (Messinian, Central Apennines): from the outcrop to tank experiments

MATTIA MARINI (*), SALVATORE MILLI (*), MASSIMILIANO MOSCATELLI (**) MARCO PATACCI (°) & WILLIAM D. MC CAFFREY (°)

Key words: *turbidites, confined basins, facies analysis, experimental fluid dynamics.*

INTRODUCTION

The architecture of turbidite systems hosted in small basins, such as those of rifted margins or foreland basin systems is greatly controlled by topographic confinement. The influence of basin topography on the physiography of transfer conduits and terminal splays also reveals its fundamental role in governing mechanics of turbidity along-their path from the feeding system to the final sink. Fluid dynamics processes induced by topography may consist for example in flow expansion or lateral constriction, partial or complete blocking by obstacles and ponding where flows are fully contained by topography (KNELLER 1995; PATACCI 2011). These processes in turn may promote modifications in turbidity currents concentration, grain size and velocity structure and be the cause for sediment deposition or re-suspension. The research we present here was intended for re-considering published field data (MILLI & MOSCATELLI, 2000) from the Salto-Tagliacozzo Basin (S-TB hereafter) under the light of recent advances in experimental studies of particulate gravity flows and an increased awareness of the effects of topographic confinement on turbidite deposition. In particular, we combined facies analysis, palaeocurrents and geometrical constraints form the outcrop to pinpoint the configuration of a turbidite onlap and devised an *ad hoc* experimental program run at the Sorby Environmental Fluid Dynamics Laboratory (SEFDL, University of Leeds, UK) to test the effect of bounding slopes on velocity structure and deposition against different initial sediment concentration and grain size distributions.

GEOLOGICAL FRAMEWORK

The S-TB is located in Central Apennines southward of the Ancona–Anzio Line, a SSE-NNW polyphasic major regional fault (L-ACP hereafter) which since Late Triassic separated the Latium-Abruzzi Carbonate Platform (L-ACP hereafter) from the Umbro-Marchean Basin. Mainly due to the rheology of its pre-orogen succession, following the involvement in the Apennine foreland basin system (Tortonian-Messinian; Upper Miocene) the L-ACP was dissected by strike-slip-extensional faults into narrow, NNW-SSE elongated turbidite basins separated by prominent horsts of Meso-Cenozoic carbonates. The faults delimiting these small turbidite basins were later on tilted and inverted into high-angle inverse faults in the building-up of the present-day Apennine structural edifice (from the Late Messinian onwards; BIGI *et alii*, 2003). Among these basins, the S-TB hosted turbidite sedimentation during the Early Messinian. Siliciclastic turbidites were point-sourced from the N-NE whilst the carbonate horsts bounding the basin on its western and eastern sides (the Marsica and Simbruini mountain ranges, respectively) sourced olistoliths and calcareous breccias. Given the small tectonic shortening affecting the outcrop area of turbidites, it can be estimated that the basin was approximately 5 to 10 km across and some 20-30 km long in the stream-wise direction and that its size might have gradually increased as a result of filling by turbidites.

Although early sedimentological studies on S-TB turbidite infill (namely, the Argilloso-Arenacea Fm.) dates back to 80', only more recently a comprehensive depositional model was proposed (MILLI & MOSCATELLI, 2000) which emphasized the role of basin topography in turbidity currents mechanics and sedimentary facies characteristics.

OBJECTIVES, FIELD DATA AND METHODS

The main focus of this study is the oblique onlap of turbidites onto the pre-turbidite substratum (Fig. 1) at the south-western basin margin, which is well exposed in extensive outcrops between Tufo and Pietrasecca villages and, in the latter locality, along a cut on the access road to the A-24 highway.

The objective of the research was to better understand

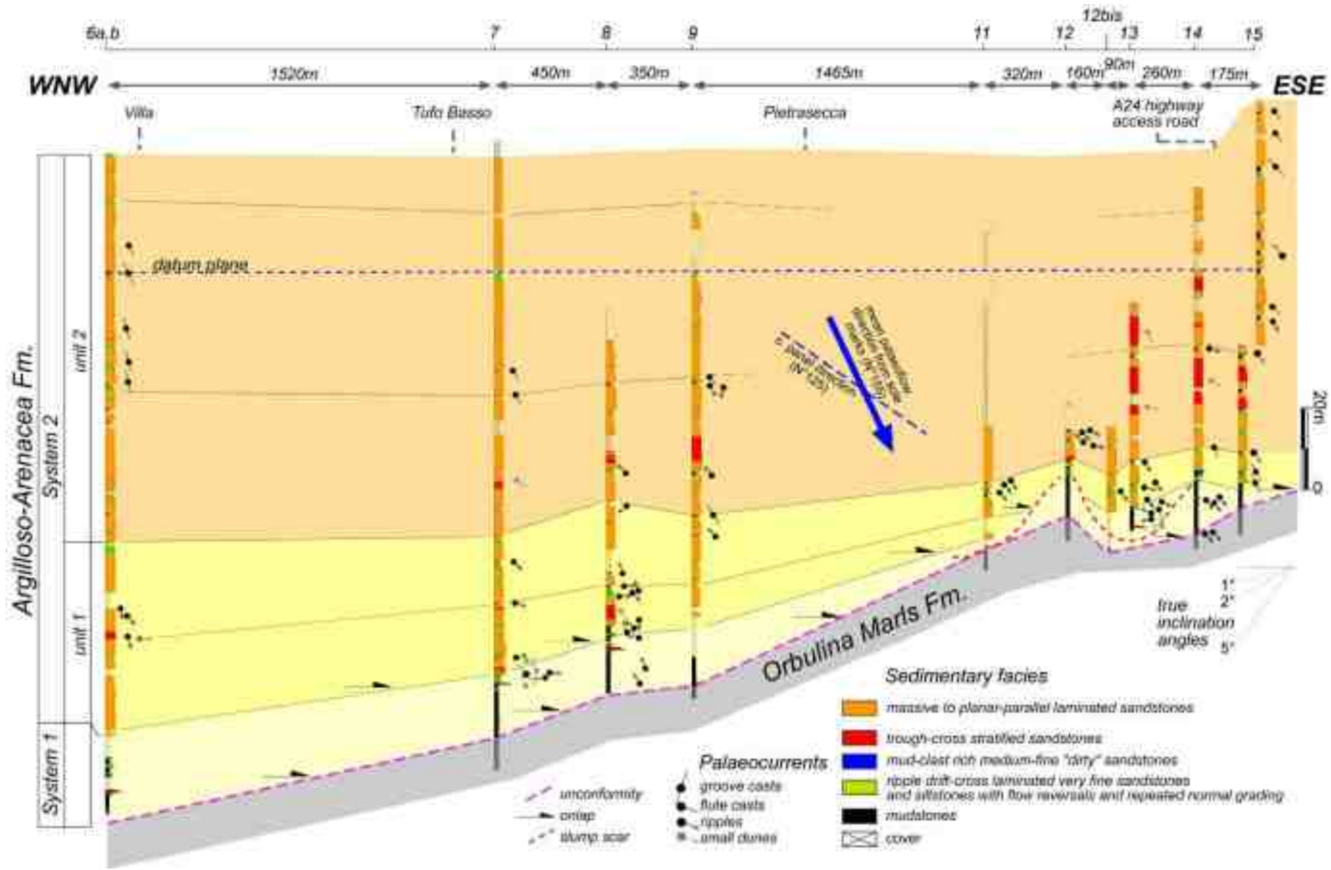

Fig. 1 – Correlation panel showing the pinch out of Argilloso-Arenacea Fm. onto the pre-turbidite Orbulina Marls. Modified after Milli & Moscatelli 2000.

palaeocurrent patterns and facies distribution in relation to the onlap configuration (i.e. the ensemble of unconformity gradient and flow incidence) and allow speculations on turbidity currents mechanics to be afterwards tested by means of on purpose-designed fluid dynamics experiments. A total of 14 stratigraphic sections were logged an correlated over a 6 km-long transect roughly parallel to the mean palaeoflow direction covering the basal 150m of the Argilloso-Arenacea Fm. Most of the measured sections were correlated walking out key-beds in the field whilst basin-scale correlations proposed by previous workers (MILLI & MOSCATELLI, 2000) were revised with the aid of ortho-aerial imagery.

FACIES, PALAEOCURRENTS AND PROCESSES

Besides classical Bouma sequence-like turbidites, which are mostly represented by thick amalgamated beds of massive-dewatered and laminated sands, a number of accessory "modified" facies were recognized that can be interpreted as the product of flow interaction with basin topography. These are: I) medium-fine grained sandstones with small 3D dunes found in the close reach of the basin margin downstream of massive-planar parallel laminated beds; II) medium-fine grained sandstones with repeated normal grading and alternating well-sorted, laminated sands and structureless, poorly sorted sands; III) mud-clast rich, structureless muddy sandstones found few m above the basal unconformity; IV) fine to very fine grained ripple-drift laminated sandstones with reverse palaeocurrents and repeated normal grading.

The occurrence of Facies I suggests a path through bedform stability regimes which departs from that of simple waning turbidity currents (BASS, 2004), possibly due to changes in the balance between sediment fall-out and bed shear stress induced by turbidity currents interaction with seafloor topography.

Repeated normal grading of both Facies II and IV would testify cyclic fluctuations in flow velocity related to internal waves forming as turbidity currents are reflected off the bounding slopes; in facies IV this feature is also associated to climbing ripples with reverse palaeocurrents (i.e. opposite to those from sole marks). Few examples of single sets of small dunes are also present which suggests that reverse flow might have attained sufficient competence and velocity to form such sedimentary structures.

The "dirty" sandstones of Facies III are found only in the mud-prone System 1 (Fig. 1) and represent the product of cohesive laminar flows forming as turbidity currents entrain cohesive sediments up to a critical concentration (BAAS *et alii*, 2009). Stratigraphic position Facies III beds points out proximity to basin margins and suggests that flow-topography interaction might have promoted both entrainment of unconsolidated mud from the seafloor and flow deceleration.

EXPERIMENTAL WORK

To better understand the meaning of some of the sedimentary features observed in the field, we devised an experimental plan aimed at addressing the effect of topographic confinement on velocity, concentration and grain size structure of contained experimental turbidity currents.

The experiments were run in a square tank 1.7 m across filled with tap water and containing a bespoke experimental basin (Fig. 2) which grossly reproduced the geometry of S-TB distal reach. The basin was roughly heptagonal in plan view and was enclosed on six sides with slopes arranged in a lower 10 cm-high ring with gentle inclinations (10° on distal slopes) and an upper one with steeper (>35°) walls which fully contained the experimental flows. On its missing side the basin hosted an inlet channel 30 cm wide and 1.6 m long through which a mixture of water and sediment analogues (fine grade glass beads and silica flour mixed in variable proportions) with different initial concentrations (from 2% to 6% by volume) was delivered by gravity at a fixed flow rate for durations of 15 and 60 s in distinct twin (i.e. with same initial sediment concentration and mixture) experiments. Velocity was measured above the distal confining slope by means of a commercial Ultrasonic Velocity Profiler (UVP, see BEST *et alii*, 2001 for the methodology) along three mutually orthogonal lines which after processing will allow 3D velocity vectors. To acquire vertical profiles of sediment concentration and grain size distribution through the inbound flow, samples were collected by suction at the inlet channel mouth. Lastly, to establish a relationship between flow type and bed characteristics, after each of the 11 runs the basin floor elevation was detected using a sonar device to calculate deposit thickness and samples collected (Fig. 2) to perform laser grain sizing.

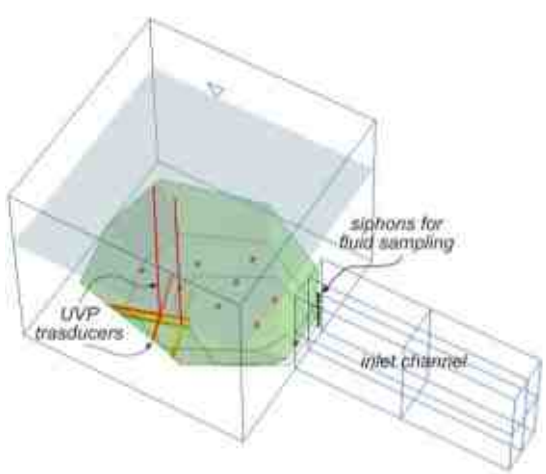

Fig. 2 –The experimental basin used for the experimental work detailed in the text. The red dots show the location of deposit samples.

REMARKS AND FUTURE WORK

Turbidites from the S-TB strongly suggest that flow containment by topography forced a number of modifications in physical structure of turbidity currents, from increase of fall-out rates and momentum dissipation to flow deflection/reflection by confining slopes. Such modifications yield their signature on facies characteristics as well as on the architecture of S-TB infill.

The preliminary analysis of the acquired experimental data, which is currently underway, will consent to explore: I) the effect of oblique incidence onto a confining slope on velocity structure of experimental turbidity currents; II) the time evolution of sediment concentration and grain size vertical stratification resulting from incipient flow ponding; III) how deposit thickness and grain size trends are related to initial sediment concentration, grain size population and total discharged volume.

Future work will be aimed at formulating predictive models for turbidite heterogeneities in marginal settings of confined basin through the integration of outcrop and experimental data.

Alpine subduction imprint in Apennine volcaniclastic rocks. Geochemical–petrographic constraints and geodynamic implications from Early Oligocene Aveto-Petrignacola Formation (N Italy)

MICHELE MATTIOLI (*), MICHELE LUSTRINO (**), SARA RONCA (**) & GIANLUCA BIANCHINI (°)

Key words: *Apennines, calcalkaline, magmatism, Oligocene, subduction, volcaniclastic succession*.

INTRODUZIONE

The Early Oligocene Aveto-Petrignacola Formation (hereafter APF) volcanic rocks are a puzzle in the geodynamic evolution of the Alps–Apennine thrust systems. The Apennine fold-and-thrust belt, which includes the APF, developed as consequence of a west-directed subduction system that involved recycling of the oceanic lithosphere of one (e.g., Neotethys or Liguride) or two (e.g., Eastern Liguride and Mesogean/Ionian) Ocean(s) beneath the southern paleo-continental margin of Europe. The subduction system produced abundant calc-alkaline/arc tholeiitic magmatism starting in Late Eocene/Early Oligocene times in SE Spain (Malaga arc tholeiitic dykes), Sardinia (e.g., Calabona microdiorite) and SE France (Esterel microdiorite). During the Middle-Late Eocene, the Alpine subduction system had already ceased, followed by Adria–Europe continental collision). In other words, during the emplacement of the APF subduction-related volcanic rocks, the Alpine subduction system was already shut down, whereas the Apennines subduction system was fully developing. Notwithstanding this, we propose that the APF volcanic rocks are genetically connected to the Alpine subduction system rather than the Apennines based on several considerations:

- The APF volcanic rocks show small but noticeable major and trace element differences from the Sardinian (i.e., Apennine subduction-related) rocks. Moreover, Rupelian age volcanic activity in Sardinia was very scarce, being the bulk of the volcanic activity developed between ~22 and ~18 Ma.

- The APF belongs to the Sub-Liguride Unit. This implies that the APF was deposited either in a foreland position or very close to the Apennines thrust fronts. In the first case (foreland position) any relation with the Apennines subduction can be automatically excluded. Even if we hypothesize amore internal position (e.g., just above the subduction hinge), the depth to the top of the subducting plate would have been too shallow, thus too cold, to reach vapor-saturated conditions necessary to lower the peridotite solidus of the mantle wedge and inducing melting.

- During the Late Eocene–Early Oligocene, the Apennines subducting plate (i.e., the Liguride-Mesogea-Neotethys oceanic lithosphere) had reached a depth of ~100–120 km (the limit of stability of amphibole in a peridotitic matrix) just beneath Sardinia, i.e. about 200 km west of the APF sedimentary basin.

- The major and trace element, as well as the mineral chemical and isotopic composition of the APF volcanic rocks resemble closely the Alpine igneous products (excluding the very rare ultrapotassic lithologies cropping out in the Western Alps), now present as plutonic roots aligned along the Insubric Line.

- A direct derivation of the APF from the dismantling and eroding Alpine volcanoes (now completely eroded) is a less likely solution, because of the long distance (>200–300 km) separating the supposed source (e.g., Bergell volcano) and the sedimentation area. The large size of the clasts in the APF, the common presence of clasts with sharp edges, and the overlapping paleontological and radiometric age of the sedimentary matrix and the volcanic fragment (~29–32 Ma) requires source areas nearby and relatively short times of sedimentation. It is worth of note, however, that other studies propose the existence of giant landslides, with debris traveling great distances (>250 km). In these cases, however, the mobilized material is the arenitic fraction not pebbles as large as the fragments found in the APF. Also the total thickness of the deposits in these giant landslides is much thinner than the 800 m recorded in the APF. Recent sedimentological studies also indicate the Alpine Chain as the possible supply area for the volcaniclastic formation in the Adriatic Alpine retro–foreland. A detailed study of the sedimentary fraction is however highly needed to completely exclude or not the possibility of derivation of the APF fragments from dismembered Alpine volcanoes.

We propose that the APF volcanic rocks are generated by a fossil mantle wedge modified by the Alpine slab, detached from the European plate during Middle-Late Eocene, wandering beneath the Adriatic lithosphere after the closure of the Alpine Tethys.

Such an ancient SE-directed subduction system would have metasomatically modified the original peridotitic matrix, allowing hydratation of the mantle wedge and leading to amphibole formation. Once the Alpine subduction system was terminated, following the Eocene collisional phase between NW Adria and southern Europe, this metasomatized mantle wedge remained undisturbed for about 10–15 Myrs. Local effects of stress release in the Apennines foreland (representing the former Alps hinterland) would have played an important role to trigger magmatism during Early Oligocene. In other words, despite the APF volcanic rocks belong to the Apennines fold-and-thrust belt, associated with W-directed subduction, their subduction-related geochemical features would be consequence of the effects related to a previous orogenesis (Alpine phase) with subduction polarity nearly opposite compared to that of the Apennine subduction system. PECCERILLO (2005) and PECCERILLO AND MARTINOTTI (2006) proposed a similar scenario to explain the peculiar composition of some Plio–Quaternary lamproites in Tuscany. In their model, these authors suggested that the subduction-related geochemical characteristics of such ultrapotassic magmas were not coeval with partial melting processes, but were acquired during the former Alpine subduction, when the former north-western Adria margin was the hinterland (upper plate) of the Alpine subduction system. The composition of the magma was therefore not genetically related with the formation of the Apennines. The relation between the ultrapotassic lamproitic magmatism and the Apennines was only geological, in the sense that the extensional processes associated with the structure of the Apennines thrusts allowed adiabatic partial melting of ancient metasomatized lithospheric sources. More recently, GIACOMUZZI *et alii* (2011) presented tomographic images of northern Italy to a depth of ~500 km where they identified the presence of high Vp anomalies that they interpreted as the relict of the Alpine slab, with a south-eastward polarity, fromtheWestern Alps towards the northern Adriatic Sea, and underlying the entire Apennine Chain. These studies reached similar conclusions dealing by means of different methodologies and from different point of views. Our model may provide further evidence for the existence of relics of an Alpine slab under the Apennine Chain, responsible for the metasomatic modification of sub-Apennines lithospheric mantle.

To summarize, the APF volcanic arc (now completely eroded) would have been generated as consequence of Alpine tectonics, but would have been involved in the Apennines thrusts soon after its formation. According to this view, the APF and the Mortara volcanoes, the latter now buried beneath the Po Plain, would have the same origin. The formation of the Po Plain (representing the foreland of the Apennines and the retro-foreland of the Alps back-thrusts would have prevented the Mortara volcano from being eroded, leaving it in its original position on the north-western margin of Adria.

Is Optically Stimulated Luminescence a reliable tool for dating the Quaternary paleoenvironmental evolution? The case of Argentiera (NW-Sardinia, Italy)

VINCENZO PASCUCCI (*), LAURA PANZERI (**), MARCO MARTINI (**), FRANCESCO MASPERO (**), DANIELE SECHI (*) & STEFANO ANDREUCCI (*)

Keywords: *Alluvial fan, Dunefield, Radiocarbon, SAR post-infrared stimulation, Single Aliquot Regenerative protocol*.

Although worldwide successful applications of the OSL methodology on alluvial/fan deposits has been long reported in the literature, the scientific community has not fully accepted yet this dating technique. Thus, aim of this study is to apply the OSL protocol on coastal apron-fan deposits of Sardinia to test the reliability of this method and to compare the resultant ages with data obtained by radiometric (^{14}C) technique.

Luminescence dating is based on the ability of quartz and potassium-rich feldspar grains to retain charges, produced by the interaction with radiation originating from the naturally occurring radioactivity present in all sediments, in meta-stable traps for long periods. During the grains transportation by wind or water, charge in the crystal is reduced (ideally) to zero by exposure to sunlight (bleaching). It reloads, however, after sediment deposition and burial. Therefore, the OSL method gives the age of the last sediment accumulation and burial event.

At Argentiera (NW Sardinia) study area, single aliquot regenerative (SAR) method on quartz grains to measure the equivalent dose (D_e) of several alluvial/fan and aeolian samples has been applied. However, the natural quartz OSL signal of some samples is too close to saturation level to be reliable (i.e. D_e>2*D_0). Thus, SAR post-infrared stimulation ($pIRIR_{290}$) at high temperature protocol on K-rich feldspar grains has also been performed.

Generally feldspar grains are affected by anomalous fading (natural electronic lost in feldspar) which causes a decrease of the Infrared Stimulating Luminescence (IRSL) signal with time faster than expected from thermal stability measurements. Thus, normally, IRSL ages tend to underestimate the burial event and a fading rate (*g* value) has to be calculated to correct the final ages. However, high temperature SAR post-IR IRSL protocol does not require any fading correction but it is reliable only for deposits older than 30 ka.

The apron-fan system of Argentiera can be subdivided in to three main areas dominated, from north to south, by debris-flow deposits that fill three incised valleys, water-flow alluvial fans in the central wider flat area and coastal dunes climbing over slightly steeper valley flank southward. Stratigraphic units were established and correlated according to sedimentary body geometries, visible unconformities and ages. Three major unconformity bounded units were recognized: U4a, U4b, U5 and dated using both OSL on quartz and K-feldspar grains and radiocarbon (^{14}C) methods.

U4a is composed of reddish silty conglomerate to pebbly siltstone deriving from the Palaeozoic metamorphic inland hills (bedrock). It has been interpreted as a debris-flow dominated fan-deposit. U4b consists of sandstone and sandy conglomerate deriving from both metamorphic inland bedrock and Quaternary bioclastic-rich sands. It has been interpreted as water-flow dominated alluvial-fan. U5 is composed of bioclastic-rich cross-bedded sand. It has been interpreted as an aeolian coastal deposit.

One sample (ARG9) was collected in U4a unit and gave ages of 74 ± 9 ka (Qz-OSL) and 75 ± 4 ka (K-feldspar-$pIRIR_{290}$), It deposited during the MIS 4 under cold climate.

Three samples (ARG6 to ARG8) were collected in U4b unit. Sample ARG6 has a Quartz-OSL age of 23 ± 4 ka. Sample ARG7 gave ages of 36 ± 4 ka (Qz-OSL) and 43 ± 5 ka (K-feld-$pIRIR_{290}$). These ages are within errors of each other indicating an average of about 40 ka. Sample ARG8 is quartz saturated; K-feldspar ($pIRIR_{290}$) analysis gave an age of 47 ± 3 ka. U4b deposited during the MIS3 (65-24 ka) under cold climate with frequently and rapid alternations of wet and dry conditions.

Five quartz luminescence samples (ARG1 to ARG5) have been collected on the aeolian U5 unit and gave ages of: 10 ± 2 ka (ARG5), 8.1 ± 1.7 ka (ARG4), 7.9 ± 1.6 ka (ARG3), 6.7 ± 1.1 ka (ARG2), 4.9 ± 0.8 ka (ARG1), with average age of about 7500±1000 years. A terrestrial shell of *Helix pomatia* was collected into the aeolianties and dated using radiocarbon

(*) Dipartimento di Scienze della Natura e del Territorio, Università di Sassari, Via Piandanna 4, 07100 Sassari, Italia (pascucci@uniss.it)

(**) Centro Universitario per le Datazioni di Milano-Bicocca (CUDaM), Dip. di Scienza dei Materiali, Università di Milano-Bicocca, 20126 Milano, Italia.

method giving an age comprised between 8060 and 7675 y-BP (calibrated ± 1σ error). This age has confirmed the reliability of the quartz OSL methodology. The coastal dune system of U5 deposited during the Marine isotopic Stage (MIS1; 11-0 ka) under relatively dry and warm climate. From the results of this study, we conclude that the OSL technique seems to be a reliable method to date the alluvial/fan and aeolian deposits over the last 75.000 years. Moreover, the relatively new technique $pIRIR_{290}$ apllied on K-feldspar grains shows great promise for samples at, or beyond, the quartz OSL age limit.

Benthic foraminiferal assemblages from the Gulfs of Patti and Milazzo (NE Sicily, Italy)

CARMELO SACCÀ, DOMENICA SACCÀ (*), PREZIOSA NUCERA (**), ANNA DE FAZIO (*) & SALVATORE GIACOBBE (**)

Key words: *Anosim test*, *Bray-Curtis similarity index*, *Foraminifera*, *Gulfs of Patti and Milazzo.*

ABSTRACT

Foraminiferal assemblages were studied in the Patti-Milazzo marine area (NE Sicily), in order to characterize microfauna related to sediments and to compare thanatocenoses of two Gulfs: Patti and Milazzo. The analysis of dead fauna gives an image of the environmental conditions in the past.

A total of 77 species of Foraminifera belonging to 55 genera and 29 families in the Gulf of Patti against the 69 species, 64 genera, 27 families of the Gulf of Milazzo were identified. In most stations, the assemblages were dominated by a number of species above 20. Non-agglutinated taxa and benthic species dominate numerically in both Gulfs.

Planktonic fraction is low and is mainly represented by *Globigerinoides ruber*, *Globorotalia inflata* and *Orbulina universa.*

Agglutinated foraminifera are rare: *Textularia agglutinans, T. sagittula, Bigenerina nodosaria, Cylindroclavulina rudis, Sigmoilopsis celata, Trifarina angulosa, Martinottiella communis*.

Multivariate analysis by means of Bray-Curtis similarity index showed that the Gulfs of Patti and Milazzo are moderately discriminated, with an internal similarity of 27.43% and 41.01%, respectively. In the former Gulf, the most responsible species of internal similarity are *Cassidulina carinata* (21.37%), *Hyalinea balthica* (14.38%), *Cassidulina crassa* (8.65%), *Valvulineria bradyana* (7.30%), *Uvigerina mediterranea* (5.40%), *Bolivina earlandi* (5.44%), *Ammonia beccarii* (4.95%) and *Nonion padanum* (4.67%) whilst in the latter *Uvigerina mediterranea* (15.15%), *Bulimina marginata* (10.47%), *Cassidulina carinata* (9.24%), *Ammonia beccarii* (6.81%), *Nonion padanum* (6.10%) are prevalent.

Bulimina marginata, *Cassidulina carinata* and *Valvulineria bradyana* are frequently dominant in colder bathyal waters (MURRAY, 1991) and have been considered a good marker of high productivity waters (PHLEGER & SOUTAR, 1973; LUTZE & COULBOURN, 1984). *Bulimina marginata* is known to tolerate dysoxia (SEN GUPTA & MACHAIN-CASTILLO, 1993). *Cassidulina carinata* is considered, in the Mediterranean Sea, one of the most important opportunistic species under eutrophic conditions (HESS *et alii*, 2005; DI BELLA & CASIERI, 2011). *Hyalinea balthica* is typical of the circalittoral zone and is more frequent in epibathyal muds between 90 and 500m (PARKER, 1958). *Ammonia beccarii* is a euryhaline species (e.g., BANDY, 1953; CEARRETA, 1989; ALVE & MURRAY, 1994; ALMOGI-LABIN *et alii*, 1995; KIM & KENNETT, 1998), tolerant to strong environmental stress and typical of infralittoral to circalittoral environment. *Uvigerina mediterranea* has mainly shallow-endobenthic infaunal distributional patterns and is typical of well-oxygenated microhabitats with a low tolerance to dysoxic conditions (e.g. LUTZE & COULBOURN, 1984; CORLISS, 1985; SCHMIEDL *et alii*, 2000). *Cassidulina crassa* is typically found as part of the shallow infauna (e.g. DE STIGTER *et alii*, 1998; FONTANIER *et alii*, 2005). In the Mediterranean Sea, its distribution is associated with oligotrophic to mesotrophic and well-ventilated conditions (DE RIJK *et alii*, 2000). *Melonis padanum* and *Bolivina earlandi* appear to have an intermediate deep infaunal microhabitat and usually indicate a high flux of organic matter (MORIGI *et alii*, 2005).

By correlation among dominant species and grain-size fractions it is evident that in the Gulf of Patti *Hyalinea balthica* (R=0.76), *Cassidulina carinata* (R=0.54) and *Bulimina marginata* (R=0.43) correlate positively with clay; *Valvulineria bradyana* and *Cassidulina crassa* with silt (R=0.8 and R=0.53, respectively); *Ammonia beccarii* with sand (R=0.9). The most species from the Gulf of Milazzo show a positive correlation with silt: *Cassidulina carinata* (R=0.86), *Nonion padanum* (R=0.8), *Ammonia beccarii* (R=0.6), *Valvulinaria bradyana* (R=0.6) and *Cassidulina crassa* (R=0.47); *Uvigerina mediterranea*, on the contrary, correlates with sand (R=0.6).

Most abundant species were also correlated with some heavy metals: *Ammonia beccarii* correlates strongly with Zn in both Gulfs and with As, Hg and Pb in the Gulf of Patti; *Valvulineria bradyana* shows a positive correlation mostly with Co and Pb in the Gulf of Patti; *Uvigerina mediteranea* with As and Cu in the Gulfs of Milazzo and Patti, respectively; *Cassidulina carinata*, *Cassidulina crassa* with Cr and Pb, respectively, and *Nonion*

padanum with both elements in the Gulf of Milazzo.

As described, the different environmental constraints differently affect the foraminifera species and assemblages throughout a complex interaction of depth, exposure, sediment texture and chemical contaminants. Such interaction has been confirmed by the Anosim test (two way crossed) for depth and sand percentage interaction (R= 0.471; p= 0.4%).

Late-Holocene to Recent evolution of Lake Patria, a coastal lagoon within the Volturno River delta system, South Italy

SACCHI M. (°), MOLISSO F. (°), PACIFICO A. (*), RUBERTI D. (*) & VIGLIOTTI M. (*)

Key words: *Alluvial delta, Coastal lagoon, Historical cartograph, Late Holocene, Volturno River.*

Lake Patria is a mesoaline coastal lagoon that develops along the coastal zone of the Volturno river plain (Campania, South Italy). The lagoon is a saline-to brackish water body, ca 2.0 long, and 1.5 km wide, with an average water depth of 1.5 m, reaching a maximum of ca 3.0 m. The freshwater input into the lagoon, is provided by a series of fresh to brackish water channels and small springs, landwards, while a permanent connection with the Tyrrhenian Sea is provided by a channel, 1.5 km long and a few meters wide.

Drilling data from 12 of boreholes acquired in the study area indicate that Lake Patria is a man-modified remnant of a larger lagoon area that developed during the last millennia along the Campania coastal zone within an alluvial delta system at the mouth of the paleo-Volturno river.

Sedimentological and stratigraphic analyses of drill cores suggest the lower Volturno delta plain developed in the last 6000 years. Depositional conditions during this period were dominated by flood-plain and alluvial plain settings, with transition to coastal bars and associated back-barrier coastal lagoons. Lake Patria started evolving at an early stage of the Volturno delta plain formation as a consequence of damming-up of foreshore deposits by littoral drift.

The first marine layers display a radiocarbon age of 6.5-7.0 ka BP and overlie a substrate represented by volcaniclastic deposits, originated by the Campi Flegrei, and associated paleosols, towards the inland area. The cored marine-lagoonal succession may be interpreted as the result of the varying ratio between the in-situ bioclastic component and the land-derived fine grained siliciclastic component of the sediment source through time, which may be in turn tentatively correlated with the major climatic changes that occurred during mid-late Holocene.

Insights into the recentmost evolution of the coastal lagoon of Lake Patria are provided by the GIS-based analysis of the physiographic changes of the region conducted on a series historical topographic maps dating back to the early XVII century. Particularly, the superposition of historical cartography reveals the secular trends in the change of coastal environments and the role of human modification of natural habitats over the last 400 years.

In conclusion, Lake Patria may be regarded as a relic of the southern part of a back-barrier lagoon-wetland area that developed between ca 4.5 and 2.0 ka BP within the Volturno River delta (Fig. 1). The extent of this ancient lagoon-wetland system can be still be detected on the Digital Terrain Model of the Volturno coastal plain which reveals a series of low-laying areas (with elevation with elevation ≤ 0 m asl) on both sides of the Volturno river. These areas approximately describe the shape and location of the former back-barrier lagoon that was progressively filled up and evolved as flood delta plain during the last millennia.

The *Halimeda* dominated prograding wedge of the Pietra di Finale (Middle Miocene, Liguria)

MARCO BRANDANO (*°), LAURA TOMASSETTI (*), VIRGILIO FREZZA (*) & MARCO CUFFARO (°)

Key words: Halimeda, *siliciclastic-carbonate mixing, Middle Miocene, shallow water.*

The 'Pietra di Finale' allows to analyse the evolution of Mediterranean during the Chattian to Serravallian interval. The 'Pietra di Finale' deposits unconformably overlies the Alpine substrate. Three main stratigraphic units may be recognized in the sedimentary succession of the Finale area. The first unit is represented by metamorphic and dolostone conglomerates and sandstone that may be interpreted as a fan delta deposits and are Chattian to Aquitanian in age. This deposits pass upward to marls and marly limestone with some sandstone intercalation. This unit, Aquitanian to Burdigalian in age, is known as Torre di Bastia unit and it is overlain with a sharp contact by mixed terrigenous-carbonate deposits. Clasts of terrigenous fraction were mostly derived from the Alpine orogenic wedge, whereas sandstone lithic fragments have a more varied provenance.

To reconstruct the paleolatitude position of the Finale succession we made plate kinematic reconstructions of the main blocks in the western and central Mediterranean area, during a time interval t=25 Ma. We explored tectonic evolution in the Eurasia-fixed reference frame, and the hotspot framework, testing both the present-day Atlantic/Indian hotspots and the present--day Pacific hotspots, for the definitions of the reference system. All the cases studied do not provide any significant variation of block positions, resulting in a range of displacements of few degrees of latitude.

The carbonate fraction mixed siliciclastic-carbonate unit is dominated by *Halimeda*. *Halimeda* is restricted to tropical and subtropical marine environments where they grow either on unconsolidated sediments or on the reef itself.

Halimeda green algae tolerate a range of hydrodynamic regimes, flourishing from the back-reef lagoon to the forereef slope, at depths ranging from <1 to 150 m. These algae grow rapidly, attaining heights up to 15 cm over their 1– 3 month lifespan. *Halimeda* tolerates high nutrient conditions. It is demonstrated that there is an increase of the algal rate of photosynthesis directly via nutrient enrichment. Palaeolatitudinal reconstruction of the investigated area during the Chattian to Serravallian interval evidence that this region was already near the Modern latitudinal position. This evidence an expansion of tropical zone (waters) during this interval up to the Northern Mediterranean. Typically Mediterranean Lower to Middle Miocene carbonate platforms are dominated by seagrass environments in the euphotic zone and coralline algae in the oligophotic zone promoting the development of carbonate ramp depositional profile. In this example regional condition had promoted a *Halimeda* dominated carbonate production that have substituted in the euphotic zone the seagrass carbonate factory, less tolerant to the eutrophic conditions. *Halimeda* substituted also the red algal production in the oligophotic zone. *Halimeda* dominance has also controlled the depositional profile. Wedge-shaped profile is the results of important nearshore siliciclastic sedimentation produced by erosional processes on the rocky shoreline and limited carbonate sedimentation in the deepest euphotic zone and in the oligophotic zone.

Sedimentary features of the Lower Pleistocene mixed siliciclastic-bioclastic tidal deposits of the Catanzaro Strait (Calabrian Arc, south Italy)

DOMENICO CHIARELLA (†), SERGIO G. LONGHITANO (*) & FRANCESCO MUTO (°)

Key words: *Calabrian Arc, Catanzaro Strait, detrital modes, mixed sediments, tidal dunes.*

INTRODUCTION

The Plio-Pleistocene infill of the Catanzaro Basin (central Calabria) includes a Lower Pleistocene (Calabrian), ~80 m thick interval made up of mixed (bioclastic-siliciclastic) sand-sized sediments. The Catanzaro palaeo-strait (Fig. 1) is interpreted as an E-W-elongated, narrow linear basin linked the Ionian and Tyrrhenian seas, producing a marine seaway or strait which was tidally-dominated during the Lower Pleistocene. Two main fault systems bound the basin: an ENE-WSW to WNW-ESE-trending system to the North and an E-W-trending system to the South, both showing an en-échelon-type pattern (TANSI *et alii*, 2007). The Plio-Pleistocene infill of the Catanzaro Basin unconformably overlies the Upper Miocene conglomerates and evaporites and, locally, the Paleozoic crystalline basement. From the bottom to the top, the Catanzaro Basin infill consists of a Pliocene unit (about 100 m thick) made up of limestone and marls, and erosively overlain by the mixed succession focus of this work. This succession is top-truncated by Quaternary terraced deposits and/or by surfaces of modern exposure (CHIARELLA, 2011).

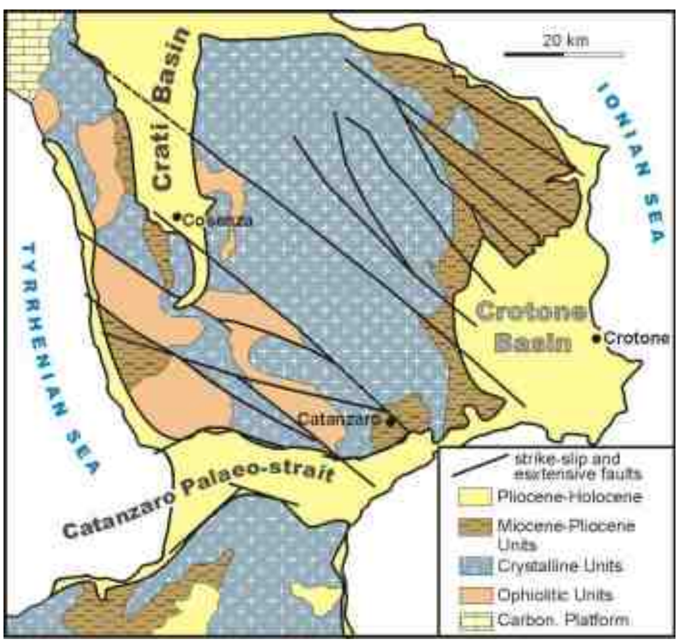

Fig. 1 – Simplified geological map of the central Calabrian Arc (modified from Van Dijk et *alii*, 2000 and TANSI *et alii*, 2007)

Mixed deposits of the Catanzaro Strait consist of a series of vertically-stacked bidirectional cross strata (Fig. 2) which exhibit a sedimentary facies association typical of tidal dominated environments, including herringbones, bundles and re-activation surfaces (e.g., LONGHITANO *et alii*, 2012a, b).

AIMS and METHODS

In this paper, we present the preliminary results of a stratigraphic and sedimentological study carried out with the aim of: (i) outline the hydrodynamic features of the Catanzaro palaeo-strait depicted from the observation of its mixed deposits, and (ii) unravelling provenance from siliciclastic and bioclastic fractions. The techniques adopted consisted on facies analysis and vertical logging of exposed sections and quantitative petrographic analyses performed by point counting on 16 thin-sectioned sand samples.

RESULTS

The Catanzaro mixed succession has been divided into two units, the lowermost Vena di Maida Unit, and the uppermost Pianopoli Unit both consisting of siliciclastic-bioclastic sandstones. The distinctive elements that allow us to distinguish these two units is the internal strata organisation: (i) the ~30 m thick Vena di Maida Unit consists of vertically-stacked trough cross-strata with 3D internal geometry, whereas (ii) the ~50 m thick Pianopoli Unit is composed of planar 2D cross-strata, passing up-ward to mostly bioturbated mudstones.

Data interpretation and preliminary conclusions

Cross strata observed in the two units indicate the existence of large dune fields, whose migration was arguably induced by strong tidal currents enhanced by a tidal oceanography. This is confirmed by the diffuse bi-directionality of cross strata mostly parallel to the main strait axis, and by the occurrence of associated tidal structures.

The different architectures observed between the Vena di

Fig. 2 – Tidal dunes in mixed siliciclastic-bioclastic deposits of the Catanzaro Strait. Palaeocurrents is towards W-NW.

Maida and the Pianopoli units suggest a vertical transition from 3D to 2D tidal dunes, occurred during the strait infill. 3D and 2D cross strata are related to high and low bed shear stress, respectively. These two hydrodynamic conditions are characterized by different turbulence in the flow propagation style producing 3D and 2D flow (ALLEN, 1968). The vertical transition from these two bedform types can be observed in many areas of the Catanzaro Strait where tidal mixed sediments are exposed. This transition is here interpreted as an important change in the strait hydrodynamics. Accordingly, 3D dunes represent a relative shallow-marine environment that generated conditions of increased turbulence in the tidal currents. 2D tidal dunes represent the depositional result of a tidal regime during which currents flowed with moderate energy, recording deeper conditions during a probable (tectonically-induced?) rise of the relative sea-level. Finally, the final stage of the relative sea-level rise (highstand) is suggested from the topmost mudstone succession, where tidal structures are virtually absent. This latter interval probably records the vanishing of a tidally-dominated oceanography across the Catanzaro Strait due to an enlargement of the area, before its definitive closure.

The general detrital-mode evolution of the Catanzaro mixed deposits indicates a homogeneous quartz-feldspathic composition. Petrologic characteristics of mixed sand suggest that the sedimentary deposits were derived mainly from the nearby metasedimentary rocks and associated Mesozoic to Miocene sedimentary source areas. The key candidates for the main source areas are the Sila and the Serre Mountains allochthon. The bioclastic fraction consits of calcareous red-algae, echinoderms, mollusks, bryozoans and benthic and planctonic foraminifera referred to an in situ *heterozoan* skeletal-carbonate factory (CHIARELLA, 2011).

Zonation of a mixed siliciclastic-bioclastic shallow-marine depositional system: Acerenza (Pliocene, Lucanian Apennine)

DOMENICO CHIARELLA (†), SERGIO G. LONGHITANO (*), LUISA SABATO (°) & MARCELLO TROPEANO (°)

Key words: *Lucanian Apennine, Mixed siliciclastic-bioclastic, wedge-top basin, wave- and tide-dominated depositional system.*

Shallow water depositional environments are dynamic systems that are mostly influenced by a number of interacting hydrodynamic processes as waves, tides, and surficial termoaline currents.

Since siliciclastic and bioclastic sediments are characterized by a different density, a consequent different response is expected when they are involved in same hydrodynamic processes. Therefore, mixed sediments may be organized into specific sedimentary structures showing a different degree of segregation between the two heterolithic components depending on the type of hydrodynamic process (CHIARELLA & LONGHITANO, 2012).

The present study describes a siliciclastic-bioclastic unit comprised in the Pliocene marine succession cropping out near the Acerenza village along the front of the Lucanian Apennine (Southern Italy) (Fig. 1).

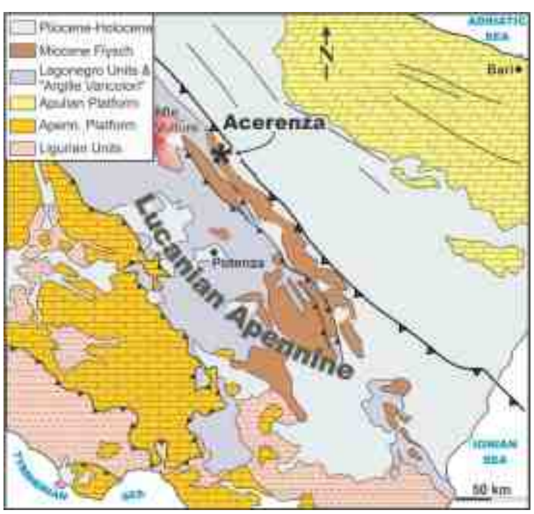

Fig. 1 – Simplified geological map of the Southern Apennine with indication of the study area (CHIARELLA *et*

In the Acerenza succession, an about 30 m thick mixed deposits developed in shallow-water environments of semi-engulfed coastal areas. These environments occupied a wedge top basin where the growth of folds produced some bathymetric high on the shallow-sea bottom. In such a setting, the occurrence of several types of cross-stratified facies, observed through a detailed stratigraphic and sedimentological study, indicates different hydrodynamic conditions, including wave-, current- and tidally-influenced environments.

The studied succession shows a gradual vertical passage from deeper to shallow marine facies, without any evidence for a talus slope or significant slope break, suggesting that the deposition occurred on a gently-inclined profile (CHIARELLA *et alii*, 2012). The deepest part of the profile corresponds to offshore environments while the middle part to offshore-transition and lower shoreface environments. The shallowest part of the profile was rarely exposed and it was represented by a waves-eroded folds-top. Likely, thrusts top was also the main source area for the siliciclastic supply induced by wave erosion. Same tops and their flanks were the site of an active carbonate factory producing skeletal debris. So, studied shallow-marine environments were characterized by the presence of both siliciclastic and bioclastic grains, affected by the same hydrodynamic processes. Consequently, sediments responded in different ways in the three main depositional zones recognised in the mixed depositional system of Acerenza. From the deepest to the shallowest, these zones are: (*i*) the offshore zone; (*ii*) the offshore-transition zone and (*iii*) the shoreface zone (CHIARELLA *et alii*, 2012).

(*i*) The offshore zone is recorded by unsegregated mixed sediments showing indistinct beds mostly bioturbated (Fig. 2A). (*ii*) The offshore-transition zone is recorded by well to moderately segregated 2D and 3D dunes attributed to tidally-modulated currents (Fig. 2B and 2C). The occurrence of either 2D or 3D dune trains, related to low and high bed-shear stress respectively, allows to distinguish respectively a lower offshore-transition zone located far to the upper wave base, from an upper offshore-transition zone located close to the wave base. Finally, (*iii*) the lower shoreface zone is recorded by high-energy facies characterized by the absence of segregation between the two heterolithic fractions (Fig. 2D). Absence of segregation was most likely due to the stronger hydrodynamics produced from waves.

Fig. 2 – Outcrop photos of main sedimentary structures characterizing different depositional zones. A) Offshore deposits characterized by mostly bioturbated unsegregated mixed sediments. 2D dunes (B) and 3D dunes (C) related to the offshore-transition zone showing respectively a well and moderate degree of segregation. D) Absence of segregation between the two heterolithic fractions in shoreface deposits.

Morphological and sedimentary signatures of tide-dominated coastlines, northern Adriatic Sea

GIORGIO FONTOLAN (*), SIMONE PILLON (*), ANNELORE BEZZI (*) & EMILIANO GORDINI (**)

Key words: *shoreline, morphodynamics, sedimentology, tidal inlet, ebb-tidal delta, northern Adriatic*

INTRODUCTION

The North Adriatic coastal area, between the Isonzo and Po rivers, mainly consists of lagoon-river delta systems fronted by barrier islands and sandbars and fed by tidal inlets (Fontolan et al., 2007). Despite the microtidal regime (mean spring range 1.1 m; mean neap range 0.3 m), the limited wave influence tends to produce tidal inlets of the tide-dominated type (Hubbard et al., 1979). The tidal inlets, particularly when not fixed by jetties, have a very high sand trapping capabilities, as a consequence of the strong interference generated by tidal currents on the littoral drift. In this paper a review of the main environmental features are presented and discussed, with a particular focus on the morpho-sedimentary signatures useful for the interpretation of the analogues in the geological record, as follow:

1) Large scale sedimentary traps (tidal deltas)
2) Medium to small scale bedforms due to tidal currents
3) Grain-size pattern

LARGE SCALE SEDIMENTARY TRAPS

A large scale morphological evidence of the tidal effects at tidal inlets is the deposit of sand in the far field hydrodynamic zone. The water dispersion through the spreading during the ebb-tide, forces the sand to settle, thus giving rise to the formation of an ebb-shoal, named ebb-tidal delta. All the tidal inlets – either natural or jettied - facing the lagoons in the examined area are tide-dominated, thus developing sand depositionary bodies. The ebb-tidal delta structure (Hayes, 1980) is clearly described by the bathymetry, that shows the typical convexity of the contour-lines seawards (Fig.1).

Also in the case of jettied inlet, the morphological control exerted by the current-induced axial jet is considerable, such to cause the development of a detached submerged linear bar on the downdrift side. In both cases the bathymetric anomaly hides a

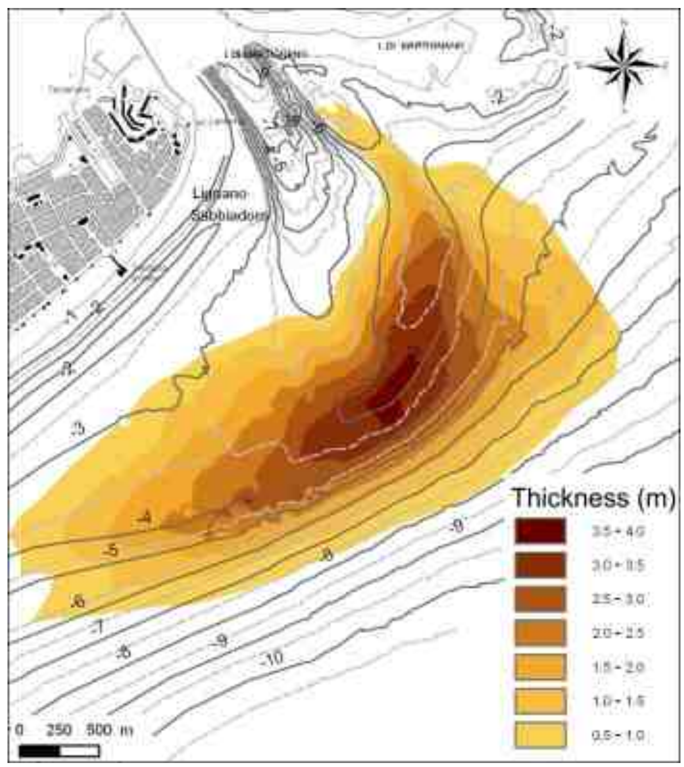

Fig. 1 – Structure of the ebb-tidal delta of the Lignano inlet, with the typical bathymetric pattern and morphology (contour lines in m, below m.s.l.). The thickness of the delta sand deposits is also reported. The total volume of the delta amounts to $10 \cdot 10^6$ m^3 (Fontolan et al., 2007)

tremendous trapping effect, calculable according to the semi-automatic method of Fontolan et al. (2007), and valuable, solely for the natural inlets, as a direct function of the tidal prism.

MEDIUM TO SMALL SCALE BEDFORMS

Tidal currents can exceed 1 m/s velocity inside the main ebb channel (Dorigo, 1965) or in the immediate neighboring, along

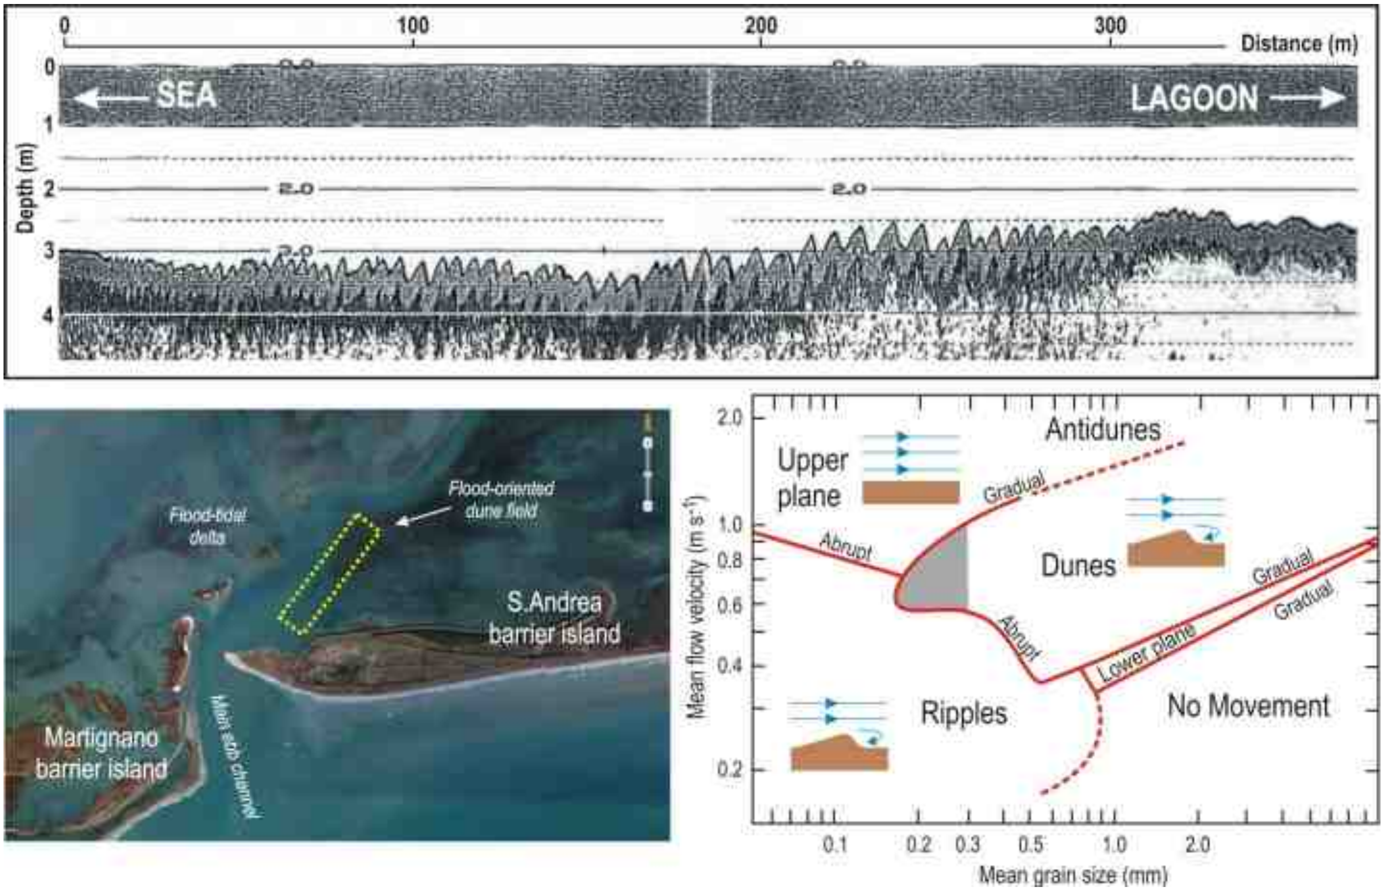

Fig. 2 – Example of the sonograph record of a flood-oriented dune field in the main channel of the S.Andrea inlet. For the given sediment size (between 0.2 and 0.3 mm) the limited dynamic condition for dune formation permits to infer the range of flow velocities, between 0.6 and 1.0 m/s (within the grey area in the bedform's diagram on the lowest right). Bedform's diagram is modified after Ashley (1990).

the secondary channels inside the lagoon, close to the bifurcation with the main channel. The effects are either erosional either depositional, in the form of well-organized bedforms of different scale. Bedforms are a proxy of current speed and pathways, since the grain size involved in the movement is restricted, for the whole northern Adriatic shoreline, to the range 0.20-0.30 mm (Fig. 2). According to the bedform's phase diagram, ripples occur over the seabed below 0.6 m/s of current speed, whereas dunes form only between 0.6 and 1.0 m/s. Upper plane conditions are reached only in limited cases, and are accomplished by scour furrows and other erosional lineament or holes, easily observable by high-resolution Swath bathymetry. The persistence of the ebb or flood domain is testified by the asymmetry of the forms; on the contrary, oscillatory wave motion tend to superimpose symmetrical ripples on the seabed, thus discriminating the tidal from the marine domain, far from the ebb-tidal delta influence and over the swash platforms.

GRAIN SIZE PATTERN

Owing to the selective action caused by tidal current and the modulation of its speed, grain size distribution is a quasi-perfect picture of the hydrodynamic process linked to the ebb-current spreading over the ebb-tidal delta, namely the far field.

Due to the fairly wave climate, in the northern Adriatic the signature of the influence of currents on the grain-size pattern is well marked. Fig. 3 represents the coastal tract between the Lignano tidal inlet on the East and the Tagliamento river mouth (immediately out of picture) on the West. The superficial grain size pattern accommodates over the morphology, strongly influenced by the spreading of the ebb jet. The coarsest sand is found alongshore, but also inside the main ebb channel until the inner terminal lobe. The large sand trap of the ebb delta is therein asymmetrical, extending for the most on the western (downdrift) side facing Lignano Sabbiadoro. On the westernmost limit, the fluvial domain of the wave-dominated Tagliamento delta is characterized by the abrupt passage from the nearshore sand prism to the mud below the closure depth, at ca. -4 m depth. The selective effects on the sand due to the currents is also a characteristics at the scale of the channel cross section. A progressive change in the mean grain size due to frequency curve translation (Fig. 4) can be observed along an ideal oblique transect crossing the main ebb channel from the coast going seawards. The high sedimentation depositional body of the channel margin linear bar (updrift side of the main ebb channel)

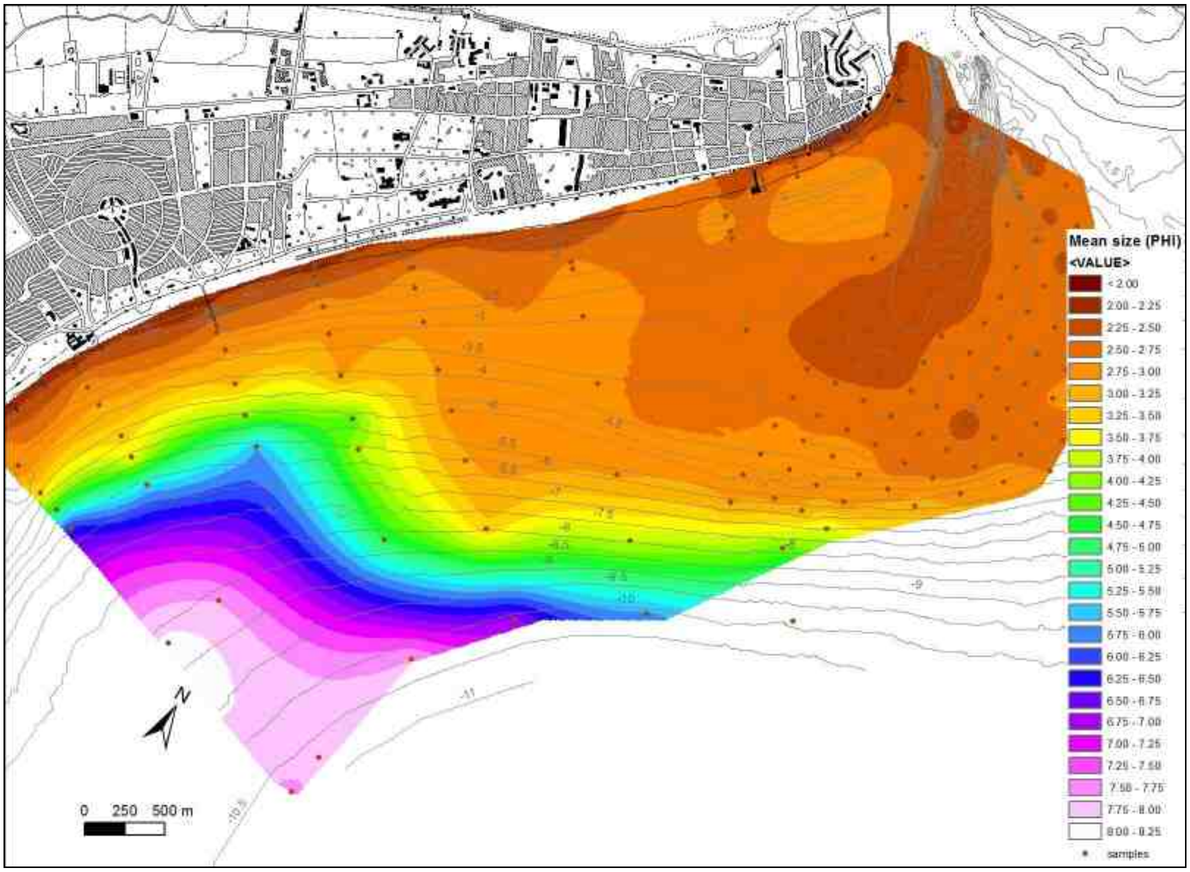

Fig. 3 – Grain size distribution in the nearshore area between the Lignano tidal inlet (on the East) and the Tagliamento river delta (on the West.

is composed by the coarsest sand available. The selective processes permit the segregation of finer and finer material either along the less dynamic environment in the tidal domain (main ebb channel, marginal flood channel and terminal lobe) or toward the higher depths in the marine domain (immediately above or below the closure depth).

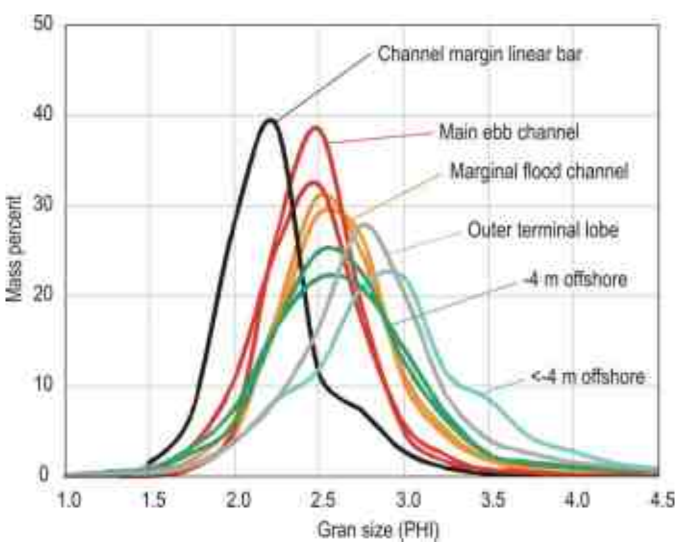

Fig. 4 – Grain size frequency curves of the typical morphologies (according Hayes, 1080) linked to the tidal domain or the marine domain. The ideal transect crosses the main ebb channel and extends seawards.

Surface sediments of seagrass meadows along the Tyrrhenian continental shelf (Italy)

G. GAGLIANONE (*), V. FREZZA (*), G. MATEU-VICENS (**) & M. BRANDANO (*), (°)

Key words: *benthic foraminifera, facies, mixing carbonate-siliciclastic,* Posidonia oceanica, *Tyrrhenian Sea.*

INTRODUCTION

Mediterranean marine phanerogam *Posidonia oceanica* (L.) Delile forms extensive meadows, colonizing soft and hard substrates. The presence of seagrass meadows represent an important factor for the stability of coastal marine systems in subtidal range (in the Mediterranean up to ~40 mwd), influencing the sedimentary processes (KOMATSU, 1996) and representing a factory of organic matter and oxygen (JAMES, 1997). Moreover, seagrass meadows host a high variety of carbonate-producing organisms, many of which epiphytic. Their presence allows a prolific bioclastic factory (PARDI *et alii*, 2006).

Three different meadows are investigated in the following locations, from north to south: Cala Cupa (Giglio Island, Tuscany, Northern Tyrrhenian Sea), Punta Madonna-Scoglio Rosso (Ponza Island, Latium, Central Tyrrhenian Sea, East Sector), Acquafredda di Maratea (Maratea, Basilicata, Southern Tyrrhenian Sea, East Sector). In these sampling sites, seagrass meadows are present both on soft and hard substrates, often forming "mattes".

In the Giglio and Ponza islands terrigenous clasts origin only for coastal erosion on outcroppings rocks represented by volcanic rock, while in Maratea meadow terrigenous clasts origin for coastal erosion on outcroppings rocks constituted by carbonate rocks. Fluvial run-off components of Noce River, located 15 km to the south of Maratea meadow are always negligible.

MATERIALS AND METHODS

A total of 41 samples of surface sediment was collected on seagrass meadows by SCUBA diving, along transect related with water depth: 10 samples from Giglio Island (4-28 mwd), 20 from Ponza Island (5-35 mwd), and 11 from Maratea (6-16 mwd).

A sedimentological and micropaleontological characterisation of bottom sediments was carried out. The samples were washed for remove organic matter; each sample was subsequently divided by rotating sample divider in order to have representative sediment aliquots, for allow all subsequent analyses. Sedimentological analyses consisted on dry sieving for gravel and sand fraction, and in wet particle size analysis with laser diffraction analyser for mud fraction. Foraminiferal analyses are preliminary and qualitative, as regard the Giglio Island and Maratea, whereas for the Ponza Island quantitative data from FREZZA *et alii* (2011) were utilised.

Geochemical analysis consists in calcimetry: it was performed for evaluate the carbonate content in the sediments.

A count of components was made for investigate sediments and perform a Q-mode Hierarchical Cluster Analysis (HCA). The components were analysed statistically by a HCA (Ward method, squared Euclidean distance), using the IBM SPSS 19 for Windows program.

Thin sections from "hardened" sediment were prepared for microfacies observations. Finally, facies analysis was performed using component analysis, grain size percentage, sorting and carbonate content and the results of HCA.

RESULTS AND DISCUSSION

Grain size analysis shows a predominance of sandy fraction in all the three locations, whereas gravel and specially mud are subordinate (Giglio Island: mud range 0.32-5.14%, sand range 54.28-94.46%, gravel range 1.57-45.09%; Ponza Island: mud range 1.35-12.33%, sand range 42.30-97.95%, gravel range 0.35-55.30%; Maratea: mud range 0.24-2.64%, sand range 56.80-97.90%, gravel range 0.20-42.86%).

A total of five sedimentary facies has been recognised. Facies are tested with Q-mode cluster analysis using components and sedimentological data. Only significant component which have values greater than 5% are used for the cluster, because low representative components have low effect on the cluster; for the same reason, the terrigenous fraction was not used because its high values might be redundant.

Facies F1 – *Terrigenous bioclastic sand*. Sand fraction is overwhelmingly (96-98%), gravel fraction is very scarce (0-3%) and mud fraction is low but noticeable (1-3%). In this facies sediments contain up to 64% (59-64%) of terrigenous elements and consist in well-rounded granules of sedimentary carbonate rocks. Bioclastic fraction is made principally of echinoid, bivalves, gastropods, red algae and their fragments. Bryozoans and benthic foraminifera are subordinate, among which include *Rosalina* spp., *Asterigerinata mamilla*, *Elphidium crispum* and rare miliolids. The samples of Maratea (G032-G036) located in bathymetric range of 10-14 mwd, in correspondence of the central part of the investigated meadow, are comprised in this facies.

Facies F2 – *Terrigenous gravelly sand*. Sand fraction is still prevalent (57-84%), but gravel fraction is here considerable, varying between 15 and 43%; mud fraction is scarcer that in facies F1 (0-1%). Terrigenous elements are predominant in this facies (about 75-91%) and consist in rounded and subrounded granules of sedimentary carbonate rocks. Bioclastic fraction is scarce and made of red algae, bivalves and echinoid fragments. Foraminifera show very scarce abundance and there are only some miliolids and, for rotaliids, *Rosalina bradyi*. This facies includes the distal samples of transect of Maratea, located at the upper margin (G028-G031, 6-9 mwd) and at the lower margin (G037, 15 mwd) of meadow, and one sample belonging the transect, but outward from meadow (G038, 16 mwd).

Facies F3 – *Red algal skeletal gravelly sand*. Sand fraction is slightly prevalent or comparable to gravel fraction content (sand 42-70%, gravel 27-55%). Mud fraction is present in low percentages (1-4%). Terrigenous elements are predominant (38-74%); bioclastic fraction is prevalently made of red algae, but bryozoans are also common. Echinoids, bivalves and gastropods are subordinated, except that in the sample G108 (Giglio Island); foraminifera are subordinate in all samples, except that in sample G064 (Ponza Island) that shows higher values. *Lobatula lobatula*, *Peneroplis pertusus* and *Miliolinella subrotunda* are the most common species.

This facies comprises the upper margin samples from Ponza (G056-G058, 5-7 mwd) and Giglio (G108, 4 mwd), but also a deeper sample from Ponza (G064, 13 mwd), that shows abundant gravelly and poorly sorted fraction such as those less deep.

Facies F4 – *Mixing siliciclastic-carbonate red algae and foraminiferal skeletal sand*. In this facies sediments are moderately to poorly sorted: sand fraction is predominant (76-98%), gravel fraction is subordinate but considerable (0-22%) and consists of subangular to subrounded terrigenous grains and angular to subangular skeletal grains; mud fraction is subordinated (0-5%).

Terrigenous fraction (38-67%) consists of quartz, feldspars and volcanic rock fragments in Ponza, while in the Giglio samples only granitic lithoclasts occurs. Skeletal fraction shows comparable amounts (33-62%) and mainly consists of red algae, foraminifera, and bryozoans, together with echinoids, bivalves, and gastropods, especially in samples of Giglio Island.

Lobatula lobatula, *Peneroplis pertusus*, *Miniacina miniacea*, *Rosalina* spp., *Asterigerinata mamilla*, *Elphidium* spp. and miliolids are the foraminifera characteristic of this facies.

The carbonate content (7-23%) is formed by skeletal components, whereas the carbonate lithoclastic grains are absent in this facies.

All samples of the Giglio Island are parts of this facies (seven samples at 6-26 mwd, in meadow, one at 28 mwd, outside the meadow), with the exclusion of the shallower sample (G108, 4 mwd), and central samples of Ponza Island (8-15 mwd) except sample G064, plus one sample deeper (CP5, 21 mwd).

Facies F5 – *Mixing siliciclastic-carbonate coarse sand*. In this facies sand fraction is predominant (75-90%) and is dominated by terrigenous subangular or angular grains (quartz, feldspars, and crystalline rock fragments); gravel fraction is up to 19% (3-19%) and is composed principally of skeletal grains (bivalves, gastropods and bryozoans); mud fraction is not negligible, is always above 6% but not more than 12%. The terrigenous fraction (22-63%) generally consists of quartz, feldspars, and crystalline rock fragments. This facies displays the highest value of carbonate content, if we exclude carbonate rock samples of Maratea (23-62%); carbonate constituents are exclusively skeletal grains: benthic foraminifera, red algae (debris and free living branches, scarcer only in CP6, 35 mwd), bryozoans and, subordinately, bivalves, gastropods and serpulid fragments. Echinoid fragments and spicules of sponges are present but scarce. The deepest samples of Ponza Island (16-35 mwd) fall in this facies, in which *Lobatula lobatula* and *Rosalina bradyi* are the most common species of foraminifera present.

CONCLUSIONS

The result of sedimentological analysis in the investigated sites show that *Posidonia oceanica* develop on sand-dominate substrate; gravel fraction is generally subordinated and variable, and mud fraction is generally low. The very low frequencies of muddy fraction can be attributable to re-suspension processes and the lack of aragonitic components that produce mud-sized particles.

The meadows of Giglio and Ponza islands show a major abundance of bioclastic content, also with a higher diversity, maybe due to a minor turbidity of water in these two areas than in the Maratea meadow. The facies F4, related to a wide bathymetric range, shows a typical infralittoral deposit, related to a well-developed meadow as evidenced by a very good ecological diversity and noticeable mud content.

In Maratea meadow the abundance of foraminifera is generally low, as well as the shallower samples of the Giglio (4-10 mwd) and Ponza islands (5-6 mwd). Only in the water depth interval of 10-14 mwd (facies F1) there is a higher percentages of skeletal fraction (including foraminifera), and of mud fraction, maybe due to a greater density of meadow that can produce more bioclasts and trap more mud. Distal and proximal samples of Maratea meadow, represented by facies F2, show a typical sandy littoral deposit.

Preliminary fatty acid data of microbialites from Kess-Kess Mounds (Hamar Laghdad, Lower Devonian, Morocco)

ADRIANO GUIDO (*), ADELAIDE MASTANDREA (*), FABIO DEMASI (*), FABIO TOSTI (*) & FRANCO RUSSO (*)

Key words: *fatty acids, microbialites, Kess-Kess mounds, Lower Devonian, Morocco.*

INTRODUCTION

Devonian Kess-Kess mounds, cropping out in the Hamar Laghdad Ridge (SE Morocco), represent a laboratory for understanding the relationships between the microbial metabolic activities and micrite precipitation in extreme environments.

The origin of these carbonate mounds has long been debated. The discovery of seep- and vent-related ecosystems from different geotectonic settings, associated to autigenic carbonate mounds, allowed the re-interpretation of some mounds as the product of chemosynthetic microbial mediation. Sound biostratigraphical, sedimentological and paleontological studies of the Kess-Kess mounds have been performed by Brachert *et alii* (1992) and Aitken *et alii* (2002). Nevertheless the origin of these buildups is still under debate and the most consistent hypotheses are related to submarine hydrothermal vents in which bacteria and/or archaea may have played a prominent role in the carbonate biomineralization (Belka, 1998; Mounji *et alii*, 1998; Joachimski *et alii*, 1999).

The micrite is the dominant component of the Kess-Kess mounds. Very fine dark and white wrinkled laminations record microbial activity (Fig. 1) and the organic matter content of this microfabrics permitted to characterize the source organisms.

The biogeochemical characterization of extracted organic matter was performed through the functional group analyses by FT-IR Spectroscopy. FT-IR parameters indicate a marine origin and low thermal evolution for the organic compounds. The organic matter is characterized by the presence of stretching νC=C vibrations attributable to alkene and/or unsatured carboxylic acids. Preliminary analysis in GC-MS put in evidence an autochthonous (<C22) organic matter sources for the free carboxylic acids. The origin of short chain fatty acids, with a marked even over odd C number predominance, is attributable to bacteria or algae and it is similar to those recorded in recent (Black Sea) and ancient (Late Jurassic to Early Cretaceous) methane-seep microbialites. These biogeochemical signature of microbial carbonatogenesis in ancient extreme environments may have implications in astrobiological research considering the recent discovery of carbonate deposits on Mars.

This research has been funded by Regional Operative Program (ROP) Calabria ESF 2007/2013 - IV Axis Human Capital - Operative Objective M2-Action d.5 (Post-Doctoral Fellowship -Adriano Guido).

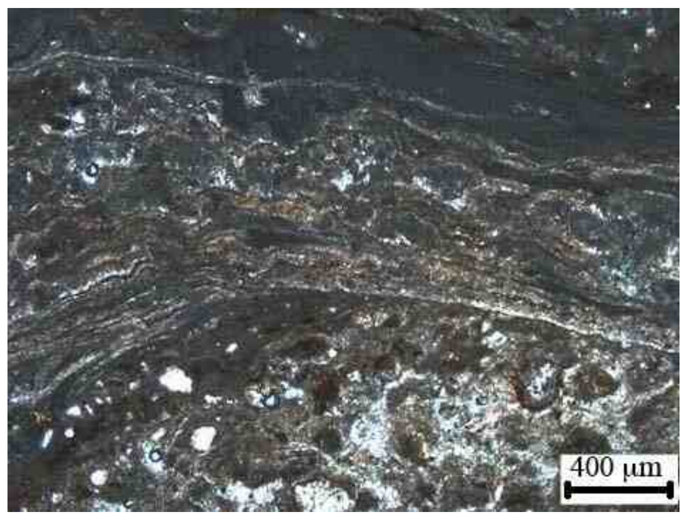

Fig. 1 – Laminated microbialites. These structures are made up of micrometer sized laminations with irregularly alternating dark and white wrinkled laminae arranged in microcolumnar structures. The very fine wavy-wrinkled laminations, showing antigravity patterns, suggests an organic origin and a syndepositional cementation of this microbialite.

ORGANIC MATTER FUNCTIONAL GROUPS

FTIR has been utilised for the characterization of kerogens through measurement of the energy absorbed by the molecules in transition to different vibrational states. Because each functional group tends to absorb infrared radiation in a specific wavelength range, it is possible to detect and discriminate different chemical compounds.

The infrared spectra showed bands between 1000 and 3000 cm^{-1}. They contain stretching aliphatic bands (νCH)ali at 2950, 2920 and 2850 cm^{-1}, and deformation bands of methyl (δCH_3; 1370 cm^{-1}) and both methyl and methylene [$\delta(CH_2 + CH_3)$; 1460 cm^{-1}] groups (Fig. 6). The spectra also display the band

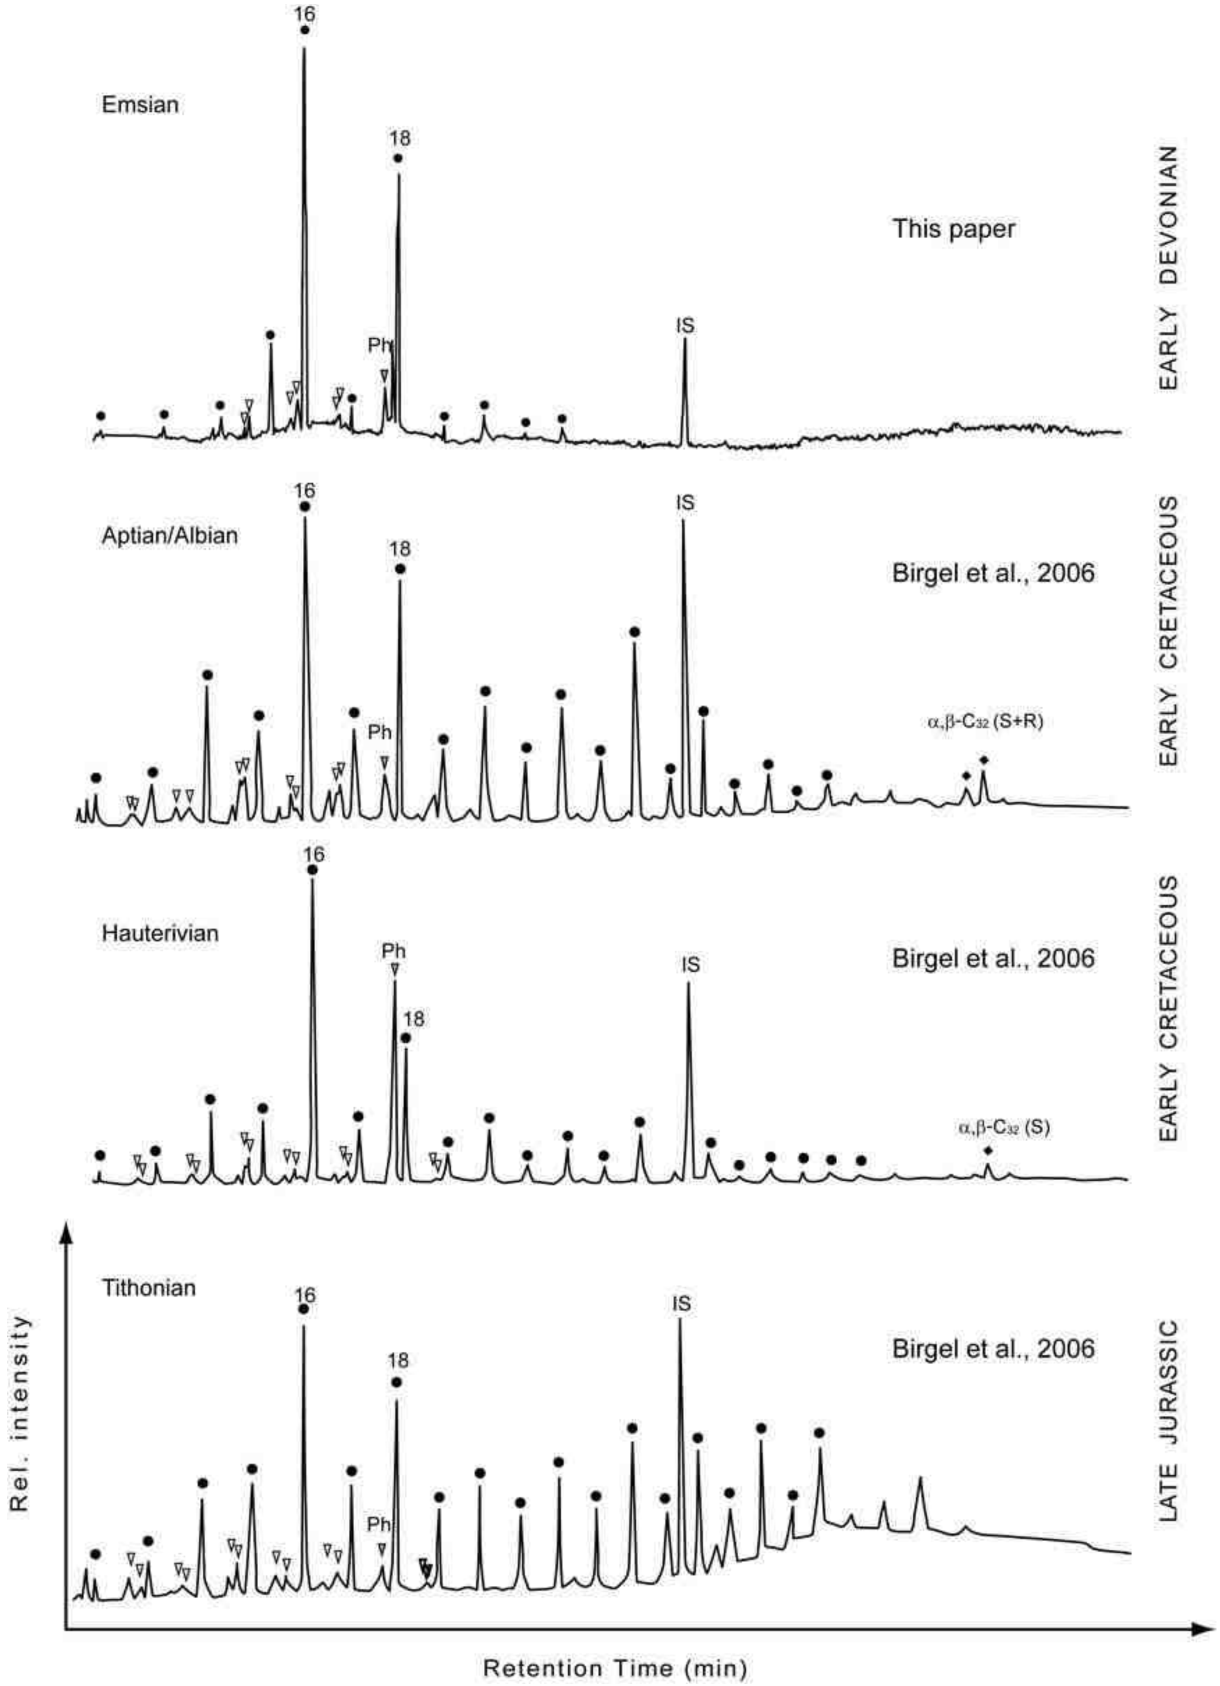

Fig. 2 – Fatty acid fractions from Kess-Kess mounds (this research) and comparison with seep-limestones (from Birgel et al., 2006). Black dots, fatty acids; small white triangles, iso- and anteiso-fatty acids; grey triangles, isoprenoidal acids; black diamonds, hopanoic acids; Ph, phytanoic acid.

assigned to carbonyl and/or carboxyl groups (νC=O; 1740 cm^{-1}). The νC-O vibration appears between 1300 and 1100 cm^{-1}. We recorded also the band νC=C probably related to unsatured compounds (alkene and/or carboxylic acids). We did not record peaks in the regions between 3000-3100 cm^{-1} and 700-900 cm^{-1} attributable to aromatics groups.

PRELIMINARY FATTY ACIDS DATA

Biomarker identifications were based on the comparison of GC retention time, the interpretation of mass spectrometric fragmentation patterns, and the mass spectra literature. Several blank runs were performed to test the analytical procedure. The absence of measurable recovered bitumen indicated that no detectable laboratory contaminations were introduced into the samples.

The GC traces of the free carboxylic acid fraction, extracted from laminated micrites, are shown in Fig. 2. Mainly straight-chains, even numbered, saturated carboxylic acids, were detected. They show strong predominance of hexa- and octadecanoic acid (C_{16}, C_{18}) and small amount of high molecular weight compounds in the region from C_{23} to C_{27}. Iso- and anteiso-fatty acids (C12–

C20) were recognized and peak at 14–18 atoms (Fig. 2). The GC-MS data confirm the attribution of stretching C=C vibrations (obtained with FT-IR analyses) to fatty acids, which excludes the presence of aromatic compounds.

DISCUSSION AND CONCLUSIONS

Frequently microbial signals of modern and ancient seep-deposits can be altered by allochthonous inputs and/or damaged by biodegradation (Hinrichs *et alii*, 2000; Peckmann *et alii*, 2002). In addition secondary migration of hydrocarbons and progressive alteration through thermal maturation may obscure original signals (Goedert *et alii*, 2003). The low thermal maturation of the organic compounds, recorded in the Devonian mounds of Hamar Lagdhad, can furnish a powerful tool to investigate biomarkers in ancient methane-seep carbonates.

The distribution of free carboxylic acids in Kess-Kess mounds put in evidence an autochthonous (<C22) organic matter sources. The origin of short chain fatty acids, that have a marked even over odd C number predominance, may be uncertain, but they can be attributed to an autochthonous origin, since they are ubiquitously observed in aquatic organisms, such as bacteria or algae (Cranwell, 1982). Some fatty acids such as palmitic and stearic acids (16:0 and 18:0 respectively) are ubiquitous. Bacteria are the major source of iso-, anteiso- and mid-chain branched fatty acids, but they can also be a significant source of palmitoleic (16:1) and cis-vaccenic acids (18:1). Diunsaturated $C_{18:2}$ acids are also known as typical bacterial components (Thiel *et alii*, 1997; Peters *et alii*, 2005). The occurrence of $C_{18:1}$ fatty acid was found in cultures of several purple sulphur bacteria living in carbonate environments, such as those involved in microbial mat formation (Russell *et alii*, 1997).

The distribution of free carboxylic acids in Kess-Kess mounds is similar to those recorded in recent (Black Sea, Thiel *et alii*, 2001) and ancient (Late Jurassic to Early Cretaceous, California, Birgel *et alii*, 2006) methane-seep microbialites (Fig. 2). In association to carboxylic acids, these authors record also ^{13}C-depleted archaeal lipid biomarkers such as crocetane and PMI. These biomolecules are commonly used as biomarkers for methanotrophic archaea thriving carbonate precipitation through anaerobic oxidation of methane (Birgel *et alii*, 2006).

Considering the immaturity of the organic compounds and the strong similarity of the fatty acids distributions between Kess-Kess mounds and methane-seep microbialites, further biomolecular analysis in Gas Chromatography-Mass Spectrometry, could permit to propose a carbonatogenetic models based on archaea methanotrophs. These data are necessary in order to evaluate the model proposed by several authors (Belka, 1998; Mounji *et alii*, 1998; Joachimski *et alii*, 1999) that controversially related the Kess-Kess mounds origin to submarine hydrothermal vents.

Micrite precipitation induced by sulphate reducing bacteria in serpulid bioconstructions from submarine caves (Syracuse, Sicily)

ADRIANO GUIDO (*), ADELAIDE MASTANDREA (*) , ANTONIETTA ROSSO (°), ROSSANA SANFILIPPO (°) & FRANCO RUSSO (*)

Key words: *serpulids, microbialites, caves, Syracuse, Sicily*.

ABSTRACT

In marine realm the bioconstruction framework is generally made up of complex relationships among different skeletal organisms (corals, algae, sponges, etc.). The oligotypic bioconstructions are built by one or a few species dominating the association (Laborel, 1987; Belmonte *et alii*, 2008). Among them the tube worms (Polychaeta, Serpulidae) are reported to assume a gregarious existence (Ten Hove & Van den Hurk, 1993). The gregarious serpulids are also known growing as single individuals suggesting the gregarious behaviour is facultative, enhanced by local conditions. Serpulid aggregations are characteristic of unstable environments (Ten Hove, 1979; Bianchi *et alii*, 1995) and are constituted mainly of euryoecious (ecological generalist) species, probably as adaptation against competition and/or predation (Ten Hove, 1979). Serpulids are the dominant component of the macrobenthos in the confined portions of submerged caves (Harmelin, 1985; Zabala *et alii*, 1989; Bianchi & Sanfilippo, 2003; Bussotti *et alii*, 2006).

The discovery of serpulid bioconstructions, miming stalactites (biostalactites), have been reported in submarine caves at Cape of Otranto (Apulia) (Onorato *et alii*, 2003; Belmonte *et alii*, 2008). In this research we studied the unusual serpulid bioconstructions (Fig. 1) that occur within submerged caves in the "Plemmirio Marine Protected Area" (PMPA), south of Syracuse (Sicily). The analyzed samples were collected from Granchi (GR), Mazzere (MA) and Gymnasium (GM) caves within the PMPA on the Maddalena peninsula. These karstic caves formed during Quaternary lowstand phases in gently dipping Middle Oligocene to Tortonian limestones. Cave entrances are situated within weakly lithified layers, at about 20 m below sea-level. The flat cave floors are largely covered by muddy deposits including bioclastic components and sparse large limestone clasts. Small speleothemes are present and stalactites project obliquely downwards from walls and perpendicularly from vaults. The analyzed stalactites are constituted mainly of skeletal encrusting macroorganisms dominated by serpulids bryozoans, and corals, revealing a biological component in their formation. The inner part is generally formed by serpulids belonging to the genus Protula. Small serpulids and other encrusting invertebrates form the external, few centimeters thick parts of stalactites. These associations are dominate by *Semivermilia crenata* and *Josephella marenzelleri*. Subordinately present are encrusting bryozoans such as *Onychocella marioni*, *Puellina (Glabrilaria)*

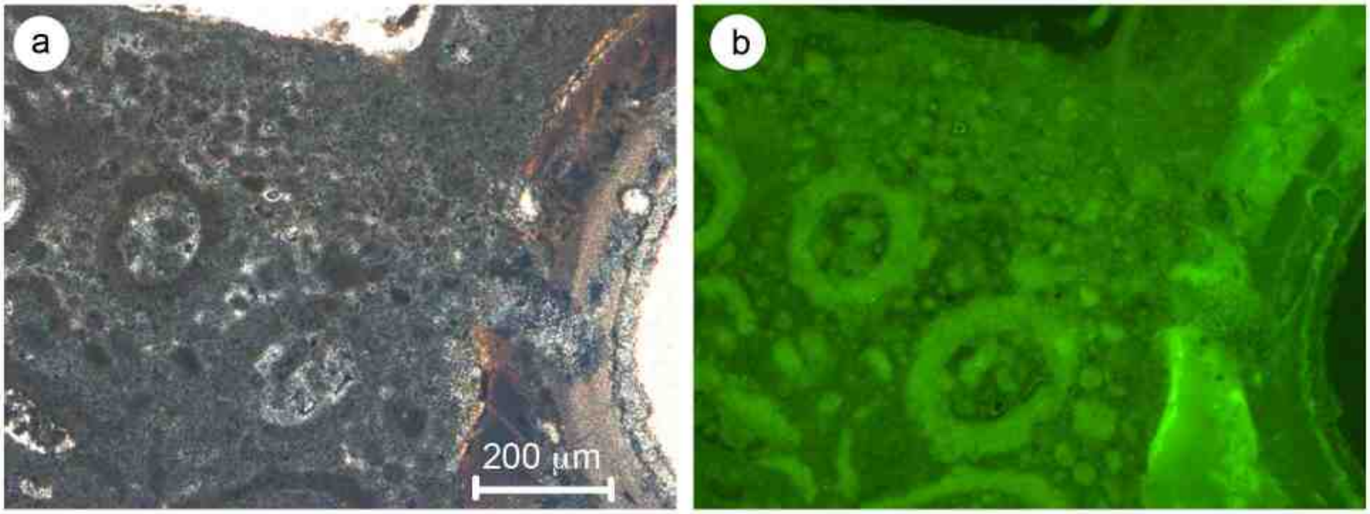

Fig. 2 – a) Thin section showing clotted peloidal micrite surrounding micritized serpulid skeletons; b) UV epifluorescence image displaying organic matter distribution. Note the abundance of organic compounds in clotted peloidal micrite and skeletons.

orientalis orientalis, *Annectocyma indistinta* and *Crisia pyrula*. Sponges and hydrozoans may occur, whereas bivalves and brachiopods are rare. Such associations are typical of these caves, but they normally do not form build-ups like those studied here. The stalactites are somewhat similar with biogenic structures recently identified in several caves along the Puglia coast (Onorato *et alii*, 2003). Thin section observations reveal that skeletal grains are cemented by clotted peloidal micrite (Fig. 2). In the inner part of the stalactites skeletons are severely micritized. Epifluorescence analyses indicate high organic matter contents of the dark peloidal micrites and micritized skeletons. In the external part of stalactites serpulid skeletons are encrusted by peloidal micrites, producing a rigid framework and minor fluorescent aphanitic automicrite with sponge spicules. The latter may result from organimineralization processes of sponge tissues. The close connection between skeletons and peloidal micrite leads to the hypothesis that microbes contributed to the formation of these unusual stalactites.

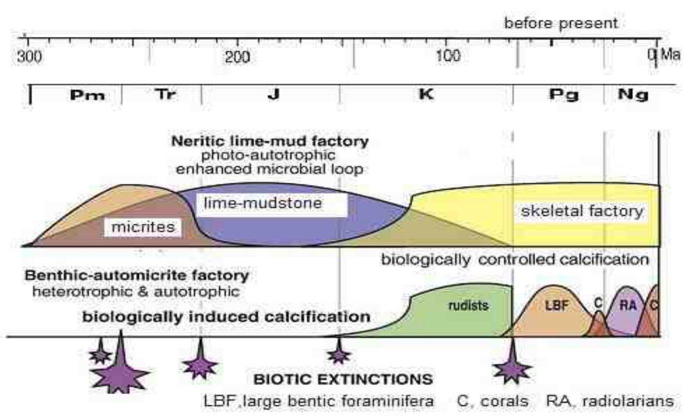
Biotic carbonatogenesis and coevolution of Life and Earth surface

ALDO LEPIDI (*), GIANLUCA FERRINI (**) & ANTONIO MORETTI (**)

Key words*: microbiology, carbonic anhydrase, carbonates*

In its more recent geological history (from Paleozoic to present), Planet Earth behaves largely as a carbonate factory: if carbonate rocks of biochemical origin now available were uniformly stratified on the planet surface a more than 100 meters thick continuous layer would be formed.

Carbonate rocks are actually found in thick sequences outcropping in the mountain ranges and continental margins while calcareous sediments continue to form in suitable environments. The study of Phanerozoic carbonatic sequences shows variations in the abundance of some kind of facies in response to the global sea level changes linking these eco/biological fluctuations to geotectonics and climate and confirming the carbonate formation strictly connected to depositional conditions eventually bound to biological factors.



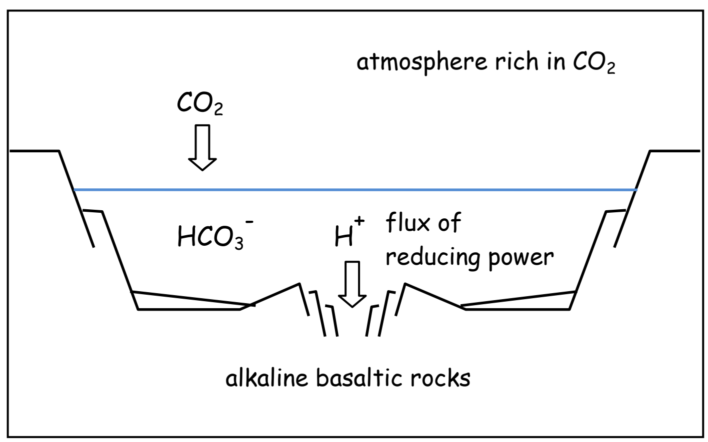
Changes on the predominant type of carbonate factories over the Mesozoic and Cenozoic and major biotic extinctions. (POMAR ET HALLOCK, 2008)

Biogenetic carbonatogenesis refers back to deep Earth past and by now it is an accepted knowledge that cyanobacteria, algae and other organisms were already building up complex calcareous structures more than two billion and half years ago (Tumbiana formation in Australia - LEPOT *et al.*,2008) and not only on our planet (MICHALSKI & NILES, 2010). Into the deep Earth past we note that many organisms used biological carbonategenesis processes in order to use profitably environments with severe constraints.

Recent studies, considering much more ancient times dating back to the first forms of life on Earth, bind the origin of carbonate deposition to a significant decrease of CO_2 in the very primitive atmosphere. Litotrophic and phototrophic prokaryots consumed CO_2 for very long times, the latters releasing molecular oxygen: carbonaceous rocks are hardly compatibile with acidic environments given by high CO_2/$HCO3^-$ concentrations.

Biological balance of CO_2 is governed by carbonic anhydrases, several enzyme families of orthologous proteins largely widespread in the living things and very deeply rooted from the phylogenetic point of view. Even today, ATP synthesis and photosynthesis depend largely on carbonic anhydrases interconverting carbon dioxide into carbonic acid and vice versa:

- ATP synthesis by chemiosmosis likely derived by evolution of primordial organomineral membranes
- In photosynthesis, Rubisco uses CO_2 but the water soluble HCO_3^- is needed to provide bacterial cells and chloroplasts with atmosphere CO_2.



The reduction/salification reactions between carbonic acid of the proto-oceans waters and the alkaline metals of basaltic rocks could activate a some kind of carbonic acid battery and release the energy on primitive pre-biotic and biotic membranes (HENGEVELD & FEDONKIN, 2007; FEDONKIN, 2009).

It seems reasonable to assume that the first carbonate pebble on the Earth appeared not before the atmosphere/water CO_2 concentrations decreased enough to allow the surface waters to become almost neutral. Biological CO_2 removal and burial/subduction of organic matter enriched sediments are likely reliable contributors to such events. Carbonate geocycling due to

(*) Dipartimento di Biologia di Base ed Appliocata, Università dell'Aquila
(**) Dipartimento di Scienze Ambientali, Università dell'Aquila

plate tectonics and volcanism is a major factor regulating C, phosphate and trace elements needed for the maintenance of life for billions of years.

Experimental confirmation of the present proposal can be reached:

- verifying the occurrence and forms of carbonate depositions within the dense fractures networks, formed by the cooling of the primary mantle magmas at the contact with the ocean waters;
- investigating the inner structure, the crystalline phases and the isotopic composition of the oldest recognized carbonates, in particular those occurring as weathering products in the old oceanic ridges.

For this purpose the genesis, the occurrence and the chemistry of ophicalcites should be reconsidered; in fact ophicalcites, a hydro-fractured carbonatized ophiolithic breccias actually dragged in correspondence of mid-oceanic ridges (fig.3), have a controversial origin ranging from hydrothermal to pedogenetic (TREVES & HARPER,1994). More recently, the intervention of microbial activities have been recognized in the origin of many ophicalcites (LAVOIE, 1997).

Fig. 3 – Typical white calcite veins in the Ligurian ophicalcites.

According to several recent investigations, we have plenty of evidences of countless macro and microscopic forms of life governing the biological deposition of calcium carbonates.

Microscopic organisms (mainly bacteria) are found almost everywhere in underground environments (including deep layers of the land and ocean floor). They escape the routinely investigation in the field but are evidenced by recent procedures of genomic, proteomic and metagenomic investigations which permit to evidence specific gene sequences and functions expected in organisms contributing to carbonate sedimentation (JONES *et al*, 2011).

In this connection, the speleothems formation in karst environments as well as everywhere in the upper crust is not fully explained by the physico-chemical equilibria but it is largely governed by biological factors (fig. 4).

Fig. 4 - Calcareous speleothems of microbial origin (Grotta del Cervo, Carsoli, l'Aquila).

Microtidal straits: outcrop analogues from Calabria, south Italy

SERGIO G. LONGHITANO (*)

Key words: *microtidal straits, sedimentary infill, cross stratification, depositional model.*

INTRODUCTION

Straits are marine seaways, commonly located between coastal rocky promontories or flanked by sandy islands, often connecting two adjacent basins (PRATT, 1990). Marine straits are generally characterized by strong hydrodynamics consisting of currents which are amplified in their strength due to a general restriction of the hydraulic cross-section throughout they flow (ANASTAS et al., 2006).

In general, water masses crossing the strait can be moved by local winds/waves or are alongshore currents forced to flow through by coastal geomorphological constrictions. In some case, currents are generated by tidal excursions occurring in one of the two interconnected basin or, more rarely, changing in opposition of phase (when in one basin there is low tide, in the other basin there is high tide, and *vice versa*).

Sediments occurring at the bottom of these straits can be transported and distributed in a variety of ways. In the narrowest strait zone, currents may have the highest velocity, thus they erode, rather than accumulate, sediments; this zone is consequently a by-pass area. As the strait margins enlarge, sediment usually produce bedforms (dunes or sand waves), whose lateral distribution and dimension depend on the strength of the tidal currents. As the strait expands, bedforms pass laterally to shelf mudstones because currents lose their energy (LONGHITANO *et al*., 2008).

A number of study cases from Neogene-to-Quaternary microtidal strait-fill successions of Calabria (south Italy) represent valuable outcrop analogues to obtain a facies models for ancient microtidal straits. The Calabrian Arc represents part of a small orogen that rapidly translated toward SE during the Neogene on to the underlying Maghrebian Chain (MALINVERNO & RYAN, 1986) (Fig. 1). The process of tectonic superimposition occurred through the formation of regional shear zones (TANSI *et al*., 2007) producing tectonically-controlled narrow straits. These transtensional depozones were locally filled by marine deposits, including sublittoral to deeper environments. Most of these straits linked the Tyrrhenian and the Ionian sea whose oceanography was characterized by semi-diurnal microtidal (<0.5m) inversions with opposite phases, at least from the Neogene until today.

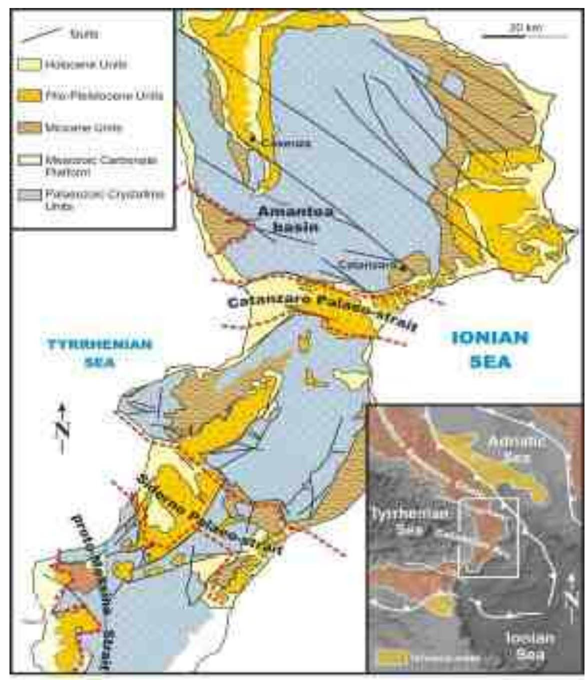

Fig. 1 – Regional setting and structural map of Calabria with indication of the main tidal straits (modified, after LONGHITANO *et al*., 2012b).

Such tidally-driven water exchanges occurring between these two adjacent basins can be observed in the present-day Messina Strait. Here, a S-directed descendant tidal prism forms during the first 6 hours of every day. Then, tidal current invert their direction, generating a N-directed opposite tidal prism during the subsequent 6 hours. These tidally-driven currents are able to generate gravel/sand dunes up to 9 m high and migrating in the two opposite zones of the Messina Strait (MERCIER *et al*., 1987).

OUTCROP ANALOGUES

In Calabria, a number of Neogene to Quaternary successions exhibit cross-stratified deposits whose facies features suggest a

(*) Università degli Studi della Basilicata, Dipartimento di Scienze Geologiche, V.le Ateneo lucano, 10 85100 – Potenza. Tel.: +39 0971 20.58.65; fax: +39 0971 20.60.77; E-mail: sergio.longhitano@unibas.it.

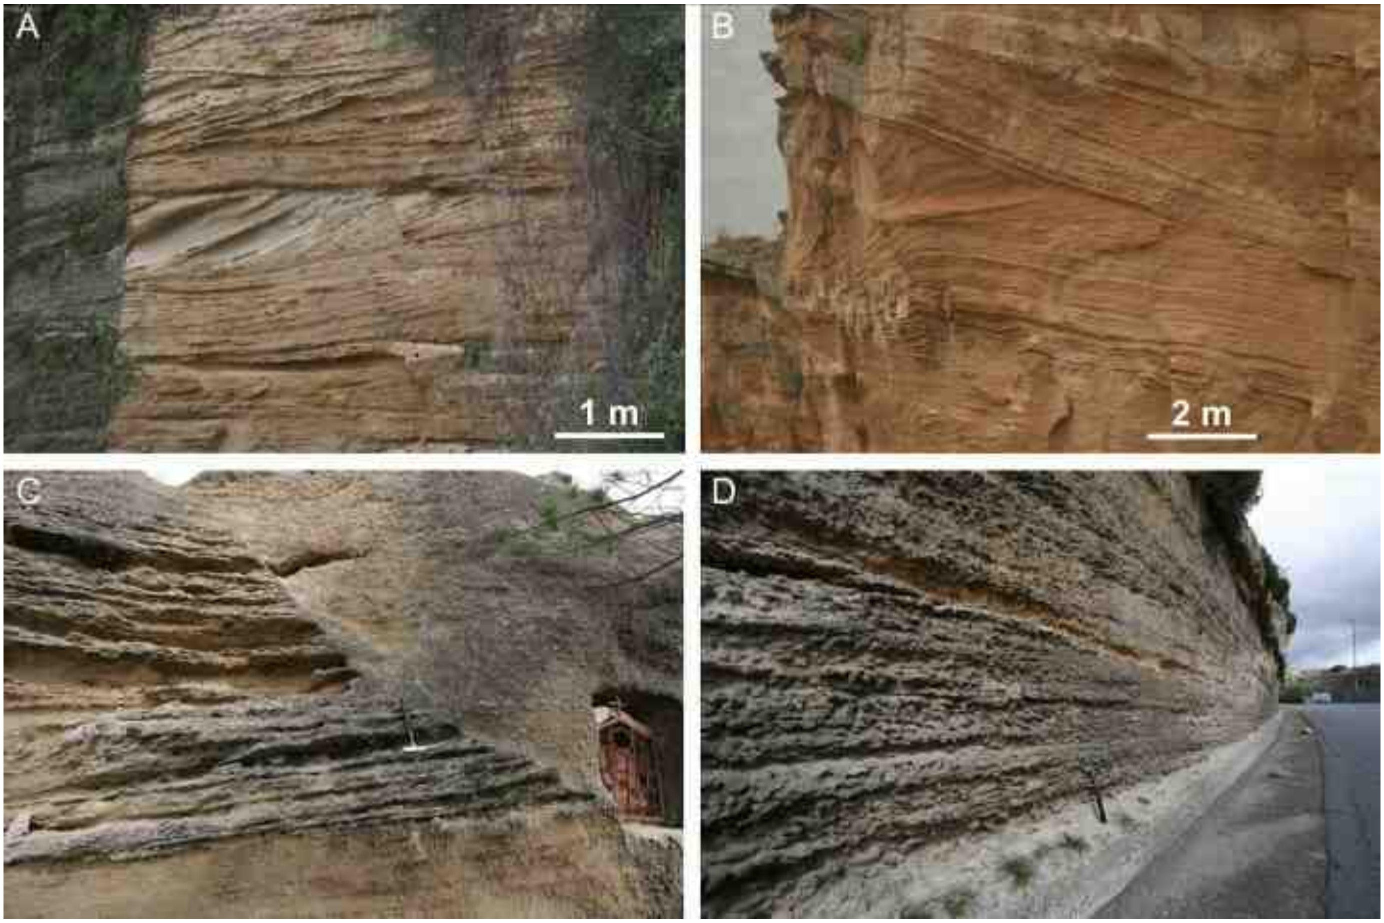

Fig. 2 – (A) Cross-stratified tidal deposits from the Pliocene Siderno Palaeostrait. (B) Tidal dunes with opposite palaeocurrent directions form the Tortonian Amantea Basin. (C) Debris flow deposit cutting cross-stratified tidal deposit from the Pleistocene of the Messina Palaeostrait. (D) Distal, intensely bioturbated siltstones alternating with cross-stratified tidal sandstones (Pleistocene, Messina Palaeostrait).

strong tidal signature. These tidalite-bearing sediments commonly include spectacular examples of tidal dunes with highly varying dimensions (1 to 10 m thick). They contain bundle cross lamination, herringbones, opposite cross strata and re-activation surfaces, which are physical attributes of tide-dominated subaqueous environments (DARLYMPLE *et al*., 1990; LONGHITANO *et al.*, 2012a).

The best exposed Calabrian outcrops are those of the Tortonian Amantea Basin, the Pleistocene Catanzaro Strait, the Plio-Pleistocene Siderno Strait and the Pleistocene Messina Strait (Fig. 1). All these successions fill E-W-, NW-SE- and N-S-elongated narrow corridors, bounded by block-faulted Mesozoic basement. In all of these outcrop analogues, sediments consist of granule- to sand-sized fully terrigenous to mixed (bioclastic-siliciclastic) deposits, commonly organized into 2 and 3D cross strata (Fig. 2A) (LONGHITANO, 2011; LONGHITANO *et al*., 2012b). Cyclical (neap/spring) lamina bundles are very common within the cross strata, forming repeated intervals of coarser/thicker to finer/thinner laminasets, often interrupted by re-activation surfaces (Fig. 2B). Locally, cross strata form herringbone structures with one dominant thicker bedding superimposed to reverse thinner strata (Fig. 2B). Intensely bioturbated horizons are rhythmically present within the dune, generally very close to neap lamina intervals or to pause planes. The palaeocurrent directions are consistent with the regional extension of each palaeostrait, with the two opposite modal ranges showing picks in the two peripheral zones of the strait (i.e., E-directed palaeocurrents dominate in the eastern strait side, whereas W-directed palaeocurrents dominate in the western strait side).

TOWARD A CONCEPTUAL MODEL

In all the outcrop analogues, four facies associations can be recognized, each indicating as many depositional zones within the strait.

(i) The *non-depositional strait-centre zone* is often characterized by absence of deposits or by condensed sediments consisting of 1-2 m thick transgressive coarse-grained horizons, overlying the basement and rapidly evolving upward to shelf mudstones. These deposits are very rarely characterized by cross stratification. (ii) This zone passes laterally in either the strait terminations to two *dune-bedded strait-side zones* which, symmetrically or not, represent the strait enlargements toward deeper sectors. These areas are commonly characterized by tidal cross strata, forming alternations of thicker and thinner bed packages (Fig. 2B), due to repeated cycles of accelerating and decelerating tidal currents, probably induced by high-frequency relative sea-level changes (LONGHITANO & NEMEC, 2005). (iii) The *strait-margin zones* are, on the contrary, characterized by debris-flow and debris-fall deposits that pass laterally to cross stratified tidal deposits (Fig. 2C), forming a marginal-type facies assemblage (LONGHITANO, 2011). (iv) Distally, the zones where tidal dunes thin up to disappear are represented by the *strait-end zones*, which are characterized by very thin cross strata (10-20 cm thick) interbedded to thicker (0.5-2 m thick), highly bioturbated siltstone strata and shell beds (Fig. 2D).

These four depositional zones indicate a system where tidal currents were the main hydrodynamic factor dominating the sediment distribution, although the studied straits developed in a microtidal oceanographic setting. These outcrop analogues are key to understand the vertical/lateral relationships between facies and associated depositional environments in modern tidal straits and to identify the various hydrodynamic zones.

The model proposed in this work represents a first preliminary depositional scenario that was common to many Neogene-to-Quaternary microtidal systems having the same history. However, more data and considerations need to better constrain the original facies distribution and the lithosome geometries and to generate models for hydrocarbon reservoirs with similar features or to well constrain the oceanographic setting of present-day microtidal strait scenarios.

Nuovi metodi analitici per l'identificazione di paleoambienti deposizionali in areniti miste: il caso studio di Acerenza (Appennino lucano)

SERGIO G. LONGHITANO (*) & DOMENICO CHIARELLA (**)

Key words: *Appennino lucano, bioclastic/siliciclastic ratio, depositi misti, Gelasiano , Segregation Index.*

INTRODUZIONE

Una nuova tecnica sedimentologica è stata affiancata all'analisi di facies di depositi misti (bioclastico/silicoclastici) di ambiente marino sublitorale ed affioranti sul fronte dell'Appennino Lucano (Gelasiano, Basilicata), con l'obiettivo di ottenere importanti informazioni circa le caratteristiche idrodinamiche dell'originario ambiente deposizionale.

Tale metodo propone l'uso del (i) *bioclastic/siliciclastic ratio* (*b/s*) e del (ii) *Segregation Index* (*S.I.*), al fine di valutare la percentuale della componente clastica dominante in un deposito misto e con lo scopo di stimare il grado si segregazione eterolitica tra le particelle bioclastiche e silicoclastiche (CHIARELLA & LONGHITANO, 2012).

Il principio di questa tecnica si basa sulla differente risposta fisica che una particella di quarzo e un frammento bioclastico mostrano se trasportati da una corrente di energia nota (PRAGER *et alii*, 1996; NEUMEIER 1998). Pertanto, un differente tipo di tessitura clastica in un deposito misto può essere considerato come il risultato di una variazione dell'energia di trasporto e come conseguenza dell'interazione di differenti processi idrodinamici (*i.e.*, moto, ondoso, correnti, oscillazioni di marea).

I depositi studiati affiorano lungo il fronte dell'Appennino lucano (Acerenza, Basilicata). Essi formano successioni cuneiformi, variamente distribuite in differenti settori del fronte orogenico e di spessore non superiore ai 30 m. Ciascuna successione mostra una transizione verticale di facies da ambienti di *offshore* ad ambienti di *shoreface* e di *beachface*, formando cicli regressivi di alcuni metri di spessore e separati da superfici di discordanza o di trasgressione marina (CHIARELLA *et alii*, 2012; CHIARELLA & LONGHITANO, 2012).

Oltre alla tecnica canonica di analisi di facies, la transizione latero/verticale dei vari ambienti è stata documentata anche attraverso l'utilizzo del *b/s* e del *S.I.*, i quali mostrano valori quantitativamente variabili a seconda dell'idrodinamismo dominante in quel determinato ambiente deposizionale e a seconda della possibile interazione tra differenti fattori di influenza idrodinamica.

METODI APPLICATI

Il *bioclastic/siliciclastic ratio* (*b/s*) misura la proporzione quantitativa delle due componenti eterolitiche in un sedimento misto. Tale caratteristica è una precondizione necessaria affinché un deposito possa essere considerato di natura 'mista' (un sedimento misto può essere realmente considerato tale soltanto se ognuna delle sue componenti antitetiche supera il 10% (MOUNT, 1985). In Figura 1 sono indicate 5 classi di b/s, il cui intervallo numerico corrisponde al rapporto reciproco tra le due componenti, secondo una progressione del 20% (Fig. 1).

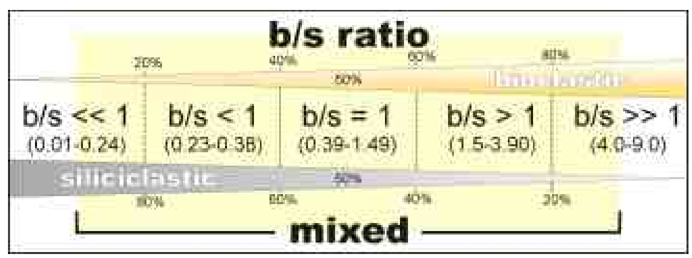

Fig. 1 – Classi di abbondanza di frazioni bioclastiche e silicoclastiche in un deposito misto determinate sulla base del *b/s* ratio (da CHIARELLA & LONGHITANO, 2012).

Il *Segregation Index* (*S.I.*) rappresenta un parametro adimensionato che quantifica il grado di segregazione eterolitica all'interno di un deposito misto. Per segregazione eterolitica si intende la distribuzione fisica che particelle clastiche di differente composizione mostrano all'interno di un deposito o di una roccia sedimentaria. La stima di tale caratteristica è stata sperimentata attraverso l'utilizzo di un comparatore visivo (Fig. 2A). Tale comparatore, il quale può essere utilizzato sia in laboratorio che in affioramento, è stato ottenuto attraverso l'utilizzo di circa 50 g di frazione silicoclastica quarzosa e di frazione bioclastica derivante da frammenti di pettinidi. Il comparatore consta di quattro classi di segregazione i cui differenti gradi sono stati ottenuti attraverso progressivi stadi di agitazione meccanica delle due componenti, da uno stadio iniziale di totale segregazione (i.e. separazione fisica delle due componenti), ottenendo via via stadi successivi di *mixing*, fino alla totale assenza di segregazione (Fig. 2A). Ciascun differente grado di segregazione è stato ottenuto

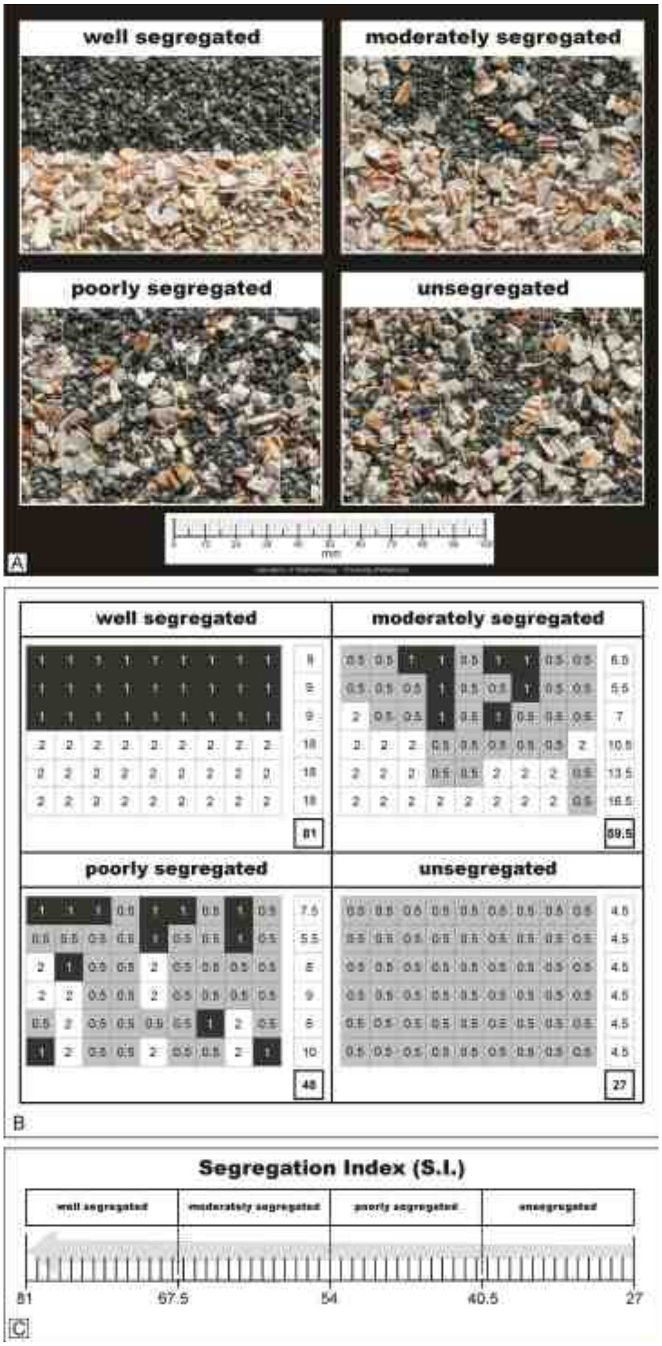

Fig. 2 – (A) Comparatore utilizzato per la stima del *Segregation Index* (*S.I.*). (B) Metodo delle matrici con indicizzazione per il differente tipo di segregazione all'interno di ciascuna cella (C) Indice di Segregazione e relativi intervalli numerici (da CHIARELLA & LONGHITANO, 2012).

dalla fotografia ad alta risoluzione (2.400 dpi) di ogni singolo campione di campo e piazzando su di essa una matrice rettangolare di 54 celle ognuna di 10 mm di lato. Ogni singola cella viene successivamente indicizzata con i valori di 1, 2 o 0,5, a seconda se all'interno di ciascuna di essa siano presenti soltanto clasti terrigeni (1), bioclasti (2) o entrambi (0.5) (Fig. 2B). Tali indici, marcati in nero, bianco o grigio per ottenere anche una sintesi visuale della loro distribuzione spaziale, vengono successivamente conteggiati per somma algebrica. Il risultato della somma degli indici individua due limiti estremi (*27* e *81* in Fig. 2C) i quali indicano un *range* di segregazione clastica. Ogni valore così ottenuto definisce un *S.I.*, il quale indica non solo il grado di segregazione delle due componenti bioclastica e silicoclastica ma anche il grado di maturità tessiturale di ciascuna facies considerata. I dati così ottenuti dall'applicazione di questo metodo hanno fornito differenti valori di segregazione i quali definiscono altrettante facies sedimentarie (Fig. 3). Tali facies riflettono differenti ambienti deposizionali in cui il grado di segregazione è risultato dipendere dal tipo di idrodinamismo dominante o dall'interazione di più fattori idrodinamici. Ad esempio, ambienti di transizione all'*offshore* hanno mostrato la presenza di sedimenti molto ben segregati (*S.I.* = 77.5), grazie a correnti unidirezionali la cui energia oscillava secondo ritmi mareali, mentre facies più superficiali (*shoreface*) sono state caratterizzate da valori di segregazione molto scarsi o nulli (*S.I.* = 45) a causa del continuo rimaneggiamento dei sedimenti assoggettati al moto ondoso. Tale metodo sperimentale può essere applicato all'interno di tutti i depositi misti il cui meccanismo di accumulo sia stato regolato da fattori idrodinamici tipici di ambienti sublitorali.

Rare Earth Elements signature in Triassic samples from Punta Grohmann and Alpe di Specie (Dolomites, Italy): evidence of Cyanobacterial *vs* Sulfate Reducing Bacteria metabolic activities

FABIO TOSTI (*), ADRIANO GUIDO (*), ADELAIDE MASTANDREA (*), FABIO DEMASI (*) & FRANCO RUSSO (*)

Key words: *Microbialites, Triassic, Dolomites, Cipit Boulders, Rare Earth Elements distribution, ICP-MS.*

ABSTRACT

Rare Earth Elements (REE) plus Yttrium (Y) patterns of modern seawater have characteristic anomalies that can be used as chemical fingerprints for paleoenvironmental recontructions. Microbial carbonates are so far very reliable proxies for the record of their depositional marine environment (BOLHAR *et alii* 2004; WEBB & KAMBER 2000). This interpretation has been confirmed from a large geological time span, including Archaean Banded Iron Formation (BIF), stromatolitic limestones, Phanerozoic reef carbonates and Holocene microbialites (KAMBER & WEBB 2001; KAMBER *et alii* 2004; NORTHDURFT *et alii* 2004; WEBB & KAMBER 2000).

The Triassic carbonate buildups of the Dolomites have been the subject of many geologic researches and were used for decades as classic examples of ancient coral reefs. Several studies tried to improve the understanding of the buildup nature, in particular the microfacies and their possible evolution and diversification.

The present research deals with the characterization of the so-called "Cipit Boulders" (Ladinian – Carnian in age). These carbonate blocks, represented by platform-derived olistoliths and clasts exported within fine-grained basinal sediments, escaped the extensive dolomitization that affected the buildups (Fig. 1).

Geochemical analyses have been carried out on selected Cipit boulders occurring in the Punta Grohmann (Wengen and S. Cassiano Formations, Late Ladinian- Middle Carnian) and in the Alpe di Specie (Heiligkreuz Formation, Late Carnian) sections.

The dominant microfacies is represented by boundstone, consisting of nearly 60% of micritic limestone showing peloidal or laminated fabrics, mostly organized into stromatolitic laminites or thrombolites. Skeletal organisms (*Tubiphytes*, skeletal cyanobacteria, sphinctozoan sponges, etc.) represent a minor component of the rock. The presence of "microproblematica" assisted in stabilizing the substrate. The stability and firmness of Cassian platforms can be related also to considerable amount of early marine cements. They are widespread and consist of fan-shaped calcite (replacing former aragonite), bladed isopachous Mg-calcite and radial-fibrous calcite.

The main component of these platforms, from which the olistoliths derived, consists of carbonate mud. Two types of micrite genesis are distinguishable: detrital micrite and microbialite.

The organic-induced nature of microbialites was already hypothesized on the base micromorphological evidence and epifluorescence observations (RUSSO *et alii*, 1997; 1998).

Fig. 1 – Cipit Boulder surrounded by basinal marly sediments. These blocks could range in size from few decimeters to some meters.

Biomarker data confirmed the presence of bacteria/cyanobacteria communities during platform deposition, indicating that microbes have played a prominent role in the genesis of these carbonates (TOSTI *et alii*, 2011).

In order to indicate paleoenvironmental characteristics and confirm the microbialite deposition model, we analyzed REE distribution patterns in both successions.

The concentration of Rare Earth Elements and Yttrium (REE + Y) in the samples was measured with inductively coupled mass spectrometry (ICP-MS). Both successions show coherent and reliable REE + Y patterns with the typical characteristics of microbial carbonates (Fig. 2). Punta Grohmann samples show enrichment in heavy REE (Nd_{SN}/Yb_{SN} = 0,73, SD = 0,06), a negative Ce and a positive La anomaly, a marine type Y/Ho ratio (Y/Ho = 55, SD = 6), and a slightly positive Gd anomaly. Alpe di

This research has been funded by Regional Operative Program (ROP) Calabria ESF 2007/2013 - IV Axis Human Capital - Operative Objective M2-Action d.5 (Post-Doctoral Fellowship -Adriano Guido).

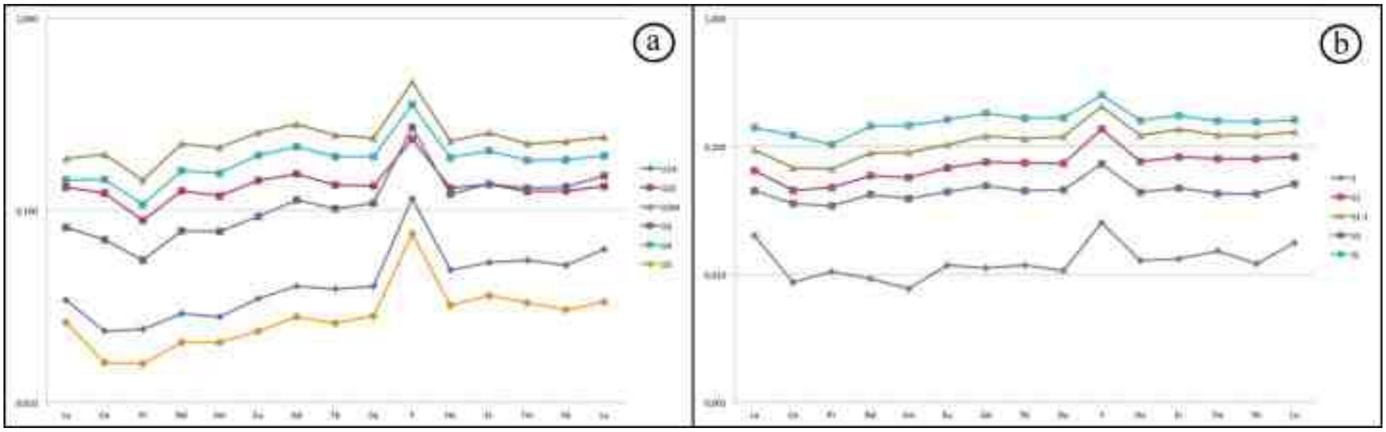

Fig. 2 – REE+Y distribution patterns of Punta Grohmann (a) and Alpe di Specie (b) samples. Note the different geochemical behavior of the Alpe di Specie (b) pattern that could indicate a more reducing environment.

Specie data indicate a lighter enrichment in heavy REE (Nd_{SN}/Yb_{SN} = 0,93, SD = 0,09), the presence of a negative Ce and a positive La anomaly, a lower marine Y/Ho ratio (Y/Ho = 45, SD = 4).

These patterns suggest that Punta Grohmann carbonates incorporated REEs in equilibrium with an oxygenated environment, while Alpe di Specie ones are characterized by a more reducing environment. The micromorphological and geochemical data permit to hypothesize that the microbialites with stromatolitic fabric of Punta Grohmann (Late Ladinian – Middle Carnian in age) deposited via cyanobacterial activities in a oxygenated environment. The microbialites of Alpe di Specie (Late Carnian) with thrombolytic fabric, their biomarker types and the reducing environment indicate a deposition involving sulfate reducing bacteria.

Recent mass-wasting processes and related geohazard at Stromboli and Vulcano (Italy)

DANIELE CASALBORE (*), CLAUDIA ROMAGNOLI (**), ALESSANDRO BOSMAN (*), FRANCESCO LATINO CHIOCCI (°)

Key words: submarine landslide, multibeam, La Fossa caldera, Sciara del Fuoco, Aeolian Islands.

INTRODUZIONE

Stromboli and Vulcano islands are two active volcanoes located in the Aeolian Arc (Southern Tyrrhenian sea). Their submarine portions account for about 98% and 80% of the whole extent of volcanic edifice, respectively (BOSMAN *et alii*, 2009; ROMAGNOLI *et alii*, 2012). The flanks of these volcanic edifices are very steep and covered by volcaniclastic sediments due to a large spectrum of mass-wasting processes, ranging from large-scale sector collapses to small landslides (CASALBORE *et alii*, 2011; ROMAGNOLI *et alii*, 2012). The geohazard related to these processes is very high, as demonstrated by the occurrence of a medium-scale tsunamigenic landslide on 30 December 2002 at Stromboli (Fig 1a; CHIOCCI *et alii*., 2008).

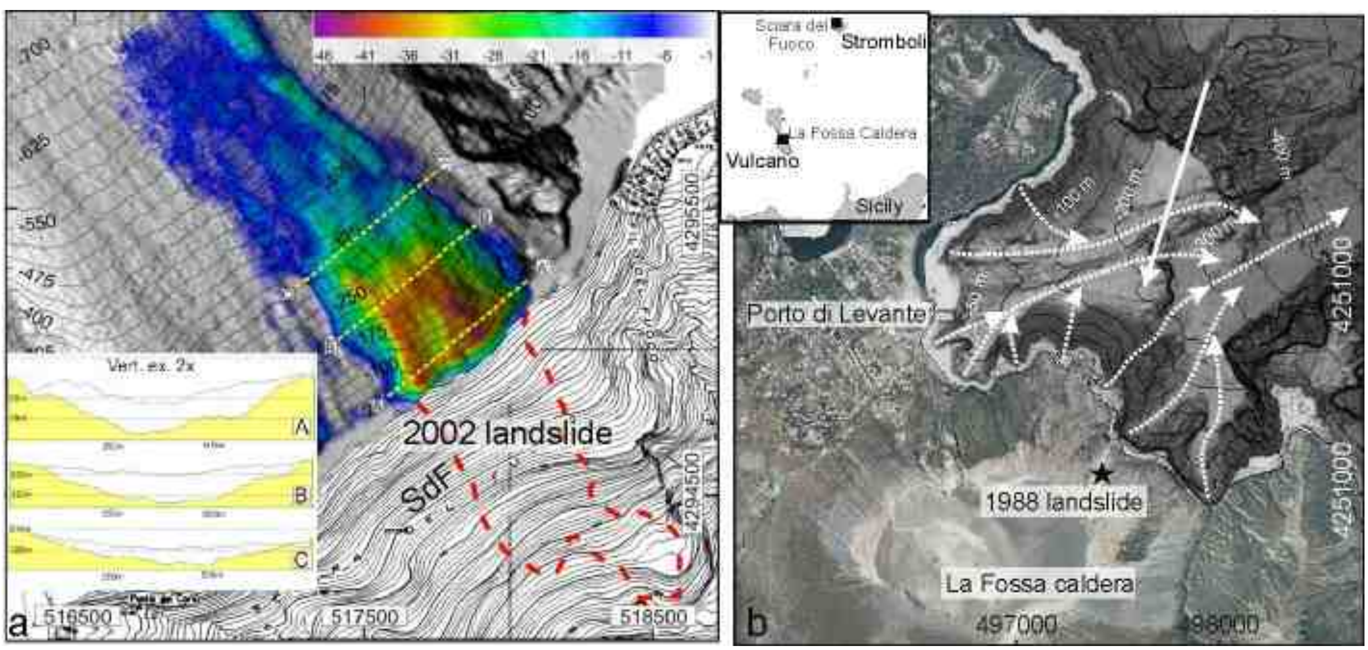

Fig. 1 – Residual map (scale bar units are in meters) obtained as difference between pre- and post-"2002 Stromboli landslide" draped over the shaded relief of Sciara del Fuoco slope at Stromboli volcano; the red dashed line indicates the limit of the subaerial landslides; three pre- and post-landslide cross-section of 2002 landslide scar are also shown (modified from Casalbore et alii, 2012). b) La Fossa Caldera emerged and submerged sectors, with the indication of the 1988 tsunamigenic landslide and erosive gullies (white arrows, modified from Romagnoli et alii, 2012); the location maps of the Fig. 1a and b are reported in the inset

The aim of this work is to depict recent mass-wasting and erosive processes that affect the submarine flank of these volcanic edifices, with particular reference to the areas offshore two very active sectors, i.e. the Sciara del Fuoco at Stromboli (Fig. 1a) and La Fossa caldera at Vulcano, where a small tsunamigenic landslide occurred in April 1988 (Fig. 1b; TINTI *et alii*, 1999). This task has been realized through the integration of multibeam, long-range side scan sonar and seismic data collected in the last ~20 years from IGAG-CNR of Rome and the Universities of Rome (Sapienza) and Bologna.

Size Distribution of Submarine Landslides along the Gioia Basin. Tyrrhenian Sea (Italy)

D. CASAS (*), F. CHIOCCI, D. CASALBORE (**) & G. ERCILLA (°)

Key words: *Geohazard, Gioia Basin, Statistical distribution, Submarine slides* .

INTRODUCTION

The magnitude-frequency relationship of sedimentary instabilities is essential for a proper hazard assessment at regional scale. The distribution of sedimentary instabilities, their recurrence of certain sizes, and triggering mechanisms are variables for determining their potential hazard. Regional inventories that incorporate these variables represent the first step to establish the probability of triggering a sedimentary instability, with certain dimensions, and during a period of time.

For subaerial landslides, it has been suggested the cumulative number-area and cumulative number-volume relationships can be described by inverse power-law distributions based on the dimensions of the failure scar, slide deposits or headwall length (GUZZETTI *et alii*, 2002; DUSSAUGE *et alii*, 2003, Guthrie and Evans, 2004, MALAMUD *et alii*, 2004). In the marine environment, those relationships have resulted successful for a few studied cases (TEN BRINK *et alii*, 2006; MICALLEF *et alii*, 2008). In most of those studies the inverse power law distribution only explained a truncated portion of mapped inventories, and the size distribution appeared to fit a log-normal distribution. In these cases, normal distribution was often attributed to an undersampling of landslides with a given size range.

The distribution based on the inverse power law results from a self-organized critical behavior. This implies that from equivalent initial conditions, a series of events resulting from additive processes can be generated. This is explained, in terms of instability processes, by the fact that the metastable region on which the instability is propagated once initiated, can grow by coalescence of smaller regions. By contrast a log-normal distribution implies that the metastable region is destabilized instantly. Then, the final size of a landslide depends on the characteristics of the trigger (e.g. magnitude) and adjusts for local variations such as slope, strength etc.

This work has been developed in the framework of the MAGIC project and the "José Castillejo" program (JC010-134).

The work here presented is based on the analysis of geological and geomorphological characteristics of a large area of Gioia Basin, in the Tyrrhenian Sea (Fig. 1), in order to generate interpretive maps that allow the identification and characterization and spatial distribution of sedimentary instabilities.

GEOLOGICAL FRAMEWORK

The Gioia Basin is an intra-slope basin located between the NE margin of Sicily and S Calabria, and is divided into two sub-basins (N and S) by the Acquarone structural high. In the southern margin of Calabria, this structural high separates also another intra-slope basin called Palmi (Fig. 1). The continental shelf is practically absent along the margin of Calabria, although locally it is about 5 km wide along the northeast coast of Sicily, facing the structural high Acquarone. The N Gioia Basin (NGB), limited laterally by structural highs, shows as a main morphological feature the Gioia-Mesima canyon/channel system (GMS). This system is characterized by a double head defining the canyons Gioia and Mesima that evolve to channels with the same name beyond the foot of slope (COLANTONI *et alii*, 1992). The GMS system is tributary of Stromboli valley (CASALBORE, 2009, 2011).

METHODOLOGY

The development of this work has been done on the basis of bathymetric data acquired in the framework of the MAGIC project (Map of Geohazard-related features of the seafloor of Italy) which aims to make the mapping of geological hazards along the Italian margins. The methodology for this study is based on the characterization and mapping of each of the instabilities as well as the definition of their headwalls. This has allowed calculating the position and length of the scars, their area, and the volume of sediment mobilized.

The volume of sediment has been calculated using Digital Elevation Model and GIS tools. The protocol is based on 4 key steps: 1) definition of the boundaries of the headwalls, 2) export of those limits (x, y, z) for generation a surface simulating the initial seafloor conditions, 3) extraction of the surface that defines the post-slide area, and 4) calculation of volume by

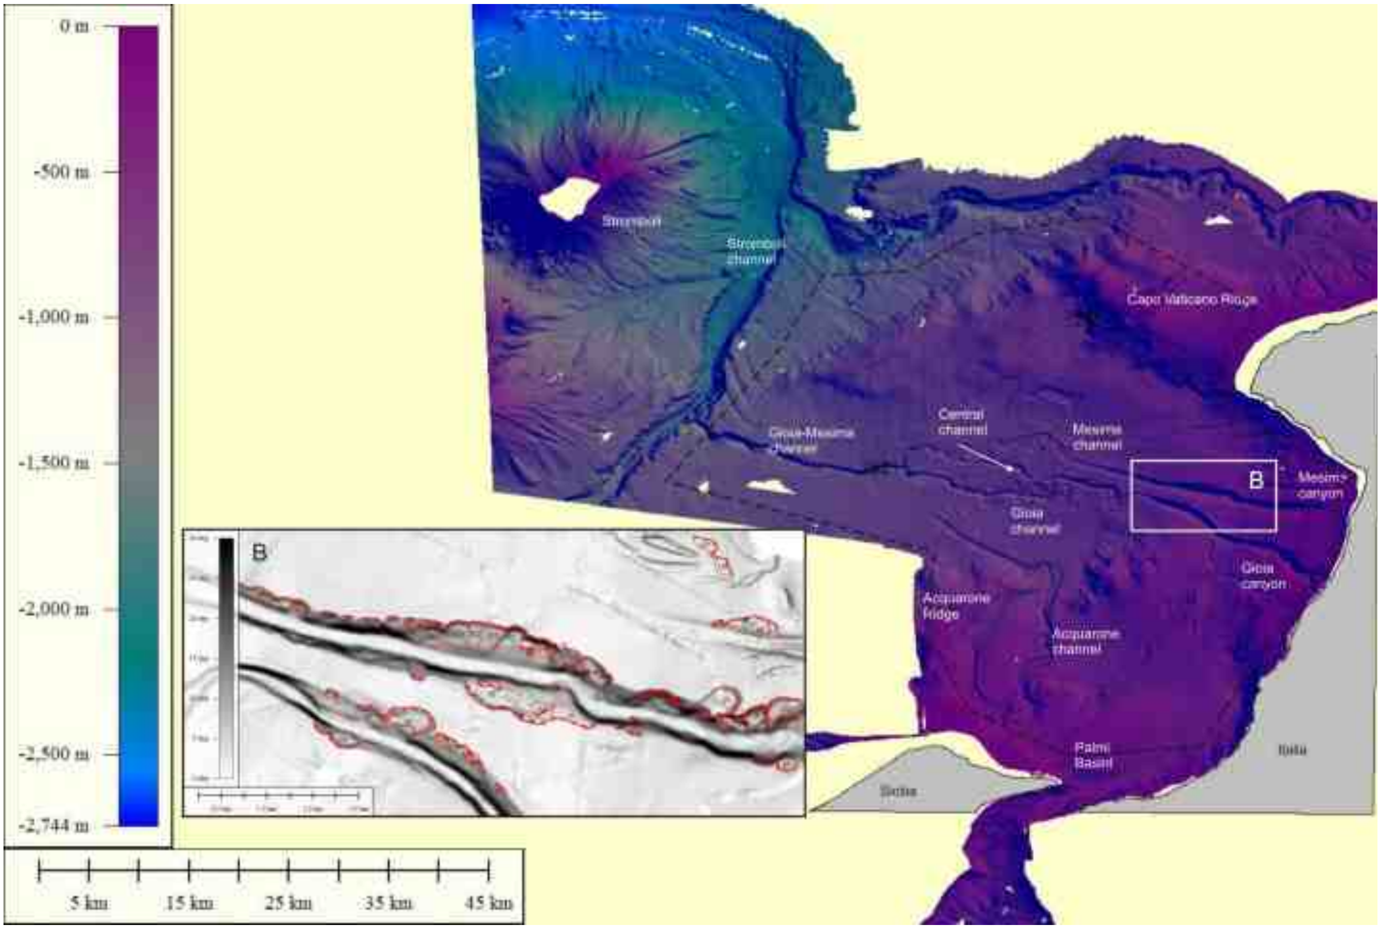

Fig. 1 – Bathymetry of the study area (dashed line). (B) Detail of the instabilities mapped on the margins of Gioia and Mesima channels.

superimposing the two surfaces.

The minimum size of an identifiable instability is a function of resolution bathymetric. This resolution is higher in shallow areas. For this reason the instabilities defined by a perimeter of less than 0.10 km have been dismissed.

RESULTS

We have studied the geology and geomorphology characteristics of an area of about 3350 km^2 in the Gioia Basin which has allowed the identification and characterization of 420 landslides. These landslides affect an area over 87 km^2 and are responsible for the mobilization of about 1.5 km^3 of sediment. The 59% of instabilities are located in the heads and sidewalls of the canyons and channels, like MSG and Acquarone (Fig. 1). The remaining 41% are located in the open slope and the walls of structural highs bounding the the Gioia Basin. The largest landslide occurs in the slope at 1500 m water depth and is defined by a scar of 7 km long. The headwall area covers 11 km^2 and involves a sediment volume of 0.4 km^3. By contrast, the smallest one is located at 19 m depth, and has a scar of 50 m long. The headwall area covers 171 m^2 and involves a sediment volume of 200 m^3.

DISCUSSION AND CONCLUSIONS

Bibliographic compilation about the Mediterranean Sea published by CAMERLENGHI *et alii*, 2010, indicates that the mapped instabilities in this sea are relatively small in size with respect others, for example from N Atlantic. That inventory identifies a total of 532 sedimentary instabilities. Most of them (419) have a size between 10 and 103 km^2 and only 77 display sizes less than 10 km^2. However that inventory lacks of observations of smaller sedimentary instabilities. By contrast, the inventory carried out in this work represents an opportunity to improve the statistical significance of the frequency distribution at different spatial scales. This is because it incorporates a large number of measurements in small landslides (<10km^2) which are often unrepresented or undersampled. Likewise, our observations practically equal to the total number of instabilities described in the Mediterranean covering only a small area of the Tyrrhenian

Sea (420 *vs*. 532).

The cumulative number-volume distribution of the instabilities described in this work, can be described by a log-normal distribution (Fig. 2). This would reinforce the findings of other authors in the marine environment (Ten Brink *et alii*, 2006 among others). Confirmation of this distribution should be made by the individual analysis of each different populations observed in the different environments defined (channel / canyon, slope, structural highs). This analysis in different geological environments can provide valuable information not only on the dynamics of the landslide processes but also on the impact on the evolution of a particular environment such as the evolution of a channel / canyon.

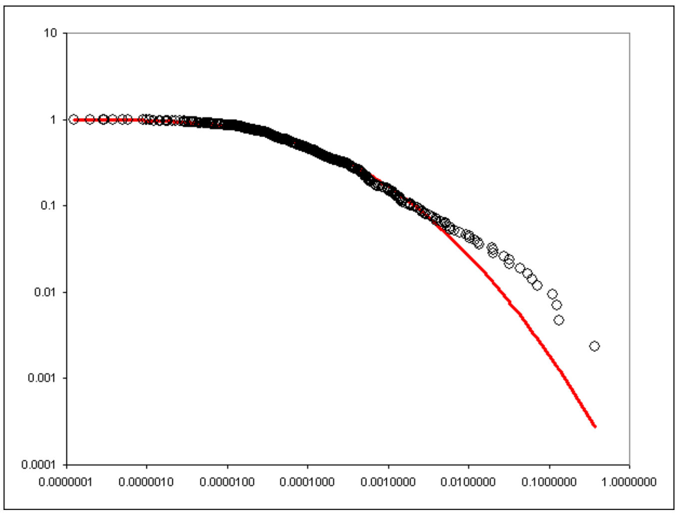

Fig. 2 – Cumulative number-volume distribution of the total instabilities described in this work. Red line represents the log-normal distribution (R^2=0.9734).

Seabed mapping for geohazard in the Gulf of Taranto, Ionian Sea (Southern Italy)

S. CERAMICOLA (*), M. R. SENATORE (**), M. COSTE (*), A. MEO (**), M. BOSCAINO (**), A. COVA (*)

Key words: *Geohazard, Gulf of Taranto, seabed morphology. sedimentary processes*

The seabed features of the Gulf of Taranto are the morphological expression of the geological processes that have occurred in this area during the Calabrian Arc subduction, where the Adria, European and African plates converge, in the NE side of the Ionian Sea. This area is characterized mainly by three different adjacent geomorphological domains: 1) the Calabrian margin, characterized by the deformations of the southern prolongation of the Appennines Chain (to the west) the Taranto valley, the seabed morphologic expression of the Bradanic foredeep (in the center) and 3) the Apulian margin, characterized by the western termination of the Apulian Ridge.

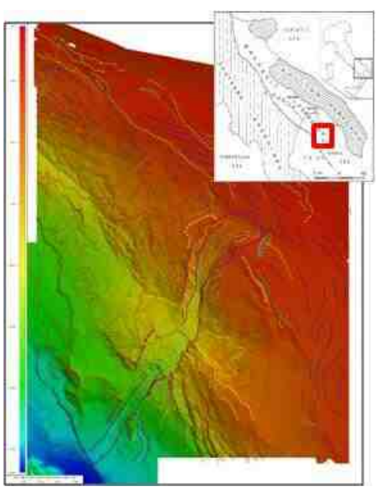

Figura 1 Seabed mapping of the Apulian margin. Color lined indicate major morphological lineaments. Contours are marked every 50m.

This area have been the object of several new geophysical investigations in the last years and the results have been used to carry out the first seabed mapping of the Gulf of Taranto seabed features in order to assess geohazards and risk related to geological processes for the coastal areas. This work has been carried out under the framework of the Magic Project (Marine Geohazards Along The Italian Seas), funded by the department of the Civil Protection of Italy.

We here present the first high-resolution seafloor and geohazard maps of the Gulf of Taranto obtained integrating swath-bathymtry, side-scan sonar, subbottom data, seismic reflection profiling and literature information from previous studies. Main geomorphological seabed features and domains have been defined, and they have been associated to main geological processes (sedimentary and tectonic) occurred in this area. Canyons at different stages of development -some of them showing important retrogressive activity, diffuse erosional along-slope features, faults depicting the seafloor at different locations, gas seepage and landslide scars are some of the most prominent features identified that could present an hazard for coastal areas. All these active features observed in the Gulf of Taranto seafloor may seriously endanger human society especially in coastal areas where most of the population reside, but also in deeper sea, where oil/gas pipelines and cables are located; our results are relevant to both monitoring of these features through time and to gain a good knowledge of their functioning.

Reconstruction of a submarine landslide and related tsunami from morpho-bathymetry and sub-bottom data on the Ionian Calabrian margin (Mediterranean Sea)

S. CERAMICOLA (*), S. TINTI (**), F. ZANIBONI (**), D. PRAEG (*), P. PLANINSEK (***)

Key words: *Ionian Calabrian Margin, morpho-bathymetry sub-bottom data, submarine slide, tsunami modelling*

Submarine landslides are natural phenomena that transport marine sediment down continental slopes into deep-marine environments. Landslides can be triggered by a number of different causes, either internal (such as changes in physical chemical sediment properties) or external (e.g. earthquakes, volcanic activity, salt movements, sea level changes etc.). Landslides may mobilize sediments in such a way as to form an impulsive vertical displacement of a body of water, originating a wave or series of waves with long wavelengths and long periods called tsunamis ('harbor waves').

The aim of this work is to reconstruct the volume and dynamics of a submarine landslide on the tectonically active Ionian Calabrian margin (ICM). The study is based on geophysical data - morpho-bathymetry (Reson 8111, 8150) and sub-bottom profiles (7-10KHz) - collected aboard the research vessel OGS Explora in the framework of the MAGIC Project (Marine Geohazard along the Italian Coasts), funded by the Italian Civil Protection

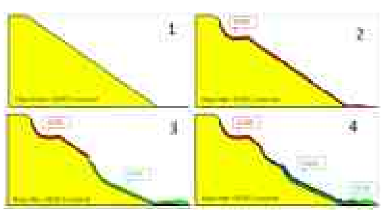

Fig 1 - Reconstructions of the Assi failure dynamic.

The geophysical data provide evidence that the ICM has been exposed during recent time to multiple failure events. Morpho-bathymetric data reveal headwall scars up to 50 m high across water depths of 700 1400 m, while sub-bottom profiles indicate stacked slide deposits at and near seabed. We estimate that the failure mobilized ca. 2 km^3 of sediment, over at least 15 km from the headwall. Together the data enable the reconstruction of the landslide dynamic considering two possible scenarios: 1) the landslide mobilized in two steps (conservative scenario); 2) the landslide mobilized all the sediment in a single step (most dramatic scenario). On the basis of these two scenarios we attempt to mathematically model the failure and simulate the tsunami that would have been generated by the considered volume of sediment.

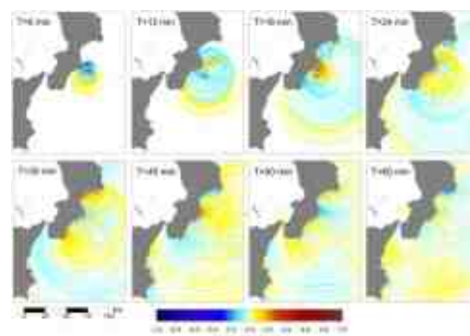

Fig 2 . Tsunami propagation at different time steps, over the near field computational domain G1. The positive signal, meaning sea ingression is marked with the yellow-red scale, the negative measure, accounting for sea withdrawal, with the cyan-blue scale

Numerical simulations have been performed using the numerical codes developed by the University of Bologna research team. We have computed the motion of the mass, the tsunamigenic effects of the motion on the sea water and the propagation of the tsunami waves. We have assessed the main tsunami features such as travel times, main wave period, polarity of the first arrival, maximum wave elevation, providing a complete picture of the coastal hazard associated to such event. It has been found that the area most affected in this tsunami scenario is the stretch of coast about 25 km long between Roccella Jonica and Monasterace on the eastern side of Calabria. Even if the resulting waves have limited amplitude they can cause relevant damage to the infrastructures located close to the shoreline.

Assessments of tsunami arrival time in adjacent coastal areas, period and wavelength of the tsunami and implication

Different morpho-structural canyon systems observed on the Ionian margin (Calabria, Italy)

COSTE M. [1,2], CERAMICOLA S. [1], MIGEON S. [2], FORLIN E. [1] & COVA A. [1]

Key words: *Canyon maturity, Ionian Calabrian margin, Ramification degree, Seabed morphology and morphometric analysis, Sub-botton data, Swath-bathymetry*

INTRODUCTION

Sediment transfer from the continental shelf to the deep-basin is a great interest as it partially controls the morphological and architectural evolution of continental margins. Downslope transfer of sediments via processes of erosion and deposition result in the construction of typical features such as submarine canyons. Because they strongly erode the continental slope, canyons contribute significantly to its morphological evolution through time.

This study aims to better understand the processes of formation and evolution of nine canyon systems identified on the Ionian Calabrian margin. In particular, two systems of canyons, the Corigliano system (in the north) and the Squillace system (in the south) have been taken as example to show the differences of their morpho-structural characteristics. Analyses of seabed morphology and morphometry have been carried out using swath bathymetry data and sub-bottom profiles, acquired by the OGS Explora vessel, along the Ionian Calabrian margin, in the frame of the Italian project MAGIC (MArine Geohazards along the Italian Coasts) funded by the Department of Civil Protection. This work is also part of a larger study which aims to compare canyon dynamics in the Calabrian and the Ligurian continental margins.

Main morphometric characteristics of the canyons (ramification degree, length, width, depth, incision shape, slope gradient, sinuosity index) have been analyzed in order to better understand their origin, construction mechanisms and evolution in relation to the regional geological context. We also studied the main characteristics of the fluvial system that could be associated to each canyon (area drainage, main slope gradient, length, theorical suspended sediment concentration and monthly discharge), to better understand what are the relations between rivers and submarine canyons.

In this work we show how submarine canyons adjust to the general evolution of the margin topography and could be used as markers of its deformation. The northern example; the Corigliano system; exhibits a poorly ramification gradient, a longitudinal thalweg convex-trend and low incision parameters (i.e. incision depth and incision width). Corigliano shows poorly branched and dendritic heads which are associated to relative large watersheds. On the contrary the southern example; the Squillace system; exhibits a higly ramification degree, a concave-trend longitudinal profile and relative high incision parameters (i.e. incision depth and incision width). Squillace heads are highly branched and are associated to smaller watersheds.

The overall objective, once analyzed all the nine canyons systems will be to bring new insights on the canyon degree of maturity and being able to discriminate between "juveniles" and "matures" canyons along the Ionian Calabrian margin. The information provided by the canyon morphometry of the Calabrian Margin are used to speculate on which factors controlled their formation and evolution, in relation to the regional geological context of this tectonically active margin.

Processes of formation and evolution of submarine canyons on the western margin of the Ligurian margin

COSTE M. (*,**), MIGEON S., (**) & CERAMICOLA S. (*)

Key words: *Bathymetry, Ligurian margin, Submarine canyons, Regressive erosion, Seismic profiles, Side‐scan sonar system, Slope failure.*

INTRODUCTION

Sediment transfer from the continental shelf to the deep basin is of great interest as it partially controls the morphological and architectural evolution of continental margins. Transfer of particles on the continental slope associates with processes of erosion and deposition that control the construction of typical features such as submarine canyons. Because they strongly erode the continental slope, canyons contribute significantly to its morphological evolution through time. Canyon heads, which have generally amphitheatre-like morphologies, commonly incise into the continental shelf and connect directly or indirectly with subaerial river systems. However, a number of studies have evidenced submarine canyons that do not connect with sub-aerial channelized systems, questioning their processes of formation and evolution.

This study aims to better understand the processes of formation and evolution of 6 submarine canyons identified on the western margin of the Ligurian Basin, along an offshore area extending from Nice (France) to Imperia (Italy). Processes of slope failure are analyzed in the same zone in order to investigate a wider range of sediment gravitytransfer processes. From morphometric and structural analyses based respectively on bathymetric and seismic-reflexion (24-channel profiles) data acquired during the MALISAR 1 and 2 surveys, we constrained the main geometric characteristics of canyons and failure scars (width, depth, incision shape); and we analyzed their internal structure in order to better understand their origin, construction mechanisms and evolution in relation with the regional geological context.

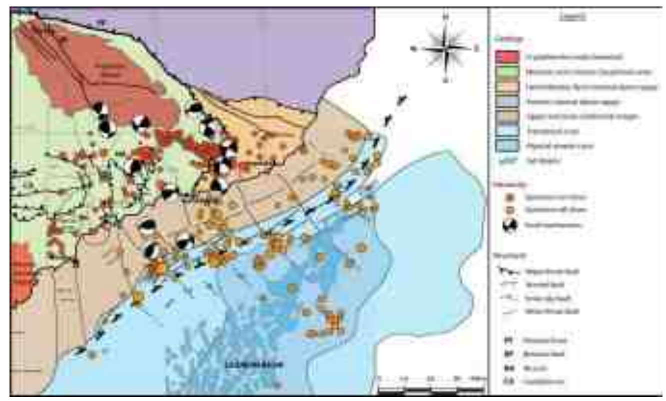

Fig. 1 – Structural map of the studied zone (Ligurian Margin), modified after Courboulex et al., 1998 ; Calais et al., 2000 ; Bigot-Cormier et al., 2004 ; Larroque et al., 2009).

The 6 canyons are characterized by a morpho-structural variability: 1/ from west to east along the studied margin-segment, and 1/ from the top to the base of the continental slope. In the context of moderate tectonics, the construction and evolution of canyons is most likely controlled by: 1/ the topography inherited from the messinian erosion, 2/ active faulting that extended during the plio-quaternary, 3/ margin deformation influenced by the uplift increasing eastward, 4/ the slope gradients, and 5/ the size of sub-aerial drainage basins.

This work also allowed us to propose two hypotheses for the origin of canyons: canyons connected to the sub-aerial river system depend directly to river sedimentary discharge, which strongly adjust to eustatic variations; whereas slope-confined canyons, disconnected from the shelf and river systems, result from regressive erosion related to repetitive small-scale failures at their head.

We demonstrated that submarine canyons adjust to the general evolution of the margin topography. Processes of adjustment include for instance regressive erosion and deviation of the thalweg axis. Canyons can therefore be used as markers of the margin deformation in the Ligurian Basin.

Composition and depositional architecture of late Quaternary sediments in the deep-water northern Ionian Basin, southern Italy

SALVATORE CRITELLI (*), ROCCO DOMINICI (*), FRANCESCO MUTO (*), FRANCESCO PERRI (*) & VINCENZO TRIPODI (*)

Keywords: *composition, detrital modes, fluvial systems, Ionian Basin, northern Calabria, provenance*.

INTRODUCTION

The Calabrian continental margin lies at the SE tip of the arcuate Apennine–Maghrebide accretionary system (e.g. SARTORI, 2003). The structural setting of this area is the result of an interplay between the south-eastward migration of the Calabria–Peloritani Arc since the late Miocene and the rapid uplift of onshore and shallow shelf areas since the middle Pleistocene. The Calabria–Peloritani Arc migra-tion resulted in a strong dissection along several NW-trending regional shear-zones, characterized by left lateral movement in the central and northern parts and right-lateral movement in the south (KNOTT & TURCO, 1991).

The sedimentary fill of basins is related to several factors concerning relationships between source areas and sedimentary basins.

This study provides insight into the petrology of modern marine sediments, based upon the coupling of both climatic and physio-graphic controls. Furthermore, the chemical and mineralogical varia-tions provide additional constraints on the behavior of the element distribution during the continental weathering. Knowledge of such coupling is important for the interpretation of analogous clastic deposits in the geological record.

GEOLOGICAL SETTING

The structural setting of the study area (Fig.1) is the result of an interplay between the south-eastward migration of the Calabria–Peloritani Arc since the late Miocene and the rapid uplift of onshore and shallow shelf areas since the middle Pleistocene.

The present northern Ionian Calabrian Basin is a wedge-top basin within the modern foreland-basin system of southern Italy. Two seabed structural settings can be recognized here, the southern Apennine fold-and-thrust belt in the north and the Crotone and Spartivento fore-arc basins in the south.

In the northern part of the study area, the Crati River and some minor streams (Trionto, Nicà and Lipuda) feed several wedge-top basins (e.g. Amendolara and Corigliano basins) separated by E–Wand NW–SE trending structural ridges (e.g. Amendolara Ridge and Rossano–Cariati High).

In the southern area the Neto and Esaro Rivers are the most important drainage basin that feed into the Ionian deep Basin through the Neto and Esaro Canyons separated by Hera Lacinia–Luna High.

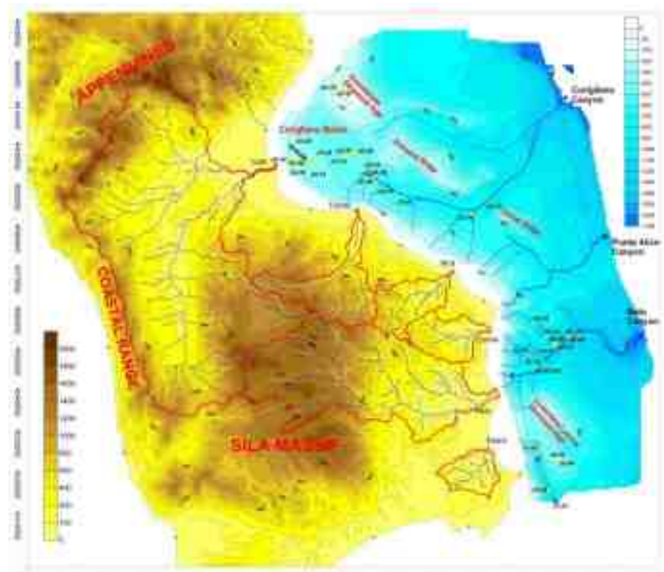

Fig. 1-General sketch map of the investigated area in the Gulf of Taranto.

COMPOSITIONAL AND DEPOSITIONAL FEATURES

The exploration of the seafloor during the last three decades has illustrated the widespread occurrence of submarine depositional systems.

Alluvional/fluvial and deltaic systems of the Ionian side of northern Calabria generate dominantly quartzofeldspathic sand,

(*) Dipartimento di Scienze della Terra, Università della Calabria, 87036 Arcavacata di Rende (CS) – e.mail: francesco.perri@unical.it

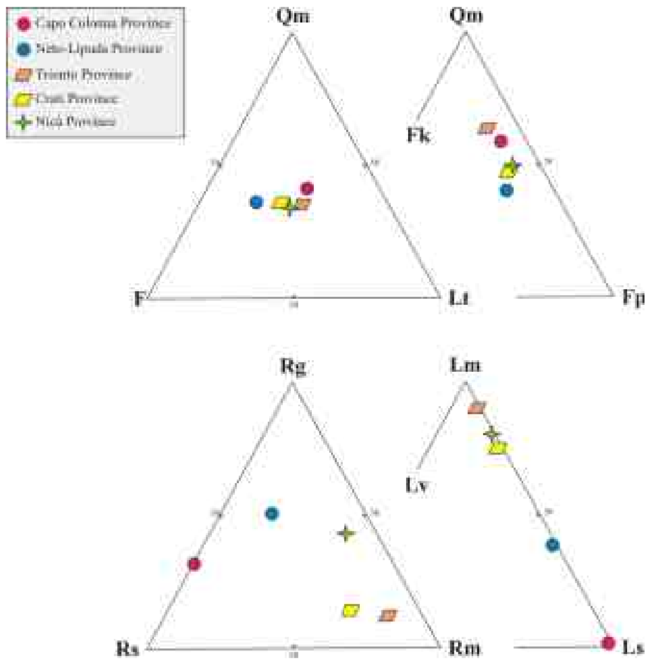

Fig. 2-Ternary plots for the sand studied samples. Qm (monocrystalline quartz), F (feldspars) and Lt (aphanitic lithic fragments); Qm (monocrystalline quartz), F (K-feldspar) and Fp (plagioclase); Rg (plutonic rock fragments), Rs (sedimentary rock/lithic fragments) and Rm (metamorphic rock fragments); Lm (metamorphic), Lv (volcanic) and Ls (sedimentary) lithic fragments. See the text for more details.

reflecting the dominantly plutoniclastic and metamorphiclastic nature of the key source massif of the area, the Sila Mountains.

Other local sources are the south-eastern flank of the Southern Apennines and Neogene sequences of the Peri-Ionian piedmont.

Sediment composition, mud geochemistry and mineralogy identifies four main source areas for late Quaternary turbidites of the Ionian margin. The turbidites originate from fluvial sources of northern Calabria and are introduced through moderate to small canyons. Deep-marine sands of the Ionian margin are quartzofeldspathic, which reflects the dominant mainland sources of the Crati (northern) and Neto (southern) rivers, with lesser contributions from small drainage systems such as the Trionto and Nicà rivers (e.g., PERRI *et alii*, 2012).

The Gulf of Sibari, is sedimentologically and compositionally dominated by the Crati Fan, a sand–mud turbidite system represented by quartzofeldspathic sand quite similar in composition to the mainland source of the Crati River main-channel and its river-mouth. Local contributions to the deep marine environment are derived from the (a) Trionto River, generating quartzofeldspathic sand turbidites, and the (b) intrabasinal source from the Amendolara bank, generating intrabasinal carbonate sand. In the southern studied area, canyons and gullies dominate morphologically, and themain source for turbidites was the Neto River. Sand– mud turbidites are compositionally quite similar to the quartzofeldspathic Neto River and delta; local contributions are from quartzolithic sand of the Lipuda and Nicà Rivers, or from carbonate sand of local intrabasinal highs and eroded late Quaternary terraces, at the southern end of the studied area (e.g., PERRI *et alii*, 2012).

DISCUSSION AND CONCLUDING REMARKS

The northern Calabria along the eastern coast provides a favorable setting in which to study complete transects from continental to deep-marine environments.

Petrography studies of coarse-grained fraction coupled to chemical and mineralogical analyses of the fine-grained fraction represent an important tool for the investigations of the processes occurred from sediment generation on the uplands to the final accommodation on bathyal plain.

Detrital modes of sand reflect the cumulative effects of source rock composition, chemical weathering, hydraulic sorting and abrasion (SUTTNER, 1974; BASU, 1985; JOHNSSON, 1993). The correlation of sand composition with weathering intensity (BASU, 1976; SUTTNER *et alii*, 1981) and duration of weathering (FRANZINELLI & POTTER, 1983; GRANTHAM & VELBEL, 1988; JOHNSSON & STALLARD, 1989; LE PERA & SORRISO VALVO, 2000) has long been established. The distribution ofmajor and trace elements related to the mineralogical composition of fine-grained sediments is a pivotal factor to reconstruct the source-area composition and the weathering and the diagenetic processes (e.g. CONDIE *et alii*, 1992, BAULUZ *et alii*, 2000; PERRI *et alii*, 2005, 2008, 2011; MONGELLI *et alii*, 2006; CRITELLI *et alii*, 2008; CARACCIOLO *et alii*, 2011). By combining the information deduced from the evolution of the X-ray diffraction (XRD) patterns and the elemental analyses formajor and trace elements concentrations obtained by X-ray fluorescence spectrometry (XRF) for the mud samples and the petrographic studies for the sand fraction, it is possible to explain and predict the sedimentary evolution and geological processes affecting the studied sediments and, thus, the relationship developed between source area and sedimentary basin.

The Ionian margin of Calabria is an exceptional area in which sedimentation and sediment composition can be examined in the total environmental context.

The northern studied area, the Gulf of Sibari, is sedimentologically and compositionally dominated by the Crati Fan, a sand–mud turbidite system represented by quartzofeldspathic sand quite similar in composition to the mainland source of the Crati River main-channel and its river-mouth. Local contributions to the deep marine environment are derived from the (a) Trionto River, generating quartzofeldspathic sand turbidites, and the (b) intrabasinal source from the Amendolara bank, generating intrabasinal carbonate sand.

In the southern studied area, canyons and gullies dominate morphologically, and themain source for turbidites was the Neto River. Sand– mud turbidites are compositionally quite similar to the quartzofeldspathic Neto River and delta; local contributions are from quartzolithic sand of the Lipuda and Nicà Rivers, or fromcarbonate sand of local intra basinal highs and eroded late Quaternary terraces, at the southern end of the studied area.

The Ionian Calabrian margin is a typical tectonically active siliciclastic continentalmargin,with canyon-fed sources supplemented by smaller scale failures coming off steep slopes adjacent to the coastline. Identification of source areas and flowpathways has revealed single sources for sand and mud turbidites; nonetheless, northeastward-flowing bottom currents may have some influence on the widespread distribution of muddy deposits.

We infer that the deformation along the Moroccan margin has been significant and is still ongoing. Our study area, on the Xauen/Tofino banks, the South Alboran ridge and the Al Hoceima area, off Morocco, shows signs of ancient and active strike-slip and thrust-related deformation with associated mass-movement deposits and contourites. Sedimentary processes and their interaction with tectonics are inferred from stratal geometries and isopachs.

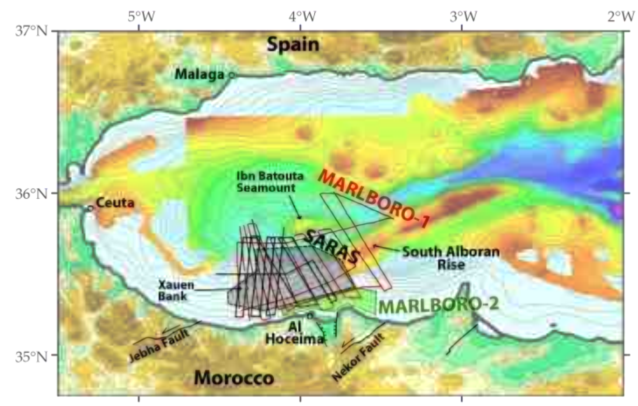

Fig. 2 – Cruise plans for the Marlboro-1, Marlboro-2 and SARAS cruises (R/V Côtes de la Manche TethysII, CNFC, INSU and Ramon Margalef IEO, Eurofleets). Topography and Bathymetry from Gebco database and bathymetric compilation (Medimap Group, et al., 2005) in the Alboran Sea. Contour interval is 100m

In the distal margin depositional features have been affected by tectonic events since at least the Messinian, e.g., the contourites along the Xauen/Tofino bank and South Alboran ridge have been extensively involved in growth-faulting. The seismic reflection data from southern Alboran Sea bathymetric steep slopes show numerous slides linked to active growth-faults as well as thrusts. Tectonic inversion is recorded since the late Tortonian with an acceleration of uplift and compression evidenced since the Messinian. The Xauen/Tofino and Alboran highs have a strong internal complexity showing tight folds, thrusts, unconformities, and intruded magmatic and mud bodies reflecting different stages and styles of deformation. Offshore Al Hoceima Bay a network of active normal faults and strike-slip faults have been imaged in the bathymetric and high-resolution seismic reflection data. Two distinct sets of faults are observed, one set striking north-south through the Al Hoceima Bay and the second west of Al Hoceima Cap, striking northeast-southwest. The latter could have been responsible for the Al Hoceima earthquakes in 1994 and 2004.

INTRODUCTION

Critical reviews of the available seismic records and analyses of CTD data in the Alboran Sea have changed the previous interpretations about the types of deposits making up the nearsurface sediments of the Alboran Sea. During the last 20 years many studies about sedimentation in the Alboran Sea suggested that turbiditic fans, gravitative deposits and hemipelagites characterized the slopes and sub-basins of the Alboran Sea. The new results suggest the dominance of contourites interrupted by submarine fans and sedimentary instabilities in those physiographic domains (Fig. 1). In this work, we'll focus in the contourites and the water masses responsible of their shaping.

GEOLOGICAL SETTING

The Alboran Sea, that is located in the southwesternmost Mediterranean Sea, is about 150 km, 350 km long, has maximum water depths of about 1800 m and can be divided into three major morpho-structural sub-basins, the West Alboran Basin, East Alboran Basin, and South Alboran Basin, delimited by the East Alboran Ridge, a major structural high that divides the region obliquely and conditions a complex physiography. The physiography of the Alboran Sea consists of four physiographic provinces: shelf (down to 100-115m) slope (575 to 1000 m), base-of-slope (575 to 945 m), and basins (400 to 1800 m). Physiographic domains are affected by several seamounts that vary in nature, being composed of volcanic rocks, basement blocks and mud diapirs. The Alboran Sea is characterized by siliciclastic sedimentation, the rivers being the main sources supplying terrigenous sediments. The late Pleistocene-Holocene stratal arquitecture is typically characterized by seismic units whose seismic facies, nature of boundaries, geometry and distribution are variable (ALONSO & MALDONADO, 1992; ERCILLA *et alii*, 1992; ERCILLA & ALONSO, 1996, ALONSO *et alii*, 1999; ERCILLA *et alii*, 2002).

Traditionally it was said that the general present-day circulation in the Alboran Sea is defined by three water masses: the surficial Atlantic Water (AW) down to 150–200 m water depth; the Levantine Intermediate Water (LIW), which extends down to 500-600 m water depth, and the Western Mediterranean Deep Water (WMDW) (below 500-600 m water depth) restricted largely to the Moroccan margin and basins. A recent study by MILLOT (2009) in the Gibraltar Strait and surroundings, has considered a more complex structure and dynamic, becoming to consider five Mediterranean water masses that are grouped as light and dense water masses. In this sense, the present day circulation consists of an alongslope displacement of the light MWs (Winter Intermediate Water –WIW-, LIW, upper-Tyrrhenian Deep Water –TDW-), located along the northern slope, and a quite motionless displacement of the dense MWs (lower-TDW, WMDW) along the southern slope (MILLOT, 2009).

METHODOLOGY

More than 1000 seismic profiles have been reviewed. They were downloaded from the ICM-CSIC (http://www.icm.csic.es/geo/gma/SurveyMaps/) and SIGEOF (http://www.igme.es/internet/sistemas_infor/BASESINTERNET/sigeof.htm) databases. These data comprise multi- and single-channel seismic records offering different degrees of resolution, from low to very high, of the nearsurface sediments. All seismic profiles were integrated in a Kingdom Suite project.

Hundreds of CTDs have been analyzed in order to define the

This work has been developed thanks to the CONTOURIBER (REF. CTM2005-08071-C03-02/MAR) and MONTERA (REF. CTM-14157-C02-02/MAR) projects, and Action Marges Program.

water masses circulating throughout the Alboran Sea. The CDT information was downloaded from the Sea Data Net website ([http:// www.seadatanet.org](http://www.seadatanet.org)) and the software ODV (Ocean Data View, http://odv.awi.de) has been used for the water masses definition. Most of the analyzed measures of the CTDs were during the following years: 1975, 1986, 1990, 1992, 1993, 1997.

RESULTS AND DISCUSSION

The contourite features mostly comprise plastered, sheeted, elongated separated, confined, and channel-related drifts (Fig. 1). They have variable sizes ranging from few km to several tens of km in length. The *plastered drifts* mainly characterize the Spanish and Moroccan slopes. Both are affected by a striking erosive terrace (up 28 km wide), between 235 and 365 m water depth in the Spanish margin, and between 330 and 510 m in the Moroccan margin. Toward the base of slope, this plastered drift connects by a steep scarp to another plastered drift in the western Spanish margin which shows a low-mound to subtabular geometry. Plastered drifts are also locally identified on the seamount walls. The *sheeted drifts* occur from about 500 m water depth on the central Spanish base of slope and on the Western and Southern sub-basins. These drifts display a subtabular geometry that makes up a smooth seafloor. The *elongated separated drifts* are locally identified in the westernmost Moroccan upper and lower slope, and at the foot of structural seamounts and diapirs, and are easily recognized by their low to high mound geometry. The *confined drifts* have also a local presence, in the surroundings of the Alboran Ridge and between highs in the narrow passages formed by steep structural walls. This type of drift has a striking monticular morphology. The *channel-related drift* has been mapped on the floor of the Alboran Trough, and is characterized by discontinuous and irregular bodies of stratified facies surrounded by a seafloor surface of high reflectivity.

In addition to the above mentioned depositional features, several types of erosive contourite features are also characterized; moats, terraces, steep surfaces, and furrows are identified. The *moats* are mapped associated to the elongated separated drifts and to some plastered drifts, mainly that occurring on the walls of the structural highs. The *terraces* are erosive surfaces playing a major role in shaping the plastered drift of the continental slopes. They connect to the shelf-break and base-of-slope by narrow *steep and erosive scarps* (respectively, between 100 to 235 m, and 365 to 600 m water depth), both roughly parallel to the margins. These scarps play a major role in shaping the transition between the physiographic provinces. *Furrows* represent linear features eroding mostly drift deposits between both margins and the distal erosive steep scarp in the Moroccan margin, both close to the Gibraltar Strait. Likewise, some furrows have been mapped in the shelf-break of the Spanish margin, also close to the Strait of Gibraltar.

The CTDs analyses give new insights into the water masses making up the circulation model in the Alboran Sea. Our study confirms that the five Mediterranean water masses defined previously by Millot (2009) in the Gibraltar Strait and surroundings occur throughout the Alboran Sea. The surficial AW (< 36-26.2 psu; 10 ºC) mostly extends down to 100–200 m water depth. The WIW (37-37.7 psu; 12.9-13 ºC) is defined in

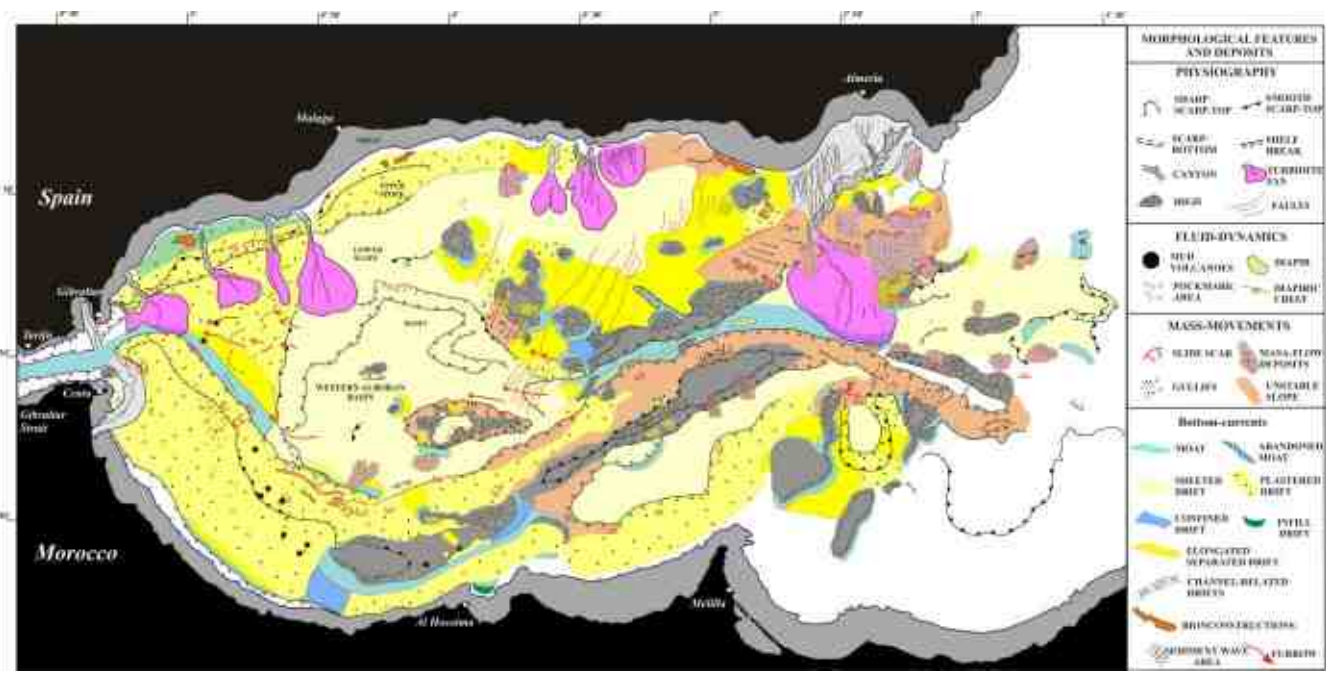

Fig1.- Geomorphologic map of the Alboran Sea.

the slope of the Spanish margin, between 100 and 300 m, and its occurrence is not permanent. The LIW (13.1-13.2 psu; 38.5 ºC) has been defined between 200 and 600 m, and mostly circulates along the Spanish margin and central basin. The TDW (38.4-38.5 psu; 13ºC) shows a core not-well defined, showing similar characteristics to the overlying LIW and underlying WMDW. Because of that, its definition is not an easy task. It is mainly characterized in the Spanish margin (400 to 550 m) and basin, and locally and/or sporadically to shallower water depths (275 to 400 m) in the Moroccan margin. The WMDW (12.7-12 psu; 38.4-38.52 ºC) moves troughout the basin of the Alboran Sea and Moroccan slope, and their water depths are very variable according to the margins it sweeps, being identified below 540 m in the Spanish margin and mostly below 300 m in the Moroccan slope, although here it has been characterized shallower, below 180 m.

CONCLUSIONS

The recognized morphosedimentary features indicate that contourites dominate the slope, base-of-slope and basin sedimentary settings in the Alboran Sea. Likewise, the recognized water masses suggest: 1) the presence of four Mediterranean water masses, WIW, LIW, TDW and WMDW; their presence is unequal in the Spanish and Moroccan margins,; 2) the mentioned water masses are responsible of the contourites deposits and features; and 3) due to the action of different water masses shaping the margins and basins, the contourites, both deposits and features, make up a sedimentary complex, named the Alboran contourite sedimentary complex. The action of the WIW and LIW is particularly marked in the Spanish margin, being responsible of the plastered drift with erosive terrace and scarps. The LIW and WMDW would have controlled the sediment distribution of the plastered and sheeted drifts in the Moroccan slope and base-of-slope and erosive scarps. The WMDW also would favor the shaping of the sheeted drift in the basins and furrows. The interaction of the mentioned water masses with highs and corridors favor the formation of elongated separated at the break of slope, plastered on the walls, confined and channel-related drifts in the passages and corridors.

A Messinian analogue for the subsurface plumbing of marine oil seeps (Maiella foreland basin, Central Apennine)

ANNALISA IADANZA (*), GIANLUCA SAMPALMIERI (*), PAOLA CIPOLLARI (*,**), DOMENICO COSENTINO (*,**), MARCO MOLA (**)

Key words: *hydrocarbon-charged fluids, Maiella basin, Messinian, microchimneys, neoformed channels.*

INTRODUCTION

Processes of hydrocarbon-charged fluid migration and the related products have been increasingly reported in the geological literature both in present-day and ancient settings (HOVLAND *et alii*, 1987; CAMPBELL *et alii*, 2002; CAMPBELL, 2006; HUUSE *et alii*, 2010). The major seep-related features revealed in active or subrecent settings include: mud volcanoes, pockmarks, authigenic seep carbonates, chimneys, gas hydrates and cold seep communities (KOPF, 2002; JUDD & HOVLAND, 2007). The precipitation of authigenic carbonates takes place at hydrocarbon seeps as a result of the increase in alkalinity produced by the release of HCO_3^- during the anaerobic oxidation of methane (AOM) and higher hydrocarbons (RITGER *et alii*, 1987; PAULL *et alii*, 1992). The identification of palaeo-cold seeps is chiefly inferred by the occurrence of δ^{13}C-depleted seep limestones (concretions and slabs) and cemented chimneys, interpreted to act as fluid migration pathways.

If compared to the extensively reported seafloor examples (e.g. CAMPBELL *et alii*, 2002; PECKMANN *et alii*, 2002; MAZZINI *et alii*, 2003; SCHWARTZ *et alii*, 2003; CONTI et *et alii*, 2004, CONTI & FONTANA, 2005; HOVLAND *et alii*, 2005; GAY *et alii*, 2006 a,b; CAMPBELL *et alii*, 2008), the subsurface counterparts of hydrocarbon seeps are poorly documented, even in correspondence to the easily accessible points offered by outcrops of palaeoseeps (AIELLO *et alii*, 2001; CLARI *et alii*, 2004; DE BOEVER *et alii*, 2006; CLARI *et alii*, 2009; NYMAN *et alii*, 2010).

The Messinian succession of the Maiella foreland basin (Abruzzo, Central Apennines) offers an interesting example of a seep plumbing system: fluid migration pathways occur at different scales and are associated to an extensively brecciated limestone-bearing unit (the *Brecciated Limestones* informal unit).

(**) Istituto di Geologia Ambientale e Geoingegneria (IGAG-CNR), Area della Ricerca Roma 1, Montelibretti

THE FLUID MIGRATION PATHWAYS AND THE *BRECCIATED LIMESTONES* IN THE MAIELLA BASIN

The *Brecciated Limestones* of the Maiella Basin belong to the early post-evaporitic phase of the Messinian Salinity Crisis (MSC) of the Mediterranean Basin: they overlay the Lower Evaporites through the well known regional unconformity (Messinian Erosional Surface, MES).

In this study the field work was addressed to the detection and the typification of structures referable to channelways and to the identification of main facies associated to them. Sedimentological and fabric observations, performed with optical and electronic microscopic devices, were integrated with stable isotopes analyses (δ^{18}O and δ^{13}C).

The *Brecciated Limestones* mostly consist of widely brecciated carbonate buildups and minor concretions laterally embedded or passing to an anoxic host sediment (marly-pelitic fraction). Tar plugs, brown concretioned patches and minor pelites trapped in are at places associated to the main geobodies. The massively or broadly stratified limestones, brecciated and cemented to different degrees, are accompanied by both mesoscale channelways and micro-chimneys collected from the surrounding sediment.

The major fluid migration pathways are extremely localized. The channels attain even several meters in height in outcrop, cutting the MSC-related stratigraphic succession at different levels. They show irregular but sharp pipe walls, often accompanied by secondary tortuous fluid channels, branching out laterally, and mushroom-like tops. According to the glossary proposed by DIÁZ-DEL-RÍO *et alii* (2003), the chimneys are generally mounded, with bended trajectories and lateral auxiliary vent orifices. Dark brown, finely contorted and wispy-microfolded pelites with subordinate carbonate concretions constitute the main facies association. Beside the concretions, secondary carbonatic components are represented by fibrous aragonitic fans and vuggy scoria-like limestones.

Micro-scale fluid channels were also observed in thin section, in terms of extremely fluidal textures and locally microbrecciated microbialite. Furthermore, collected from the barren host sediment, hollow cylindrical carbonate precipitates occur, inferred to represent micropipes on the basis of their depletion in $\delta^{13}C$ and their strikingly resemblance to (sub)recent counterparts (PECKMANN *et alii*, 2001, 2005; JONES *et alii*, 2009). From a morphological point of view, they are cylindrical and typified by broadly circular cross-sections, displaying a variety of enigmatic morphologies (single, double, bifurcated, dumb-bell shaped or even multiple composite microtubes).

Together with the fluid migration features detected at any scale (outcrop-scale pathways, microchimneys, fluidal microtextures), a number of seep settings markers were also encountered: 1) at the mesoscale: patchiness and knotted fabrics, widespread brecciation; 2) at the microscale: tar impregnations, framboidal pyrite, celestite and barite, botryoidal aragonite; 3) in the geochemical dataset: wide ranges of negative $\delta^{13}C$ data.

The detection of tar-bearing facies and the geochemical dataset in fact, showing wide ranges both in $\delta^{18}O$ (~ +5 down to -10 ‰ PDB) and $\delta^{13}C$ values (~ +5 down to -40 ‰ PDB), point to fluids charged by hydrocarbons, at least to some extent.

Interstingly, two end members in the carbon stable isotopes record are represented by: a) the carbonates yielding the less depleted δ13C values, associated to the mesoscale fluid migration pathways and to higher brecciation degrees, pointing to focused fluid flow with high flux rates and subsequent low fluid-rock interaction (AOM secondarily involved in authigenesis); b) the most δ13C-depleted carbonates, i.e. chaoticized patchy limestones associated to the host sediment, the microchimneys and the carbonates yielding lower brecciation degrees, testifying the occurrence of pervasive fluid flow, low flux rates (seepage) and subsequent high fluid-rock interaction (AOM directly involved in authigenesis).

Similar phenomena are known also from modern counterparts, where hydrocarbon emissions, for instance, range from slow and diffuse - forming seep-carbonates - to fast and vigorous, developing chimneys and mud volcanoes (RITGER *et alii*, 1987; AHARON, 1994).

CONCLUSIONS

The presumable origin of the *Brecciated Limestones* of the Maiella Basin from the subsurface, within the sedimentary column, is inferred by the occurrence of widespread autobrecciation accompanied by fluid channels, together with the absence of chemosynthesis-based paleocommunities. In view of that, the *Brecciated Limestones* of the Maiella Basin, with their fluid migration pathways and microchimneys, are interpreted to represent possible vestiges of a mud volcano feeder system. The proposed scenario for the late Messinian Maiella Basin depicts an upward hydrocarbon-rich fluid migration through the Messinian succession, developed with major fluxes along giant neoformed channels and seepage through the host sediment via cemented microchimneys. In the upper Miocene of Italy, a similar case is known from the Tertiary Piedmont Basin (NW Italy) (CLARI *et alii*, 2009; MARTIRE *et alii*, 2010; DELA PIERRE *et alii*, 2010).

INTRODUCTION

The Alboran Sea is a Neogene extensional basin developed in a convergence tectonic setting that generates a complex physiography. The SW-NE-trending Alboran Ridge separates three main basins, Western, Eastern and Southern.

The filling of the Alboran Basin is composed of Early Miocene to Quaternary deposits (CAMPILLO *et alii*, 1992). The Plio-Quaternary deposits lies over a strongly erosive surface (the Messininan surface -M reflector-) with three major types of features: the Zanclean Channel, several terraces, and canyons (ESTRADA *et alii*, 2011). The Plio-Quaternary sedimentary evolution has been controlled mainly by the interplay of tectonics, sea-level changes, and a complex ocean circulation (ERCILLA *et alii*, 1994).

Most of the geological studies done since the 80's in the Alboran Sea suggested that downslope processes were dominant, (ERCILLA *et alii*, 1992). Locally, contourite features had been defined in the westernmost slope of the Moroccan margin (ERCILLA *et alii*, 2002).

Critical reviews of the available seismic records and of our previous literature allowed us re-interpreting the morphosedimentary features that characterize the Alboran Sea. We propose the dominance of alongslope processes in the Alboran Sea, that are locally modified by the downslope processes at the margins, submarine fans, and walls of the Alboran Ridge and seamounts.

RESULTS AND DISCUSSION

Recently we defined and correlated three new chronostratigraphic limits at the Western Alboran Sea (JUAN et al., 2012): Lower Pliocene Revolution –LPR- (4.2 M.a.) related to a 3rd order global sea-level fall, Base of Quaternary Discontinuity –BQD- (2.6 M.a.) also related to a major sea-level fall and an important change in the climatic cyclicity trend, and Middle Pleistocene Revolution –MPR- (0.92 M.a.) that marks the onset of the first major glaciations in the northern hemisphere and a shift to large amplitude (100 k.y.) and asymmetric climatic cycles. The addition of these boundaries, with paleoclimatic and paleoceanographic significances, is a key change in the Alboran stratigraphy, since the purpose of the present work is to analyze the climate-driven paleocirculation patterns. In order to correlate the different stratigraphic divisions and limits, we summarized the most relevant stratigraphies in Table I.

Based only on these paleoclimatic and paleoceanographic boundaries we have divided the Plio-Quaternary sedimentary register into four major seismic units: A to D, from older to younger.

Unit A (Early Lower Pliocene)

This unit is bounded by M and LPR discontinuities (Table I). The M limit (i.e., the Messinian surface) is a strong, laterally continuous erosive boundary. The LPR shows low acoustic amplitude. The lower M limit shows onlap reflection terminations on the structural highs, and the upper LPR limit shows a local erosive character. At the Eastern Alboran Basin this unit drapes and infills the irregular paleoreliefs showing variable thickness (0 to 275 ms). This unit comprises mainly deposits characterized by low reflectivity discontinuous stratified facies (Fig. 1), locally affected by slope apron facies. The seismic facies have been interpreted as an extensive sheeted drift covering most of the basin, locally affected by contouritic channels and deformed by the regional tectonics.

This work has been developed thanks to the CONTOURIBER (REF. CTM2005-08071-C03-02/MAR) and MONTERA (REF. CTM-14157-C02-02/MAR) projects, and Action Marges Program.

Unit B (Late Lower to Upper Pliocene)

This unit is bounded by LPR limit at the base and BQD limit at top. The BQD boundary shows medium to high acoustic amplitude and locally the top of the unit is eroded. Deposits of this unit even drape structural highs, onlapping at the flanks. The unit shows great thickness, reaching 750 ms near the Alboran Through. Deposits are characterized by a vertical change from low to high acoustic amplitude and show an aggradational pattern. Contourite features as sheeted, plastered and elongated separated drifts have been defined both at the slopes and the basin, showing strong influence of tectonic activity.

Unit C (Lower Quaternary)

This unit is bounded by the BQD limit at bottom and the MPR limit at top. Its lower boundary is generally a concordant surface. The MPR limit shows medium to high acoustic amplitude and is an erosive surface. The maximum depocenter is located to the north (300 ms). Acoustically, deposits are defined by stratified facies of high acoustic amplitude and chaotic facies. This unit is mostly made up of plastered and sheeted drifts at the slopes and structural highs, showing stratified facies with high acoustic response . The lateral continuity of these deposits is interrupted by the turbiditic lobes of the Almeria TS, with interbedded reflectors showing high to very high acoustic response.

Unit D (Middle toUpper Quaternary)

The last unit is bounded by the MPR limit at base, and by the seafloor at top. These boundaries are mostly concordant surfaces. The depocenters are located in the Almeria Fan (250 ms), and near the Alboran Through (250 ms). This unit is characterized by an aggradational pattern (Fig. 1). Sheeted and plastered contourite deposits are common at the slope and structural highs, and we find again sheeted drift facies mixed with the distal turbiditic lobes to the south of the basin.

CONCLUSIONS

The definition and correlation of the new chronostratigraphic boundaries, named LPR, BQD and MPR, has allowed defining a new Plio-Quaternary sedimentary model for the Alboran Sea. In fact, this new stratigraphy has highlighted the effects of the Mediterranean water masses, and the role played by the contourites, deposits and features, in the outbuilding of the Spanish and Moroccan margins and basin infilling.

ABSTRACT

Multidisciplinary investigations of submarine mud volcanoes on the Calabrian accretionary prism led by OGS provide evidence of late to post-glacial eruptive activity, and of ongoing seabed seepage that supports 'hotspot' ecosystems. Data were acquired from two structures, the Madonna dello Ionio and Pythagoras mud volcanoes (MVs), in water depths of 1600-2300 m (Fig. 1), using geophysical methods (multibeam, seismic), cores and remotely-operated vehicles (ROVs), during campaigns of Italian, German and French research vessels. The two sites include a variety of positive and negative morphologies (cones, caldera, broad dome – Fig. 2), all associated with high seabed backscatter, consistent with relatively recent extrusive activity; this is confirmed by gravity cores that recovered mud breccias near seabed. Dating of overlying sediments at one site (Madonna MVs) indicates at least one extrusive episode since the last glacial maximum (c. 20 ka). At both sites, bottom water samples obtained using ROVs indicate seepage of gas to the water column. At the Madonna MVs, evidence of seabed fluid seepage is also provided by: a) elevated geothermal gradients at three extrusive centers; b) localized outflows of warm mud; and c) chemosynthetic ecosystems. At the Pythagoras MV, such indications are absent, but ROV investigations reveal an area of chaotic seabed suggestive of a recent, violent eruptive episode. The ongoing activity of the mud volcanoes may reflect either long-term tectonic drivers, or climate-driven post-glacial destabilization of gas hydrate that are theoretically stable at both structures.

Petrographical and mineralogical characterization of marine sediments in the mud diapir province of the Paola Basin (Southern Tyrrhenian Sea)

HEBA RASHED (*), MARZIA ROVERE (**), ELENA PECCHIONI(*), FABIANO GAMBERI (**), ORLANDO VASELLI (*,***), GABRIELE BICOCCHI (*), FRANCO TASSI (*,***)

Key words: *Geochemistry, Mineralogy, Paola Basin, Plio-Quaternary sediments, South Tyrrhenian Sea.*

INTRODUCTION

The study area is located within the Paola Basin along the southeastern margin of the Tyrrhenian Sea. The geodynamic evolution of the Paola Basin is related to the extensional tectonics that led to the opening of the Tyrrhenian Sea. The basin is characterized by a thick Plio-Quaternary sedimentary sequence, whose origin is likely related to turbiditic currents (TRINCARDI *et alii*, 1995). The study area is bounded by a calc–alkaline volcanic complex (Alcione and Lametini) to the west, while to east is bordered by a system of normal faults that separate it from the Coastal Range in Calabria (Fig. 1). The Paola Basin hosts a 60-km-long NNW-SSE oriented prominent anticline, the Paola Ridge, interpreted to be the result of an episode of early Pleistocene compression (ARGNANI & TRINCARDI, 1988). A more recent interpretation defines the Paola Ridge as due to a mobile mud belt connected with a set of extensional faults trending NW-SE to NNW-SSE (GAMBERI & ROVERE, 2010). With the aim of proving this latter interpretation, the MVP11 oceanographic cruise was carried out in August-September 2011 on board the R/V CNR URANIA, during which very high resolution swath bathymetry and shallow seismic data were collected plus 30 gravity coring sites and 30 box-cores stations were performed in order to define the petrographical, mineralogical and geochemical composition of the cored sediments and the collected rock samples (Fig. 2).

This study is part of a PhD fellowship carried out in collaboration with the Department of Earth Sciences of Florence and the CNR-ISMAR (Institute of Marine Sciences) of Bologna (Italy) and aimed to: i) define the mineralogical and geochemical characteristics of marine sediments related to mud diapirism sampled in the study area and ii) verify the presence of gas emissions at the seafloor through the analysis of the gas-related products.

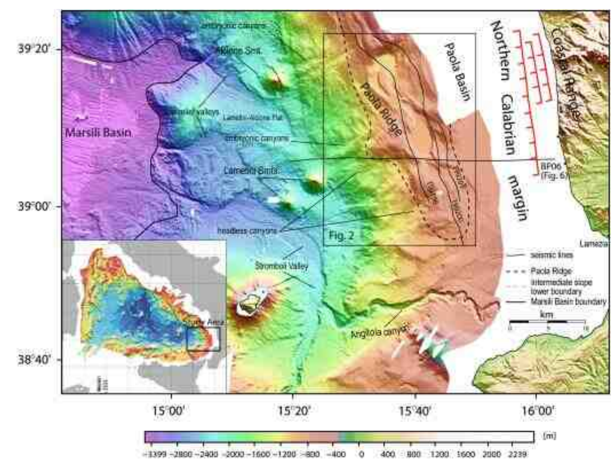

Fig. 1- Bathymetry of the southeastern Tyrrhenian Sea, Paola Basin. The study area is enclosed in the box that corresponds to the area of Fig. 2, where sampling sites are enlightened. From Gamberi & Rovere (2010).

MATERIALS AND METHODS

For this work we have analyzed different kind of samples (rocks/sediment):

a) limestone crusts cored along faults dissecting mud diapir structures; authigenic carbonates retrieved from the core catcher of stations performed over mud volcanoes and their downslope mudflows;
b) iron oxy-hydroxide crusts found in the box cores stations on top of the mud volcanoes structures, where strong gas emissions were recognized by water column multi-beam records and direct sampling;
c) flat crusts of pyrite and sulfur retrieved in the upper section of the cores and in the box cores performed on top of the mud volcanoes;
d) cohesive mud sampled along the coring sections of the most energetic mud volcanoes structures discovered in the area.

The sampling was carried out using a 1.2 t gravity coring

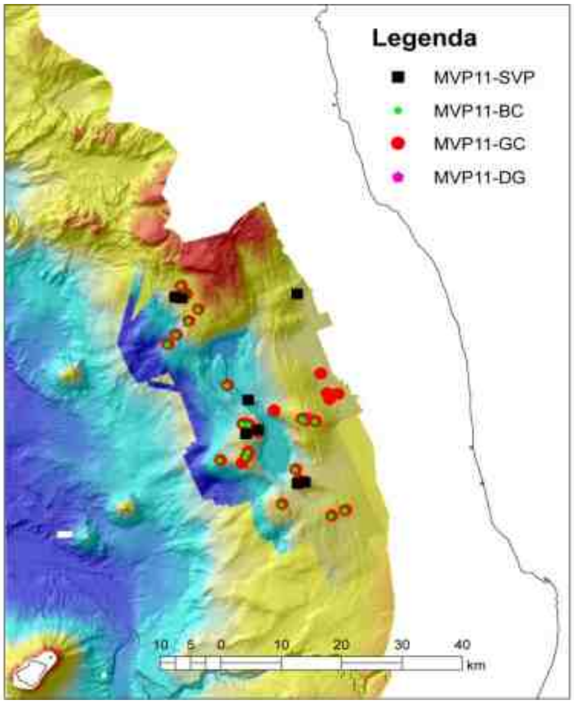

Fig. 2- High resolution swath bathymetry acquired during cruise MVP11 in the samples, MVP11-BC Box core stations, MVP11-GC gravity coring stations, MVP11-DG dredge stations.

device with a penetration length between 4 and 12 m. Box cores were collected with an oceanic box corer with a hollow metal cylinder of 50 cm in diameter and a volume capacity of 100 L. All the samples were dried (at 40 °C), grinded and grounded (with a planetary agate mill device). Both sediments and rock fragments were analyzed to determine the semi-quantitative composition of the main mineralogical phases. In the sediments the <4 μm granulometric fraction was also separated for the determination of the clay minerals content.

The mineralogical analyses were carried out by XRD with a Philips PW 1050/37 diffractometer, operating at 40 kV-20 mA, with anode a Cu, graphite monochromator at an interval 2θ of 5-70° e 2-32° (limit of detection 4%), using the X'Pert PRO Philips acquisition system. Polished thin sections of rock samples were prepared for petrographic observations by using an optical microscopy in transmitted light for the textural characterization of the samples and point out the presence of mineral index, using a microscopy ZEISS Axioskop, equipped with video camera (resolution 5 Megapixel), provided with image analysis Axiovision.

RESULTS AND DISCUSSION

The petrographic analyses by microscopy in transmitted light were only carried out on the limestone crusts, and the observations have allowed to characterize different sample types: a) fractured and porous mudstone-wackestone with the presence of pyroxenes and rare quartz and plagioclases; b) mudstone with rare presence of quartz; c) biomicrite with rare presence of quartz and medium porosity.

The preliminary mineralogical analyses on the different rock samples were used to recognize the three groups: a) carbonates mostly containing calcite, quartz, siderite, feldspars (plagioclase), and phyllosilicates and carbonates with calcite, aragonite, dolomite, phyllosilicates (muscovite and clay minerals) and pyroxene; b) sulfides mainly consisting of quartz, pyrite and/or sphalerite, marcasite and plagioclase and traces of phyllosilicates; c) iron oxy-hydroxides dominantly characterized by goethite, quartz, feldspars (plagioclase) and phyllosilicates.

The mineralogical analyses carried out on the marine sediments (cohesive mud) have indicated the presence of quartz, halite, feldspars (plagioclase and k-feldspar), muscovite and clay minerals (illite, vermiculite, chlorite, kaolinite) unless one sample where chlorite was absent; occasionally, some samples were composed by calcite and/or dolomite, siderite, hematite and pyrite.

CONCLUSIONS

The Paola Basin is a key area for better understanding the evolution of the southern part of the Tyrrhenian Sea. Regional structural studies describe the area as affected by relevant tectonic compression, but more recent high resolution investigations have revealed the presence of gas-related structures, probably activated by normal faulting. Sampling data are now available in the area. The petrographical and mineralogical data presented in this work have allowed to highlight important features that can be used to understand the geochemical processes affecting the depositional environment into which the marine sediments were deposited. In this framework, the petrographic characterization and the interpretation of the mineralogical composition will be related to the active structures (mud diapirs and mud volcanoes) recently recognized in the Paolo Basin. Furthermore, the chemical composition of the carbonate-hosting pyroxenes may shed light on their provenance studies, along with chemical and isotopic investigations in both cohesive mud sediments and pyrite and sulfur crusts that are presently in progress, the latter to be investigated in order to comprehend the effects due to the gas discharges.

Large deep-seated slump structure off Ischia volcanic island, Eastern Tyrrhenian sea (Italy)

CRESCENZO VIOLANTE (*), GIOVANNI DE ALTERIIS (*), FABRIZIO PEPE (**) & SALVATORE MAZZOLA (*)

Key words: *Ischia Island, Slump, Volcano-tectonic uplift, Vocanic spreading.*

INTRODUCTION

Ischia island is located over the Campania sector of Eastern Tyrrhenian margin and represents the sub-aerial section of a larger, E-W trending volcanic ridge including others submerged or buried volcanic edifices. The island itself result from the coalescence of a multitude of small to medium scale eruptions leading to the emplacement of domes, lava flow and pyroclastic deposits and ignimbrites (VEZZOLI *et alii*, 1988) ranging from alkali basalts to trachytes. The oldest basement dates back to 150 ky and crops out along the perimeter of the island especially to the south. Latest eruption occurred in 1302 A.D. and together with strong hydrothermal activity, ground uplift and seismic shaking indicates the presence of a still active magmatic reservoir at depth. Most recent (Holocene) magmatic activity with local volcanic eruptions has clustered in the eastern island's sector the while central sector is dominated by the Mt. Epomeo, consisting of an ignimbritic tuff (Green tuff Auct.) uplifted of 600-700 m in the past 33ka.

In the past decade the island's offshore has been the object of extensive hydrographic and marine geophysical surveys that have shown the structural complexity of the undersea sections and have overall shown the importance of gravity failures in island's evolution. In particular a 1.5-3 km^3 debris avalanche due to a subaerial and/or submarine flank collapse was emplaced along the steep and unbuttressed island's flank during pre-historical or even historical times (CHIOCCI & DE ALTERIIS, 2006; DE ALTERIIS *et alii*, 2010) whereas three other similar deposits of comparable volumes were found over the continental shelf to the west and to the north (VIOLANTE *et alii* 2004; DE ALTERIIS & VIOLANTE, 2009).

Here we report a previously unrecognized deep-seated slump structure and associated surficial mass wasting phenomena which occur off Ischia south-western flank. Recently acquired hydrological and geophysical data lead to identify the morphological features and the internal organization of the failed sediments which spread along the continental slope. The extent of this deep-seated deformations and the deep structural levels involved lead to investigate on the influence played by volcanic processes on slope failure.

DATA AND METHODS

Our dataset was acquired during the geophysical cruise PECOS 2010 carried out on R/V Urania (Consiglio Nazionale delle Ricerche, CNR, Italy) between December 22th 2010 and January 2nd 2011 in the frame of a project leaded by Istituto per l'Ambiente Marino Costiero, (IAMC-CNR), Naples-Italy with the collaboration of Dipartimento di Scienze della Terra e del Mare (Palermo University), Palermo-Italy regarding coastal and offshore slope instability in the Bay of Napoli.

The Ischia southern slope was explored through a multibeam survey and a single-channel seismic survey. Acquisition was carried out between 400 and 1200 m. The bathymetric data were collected using a hull mounted Reson 8160 multibeam sonar. Resolution resulted in a 20x20 m implemented with 50x50 gridded size provided by a previously collected data. The seismic survey consisted of 6 dip-lines NNE-SSW run along the slope and 5 cross lines parallel to the slope totalling 170 km. Average spacing between diplines was slightly less than 1 km while spacing between crosslines was variable from 1.2 to 2.5 km. NNE-SSW and WNW-ESE directions. The acoustic source used was a 1Kjoule high-energy power supply system with a multi-tips (400) sparker array, fired at 2s time interval.

RESULTS

The collected data show that a wide submerged area of 350 km^2, between 400 to 1200 m depths is undergoing slow-moving deformation and associated secondary mass wasting phenomena. Morphological features include trenches, counterscarps, bulging and both extensional and contractional features while internal deformations show typical landward dipping reflectors with strong evidence of synsedimentary faulting and asymmetric anticlines.

Deformation processes operate at various scales generating

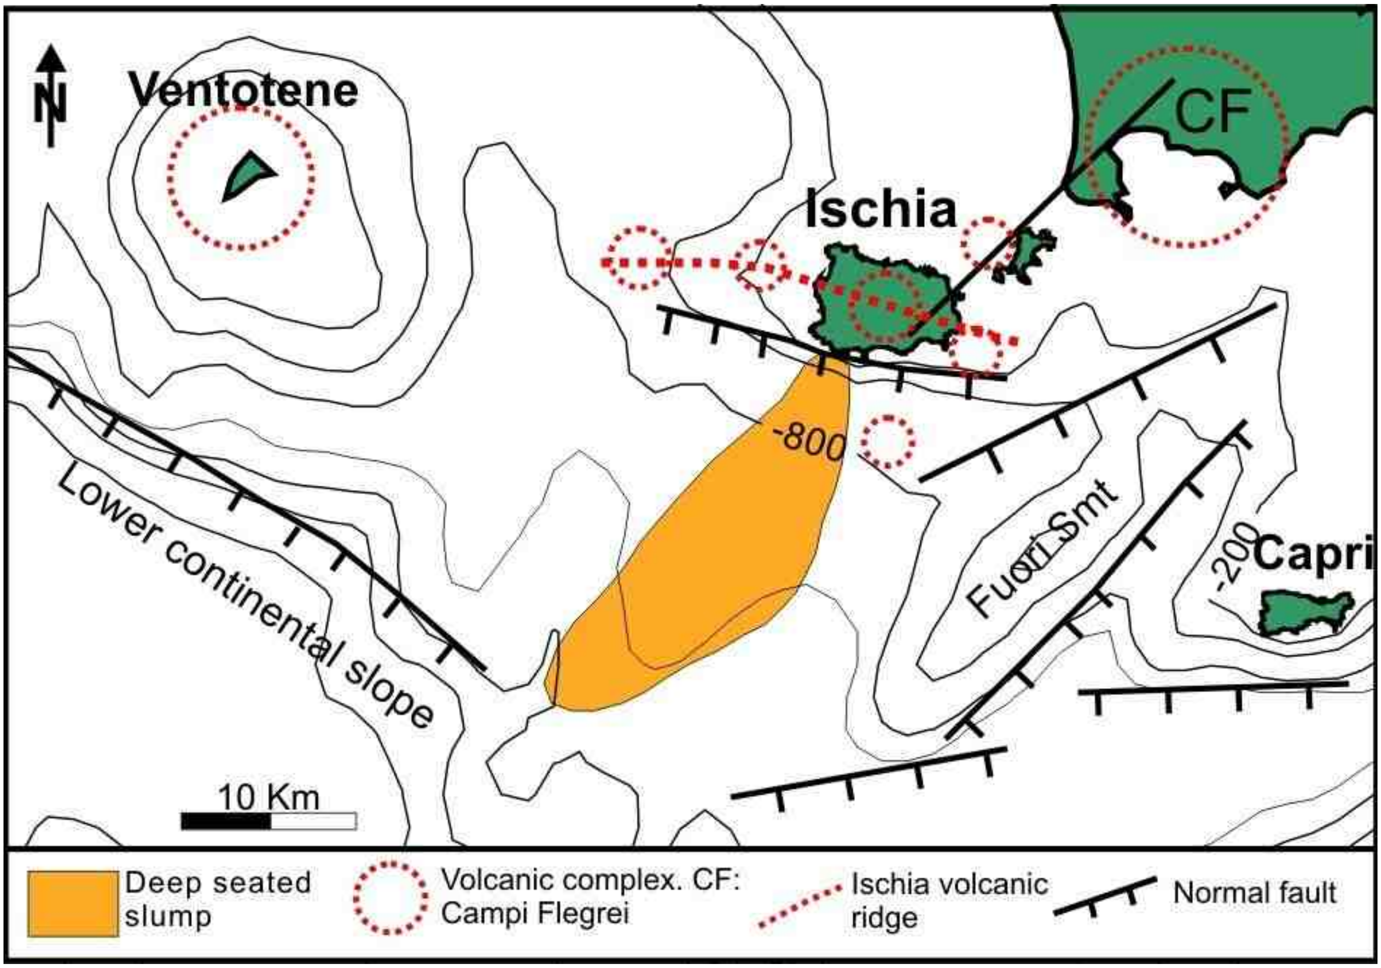

Fig. 1 – Geologic sketch map of the study area

folds with wavelength ranging from hundreds meters to kilometers. Extensional and rotational rupture surfaces sole out at various low-angle detachment planes located at depths from few hundred meters to 1 kilometer in subsurface.

The internal organization of the failing mass shows different pattern of deformation that allows the identification of three main units: 1) a basal unit consisting of a very broad, asymmetric slump fold with a wavelength of about 5 km and amplitude of some 100 m. The fold axis is not vertical and the three dimensional interpretation indicates that the structure is not cylindrical. The fold strictly correlates with a morphological bulge seen on bathymetry at about 20 km south of Ischia Island. 2) A wedge shaped intermediate unit characterized by discontinuous and folded reflectors, locally showing basal detachment planes and compressional features. 3) A surficial slump unit affecting the upper and middle slope characterized by a basal decollément surface and normal growth faults that sole out at depths ranging from 70 to 40 m in subsurface. It is still unclear whether the landslide process can be favored by the volcano-tectonic evolution and rapid vertical accretion of Ischia volcano or is solely due to possibly volcanic spreading of the Ischia Island.

A cliff overstep model for high-gradient shelves: the case of the Ionian Calabrian Margin (southern Italy)

MASSIMO ZECCHIN (*), SILVIA CERAMICOLA (*), EMILIANO GORDINI (*), MICHELE DEPONTE (*), SALVATORE CRITELLI (**)

Key words: *Calabrian shelf, post-LGM transgression, subbottom profiles.*

The present study is focused on features developed during the post-LGM transgression on the narrow, high-gradient shelf off the Crotone area (southern Italy) and on the southern part of the Amendolara palaeo-island (API). In particular, peculiar features such as submerged coastal cliffs and a seabed typified by irregular step-like geometry characterize the present area. We recognized this area as suitable to develop a transgressive model for very high-gradient settings characterized by coastal cliff development and irregular topography. Such a model may be useful in recognizing and understanding the features and style of transgression and variations in its rate, particularly for the post-LGM glacio-eustatic rise.

The seabed morphology of the Ionian Calabrian margin reflects the complex interplay between the south-eastward migration of the Calabrian accretionary wedge since mid-Miocene and the rapid uplift of onshore and shallow shelf areas since mid-Pleistocene (MALINVERNO & RYAN, 1986; BONARDI *et alii*, 2001). The uplift, documented by a staircase of marine terraces in the subaerial Crotone Basin, still continues today, and it has been characterized by a rate that, in this area, approximated 1 m/ka (ZECCHIN *et alii*, 2004; ANTONIOLI *et alii*, 2006).

The geophysical data used for this study consist of CHIRP subbottom profiles (SBP) acquired across the Ionian shelf margin (ISM) and the southern side of the API. The information coming from the acoustic character of the SBPs have been combined with the morpho-bathymetric information coming from a high-resolution multibeam dataset.

Two seismic units (Unit 1 and Unit 2), separated by a key stratal surface (Unconformity *U*) are recognizable in the considered SBPs, both along the ISM and API.

Unit 1 is the lower unit, and is truncated above by *U*. This unit is almost opaque along the ISM, but it may show basinward-inclined to variably folded reflectors along the API. A prograding wedge, typified by basinward-inclined oblique reflectors that downlap on a less inclines reflector, is recognizable between 90 and 130 m water depth at the margin of the API and locally along the ISM.

The unconformity *U* separates the older Unit 1 from the younger Unit 2, and is characterized by both concave- and convex-up profiles in dip direction. It exhibits a variable dip from 0.5° to a maximum of ca. 30° at relict scarps locally exposed. One of these features is recognizable between ca. 75 and 100 m water depth along both the ISM and API.

Unit 2 is up to 30 m thick and locally appears as a prograding wedge whose reflectors downlaps on the unconformity *U*. In other cases, it shows onlap relationships with *U*.

The unconformity *U*, which truncates a unit characterized by variably inclined reflectors (Unit 1), is overlain by a younger unit (Unit 2), and is locally exposed forming scarps, represents a surface of regional significance. In particular, it is interpreted as a wave ravinement surface (WRS), produced by wave erosion on the shelf during the post-LGM transgression, truncating a Plio-Pleistocene unit. The prograding wedge located between 90 and 130 m water depth in Unit 1 is interpreted as the lowstand wedge. The deposition of Unit 2 above *U* has been related to the post-LGM glacio-eustatic rise.

The scarp recognizable between 75 and 100 m water depth along both the ISM and API is interpreted as a partially preserved palaeo-coastal cliff. Moreover, such a depth closely matches with the depth range of melt-water pulse (MWP) 1A, during which the eustatic sea-level rose from 96 to 76 m below present sea-level, between 14.3 and 14.0 ka BP (LIU & MILLIMAN, 2004). This suggests a correlation between the stepped sea-level rise following the LGM and the preservation of coastal cliffs along the continental margins. In particular, it is suggested that the palaeo-coastal cliff recognized between 75 and 100 m water depth generated and started to recede during a phase of slow eustatic rise, and was then overstepped and partially eroded during a subsequent phase characterized by very rapid eustatic rise (i.e. the MWP 1A), otherwise its progressive dismantling would have occurred. This consideration is valid assuming a rough balance between regional uplift and subsidence of glacio-hydro-isostatic origin as shown by PIRAZZOLI *et alii* (1997).

(**) Dipartimento di Scienze della Terra, Università della Calabria, 87036 Arcavacata di Rende (CS), Italy

Younger accelerations and decelerations of sea-level rise, such as MWP-1B (58-45 m below present sea level, 11.5-11.2 ka BP), could be responsible for the formation of some shallower scarps found in our SBPs.

A transgressive model for high-gradient shelves during the post-LGM glacio-eustatic rise is proposed. Where the transgressed topography is very steep, coastal cliffs developed and retreated during the initial phase of relatively slow sea-level rise, due to wave erosion acting at the toe of the cliff. During phases of very high rate of sea-level rise, coinciding with melt-water pulses, cliffs tended to be overstepped and not completely eroded by the WRS. This model needs further testing in other contexts characterized by high-gradient shelf topography, but it has the potential to be useful in recognizing variations in the rate of sea-level rise and in general in reconstructing the Late Quaternary evolution of shelf to coastal areas.

Environment and climate during sapropels deposition in the Mediterranean sea. Planktonic foraminiferal evidences

BERGAMI CATERINA (*), CAPOTONDI LUCILLA (*), DUCASSOU EMMANUELLE (**), SALVAGIO MANTA DANIELA (***), SPROVIERI MARIO (3) & VIGLIOTTI LUIGI (*)

Key words: *Mg/Ca ratios, paleotemperature reconstruction, sapropels, planktonic foraminifera , river runoff*

Organic- rich layers, termed sapropels, characterize the Neogene stratigraphy in the Mediterranean Sea. The specific cause remain controversial, however their deposition have been related to the enhanced monsoon penetration into North Africa during precessional summer insolation maxima (ROSSIGNOL-STRICK, 1983;1985). During this time intervals, paleoceanographic investigations document increased regional precipitation with altered freshwater flows, changes in hydrology and productivity.

The youngest sapropel S1 has been investigated by a

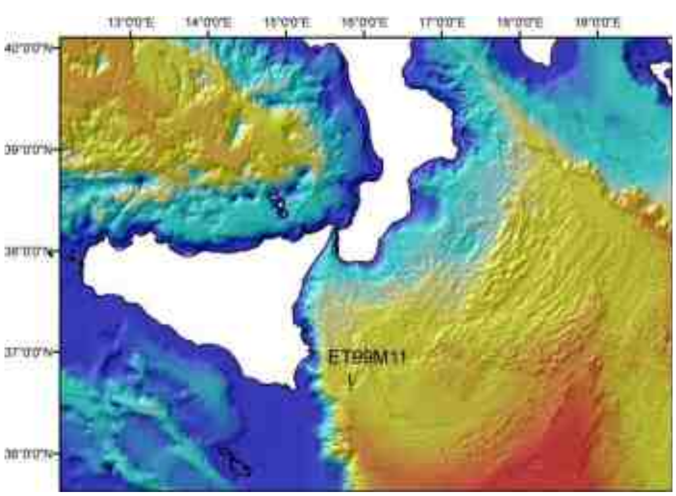

Fig. 1 – Location map of core ET99M11. DTM 450 m resolution retrieved from http://portal.emodnet-hydrography.eu/EmodnetPortal/index.jsf#

multiproxy study on a core (ET99-M11, Fig. 1) collected in the western Ionian Sea at a water depth of 2800 m, which is considered to represent anoxic conditions in the eastern Mediterranean at the time of sapropel formation (VIGLIOTTI *et alii*, 2011).

Planktonic foraminifera have proven to be excellent indicators of sea surface temperature, salinity, food availability and they have been used for the detection of long- and short-term climate changes in the Mediterranean Sea.

Quantitative and qualitative characterization of the planktonic assemblages, stable isotopes ($\delta^{18}O$ and $\delta^{13}C$) and trace elements measurements on the planktonic foraminifers *Globigerinoides ruber* and *Globigerina bulloides* have been performed to reconstruct Sea-Surface Temperatures (SST), Sea Surface Salinities (SSS), and riverine inputs at the time of sapropel S1 deposition.

The beginning of S1 is marked by a significant decrease in SSS and by a change in the planktonic foraminiferal assemblage with the increase of warm waters taxa, near absence of *Globorotalia inflata* and the significant decrease of *Neogloboquadrina pachyderma*.

The sapropel S1 interval was characterized by a general increase in water temperatures (documented by calculated isotopic temperatures) both at surface and in the sub-surface layers. In addition, several short- term cold oscillation documented at around 10.4, 9.3, 8.2 and 5.9 ka BP can be correlated with millennial scale climate events in the North Atlantic region (numbered 7, 6, and 5 by BOND *et alii*, 1997). This indicates a possible atmospheric connection between the central Mediterranean and the North Atlantic region and the strong relation between climate and oceanographic changes during the sapropel deposition.

In addition, it is noteworthy that the cold periods can be correlated with intervals of weak Asian southwest monsoon (GUPTA *et alii*, 2003) suggesting that the Holocene climate changes in the North Atlantic can be have counterparts in the Asian southwest monsoon system.

Paleotemperature reconstruction based on Mg/Ca ratios shows higher values during the two sub-units of sapropel S1, and low values during the sapropel interruption. Discrepancies between Mg/Ca ratios and calculated isotopic temperature suggest that these ratios during sapropel intervals may be significantly influenced by other factors such as seawater carbonate chemistry, lower salinity, and possibly diagenetic effects.

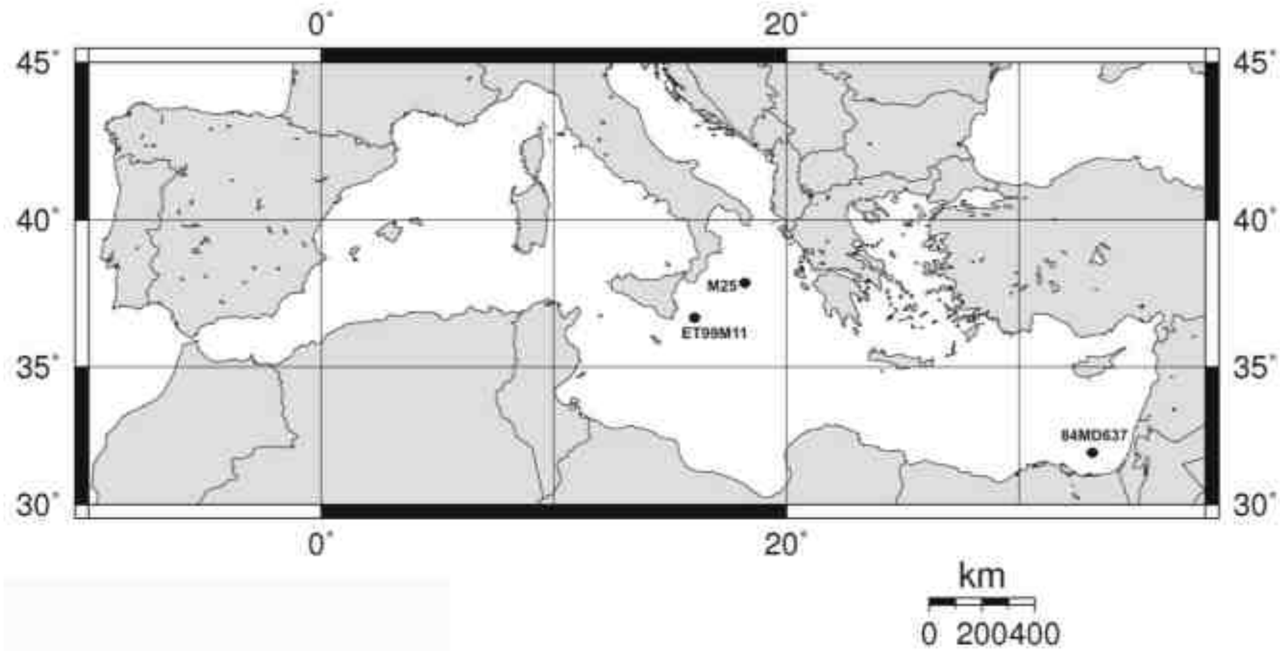

Fig. 2 – Location map of the studied areas.

An index based on planktonic foraminiferal abundances was used to reconstruct riverine inputs during sapropel S1 deposition in the studied core and during other sapropel layers deposition in two cores collected in the Ionian Sea (core M25) and from the Nile deep-sea turbidite system (eastern Mediterranean, core 84MD637) respectively.

In the studied core, the ecosystem composition suggest a rising riverine input at the onset of the sapropel deposition and during the sapropel interruption. The same increase is clearly observable in the other Ionian core during several sapropel layer deposition (from S1 to S9) and may be imputable to a freshwater source proximal to the Ionian Sea site, indicating a reactivation of rivers flowing northward from the central Saharan watershed (Osborne *et alii,* 2010). In the easternmost core, the index shows that enhanced riverine inputs is restricted to the deposition of sapropels S1 and S5 excluding a large influx of freshwater from the northern borders of the eastern Mediterranean and from Nile river during some sapropel layer deposition. Future work will focus on neodymium isotopes in planktonic foraminifera from the most recent sapropel S1, in order to distinguish freshwater inputs from monsoonal (tropical) versus mid-latitude sources in the studied areas.

Warming and cooling episodes across the early Aptian Oceanic Anoxic Event 1a: the role of *p*CO_2 on climate changes

CINZIA BOTTINI (*), ELISABETTA ERBA (*) & DANIELE TIRABOSCHI (*)

Key words: *calcareous nannofossils, oxygen isotopes, Oceanic Anoxic Event 1a, Early Cretaceous, climate changes.*

INTRODUCTION

The early Aptian Oceanic Anoxic Event 1a (OAE 1a: ~120 Ma) is a global phenomenon of organic matter burial in oxygen-depleted oceans. Volcanism, associated with the emplacement of the Ontong Java Plateau (OJP), is thought to be the main triggering mechanism for global anoxia, ocean acidification and greenhouse conditions (e.g. ERBA, 1994; LARSON & ERBA, 1999; JONES & JENKYNS, 2001; MÉHAY *et alii*, 2009; TEJADA *et alii*, 2009; BOTTINI *et alii.*, in press). Independent studies on TEX_{86}, sporomorphs and oxygen isotopes (e.g. MENEGATTI *et alii.*, 1998; DUMITRESCU *et alii.*, 2006; ANDO *et alii*, 2008; KUHNT *et alii.*, 2011; MILLAN *et alii.*, 2011; KELLER *et alii.*, 2011) provided evidence for climate instability during OAE 1a. Nevertheless, the direct/indirect role of OJP volcanism, weathering rates and *p*CO_2 on climate changes has not been established.

We have performed a high-resolution integrated nannofossil-geochemical investigation of OAE 1a in three sites: Cismon core (Italian Southern Alps), Piobbico core (Umbria-Marche basin, Italy) and DSDP Site 463 Mid-Pacific Mountains. The existing stratigraphic framework for the three sites and available cyclochronology for the Cismon core (MALINVERNO *et alii.*, 2010) allows high-resolution dating of biotic and environmental fluctuations.

The nannofossil Temperature Index correlated with the oxygen-isotope record has revealed systematic and synchronous changes in the three sites. A warming pulse is registered prior to the onset of OAE 1a and corresponds to a prominent volcanic phase documented in the Os-isotope records (TEJADA *et alii.*, 2009; BOTTINI *et alii.*, in press). During OAE 1a, in correspondence of the core of the negative carbon-isotope excursion, temperature shows a maximum. This interval coincides with the most intense volcanic phase, as suggested by biomarkers, calcareous nannofossils and Os-isotope (MÉHAY *et alii*, 2009; TEJADA *et alii*, 2009; ERBA *et alii.*, 2010; BOTTINI *et alii.*, in press). This correspondence is suggestive of a (super)greenhouse climate triggered by excess volcanogenic CO_2. Our data indicate that the beginning of the prolonged volcanic phase during OAE 1a coincides with warmest temperatures.

The end of global anoxia is paralleled by a cooling episode which slightly postpone the end of the major OJP volcanism.

High resolution analyses allow the identification of rapid cooling and warming during OAE 1a. Warm conditions in the early part of OAE 1a are interrupted by a brief (~35 ky) cooling interlude traced either by oxygen isotopes and calcareous nannofossils. This temperature change follows a ~100 kyrs-long interval characterized by accelerated continental weathering rates (BOTTINI *et alii.*, in press). Arguably, warming at OAE 1a onset promoted methane hydrate dissociation (also suggested by carbon isotopes and biomarkers analyses; MEHAY *et alii.*, 2009), which was perhaps instrumental in triggering continental weathering. Subsequent CO_2 draw down, possibly during OJP quiescence, might explain the brief cooling interlude annihilated by warmest temperatures coeval with the onset of OJP paroxysmal phase.

In the second part of OAE 1a two more cooling events (around segments C4 and C6 of the carbon-isotope curve) sandwich an interval of intermediate and fluctuating temperatures. Major and minor cooling episodes correlate with high TOC content, suggesting that burial of organic matter acted as storage of excess CO_2, thus temporarily mitigating greenhouse conditions, although under persisting OJP activity.

The data collected combined with an improved chronology show that volcanism of OJP caused general global warming. The excess burial of organic matter acted as an additional and alternative process influencing climate change.

The micropaleontological data presented confirm and provide evidence for even more temperature fluctuations during OAE1a, although under persisting OJP volcanism. This observation may imply that volcanism was not the only factor influencing climate. The ocean/atmosphere system during OAE 1a was extremely dynamic and affected by a series of complex

(*) Dipartimento di Scienze della Terra "Ardito Desio" Milano.

processes. In fact, positive and negative feedbacks alternated over 1.2 My and controlled climate variability.

Calcareous nannofossil biostratigraphy across the Toarcian Oceanic Anoxic Event (T-OAE) (Colle di Sogno section, Southern Alps) and their response to high CO_2 concentration: preliminary results

CRISTINA EMANUELA CASELLATO (*), ELISABETTA ERBA (*)

Key words: *Toarcian-OAE, calcareous nannofossil.*

The Toarcian-OAE (ca.183 Ma, Early Jurassic) is a major global climatic and oceanographic perturbation (JENKYNS, 2010 and references therein), marked by a huge C-isotopic anomaly (a negative $\delta^{13}C$ shift interrupting a positive wider excursion) (HESSELBO *et alii*, 2000). It was caused by a huge atm-CO_2 increase, which in turn accelerated hydrological cycle, continental weathering, and increased nutrient availability, organic productivity and carbon flux to the oceans resulting in the widespread deposition of C_{org}-rich black shale.

Similarly to the Cretaceous OAEs, the calcareous nannofossil assemblages display variations that precede and continue through the T-OAE, namely a major reduction of bio-calcification, interpreted as the response to global climatic-oceanographic perturbations. These changes are anticipated by a marked nannoplankton speciation event and by a general increase in abundance of coccoliths as well as in species richness during the Early Toarcian.

This study aims to achieve high-resolution calcareous nannofossil biostratigraphy across the T-OAE, in order to achieve an integrated bio- chemo- magneto- stratigraphic framework to explore the response of calcareous nannoplankton and compare it with available data for Cretaceous OAEs.

The historical Colle di Sogno section (GAETANI & POLIANI, 1978; ERBA, 2004) represents one of the best sections of the central Southern Alps exposing the interval across T-OAE. It is characterized by pelagic limestone (Calcare di Domaro) passing to an alternation of reddish and greenish limestone, marlstone and shale (Sogno Formation, Lithozone 1), showing a decrease in carbonate content toward the mainly organic and locally bio-siliceous black shale, representing the sedimentary expression of the T-OAE.

Calcareous nannofossil biostratigraphy has been preformed on a total of 196 samples taken in a 26 metre-thick interval. Calcareous nannofossils are frequent to abundant, and moderately to well preserved. Several calcareous nannofossil events spanning the latest Pliensbachian-Early Toarcian interval were observed, and NJT-4, NJT-5 and NJT-6 Zones (MATTIOLI & ERBA, 1999) have been recognized. Genera Schizosphaerella and Mitrolithus dominate the latest Pliensbachian nannofossil assemblage, and show a decrease in abundance through the earliest Toarcian paralleled by a dimension decrease of a part of the schizosphaerellids. These genera display a further abundance reduction prior the anoxic interval ('schizosphaerellid crisis' – ERBA, 2004). These nannofossili variations mimic the lithological change from uppermost Pliensbachian carbonate-rich lithologies to lower Toarcian marly ones. Small species of Lotharingius and Biscutum genera characterize the Early Toarcian assemblage. An overall increase of calcareous nannofossil abundance characterizes the upper part of the section, above the anoxic interval, possibly as consequence of calcareous nannoplankton recovery after the paleoenvironmental perturbation. The Early Toarcian nannoplankton speciation event causes the general increase in placolith-bearing species.

The data achieved so far suggest that the drop in abundance of rock-forming genera along with the diffusion of small coccolith genera, might reflect the calcareous nannoplankton response to the T-OAE, specifically to changes in alkalinity and/or fertilization of surface water, associated to by global climatic perturbations.

Plio-Pleistocene high-low latitudes climate interplay: a Mediterranean point of view

F. COLLEONI (*), S. MASINA (*,°), A. NEGRI (***) & A. MARZOCCHI (*)

Key words: *Plio-Pleistocene climate transition, Mediterranean surface water, high-low-latitude interplay, spectral analysis*. Sapropels.

ABSTRACT

The high–low latitude climate interplay during the Plio-Pleistocene global cooling is not yet well understood. Insight on the Mediterranean region can provide some clues about past significant climate changes since the basin reflects the climate dynamics of both high-latitude and low-latitude regions, being connected to the North Atlantic and subjected to monsoon influence. Here we shade light on this connection problem by performing a spectral analysis on an Eastern Mediterranean stack of planktonic records spanning the last 5 Ma and by further comparing it to North Atlantic and Pacific deep- and surface-water records. Our main conclusion is that the Mediterranean detected the main global climate transitions over the last 5 Myr although sapropel depositions indicate that it remained influenced by the African summer monsoon during the whole interval. Our analysis reveals that until 2.2 Ma the Mediterranean planktonic record is driven by regional processes dominated by precession. The progressive emergence of the 41-kyr frequency in the Mediterranean records around 2.8 Ma suggests that, since this date, the Mediterranean was more and more affected by the high-latitude climate dynamics forcing than by the low-latitude one. Moreover, during the ongoing Plio–Pleistocene cooling, the 41-kyr frequency signal in the Mediterranean records anticipated high-latitude deep-water response to the intensification of the Northern Hemisphere Glaciations (NHG) and lagged the signal in tropical latitudes. Finally, toward 1.2 Ma the results suggest that the progressive shift from the 41-kyr to the 100-kyr frequency was led by the northern high latitudes. Overall, our results confirm that the Mediterranean is an ideal site to study the interplay between high and low latitude climates.

Possible solar forcing on the fluctuations of the coastal salt-marsh of the Tavoliere Plain (Apulia, Italy) during the Holocene

FEDERICO DI RITA (*)

Key words: *solar activity, pollen, Tavoliere Plain, Holocene*.

Detecting solar forcing in palaeoenvironmental records may be crucial to distinguish natural and anthropogenic factors in climate changes, especially in the light of the recent expected global changes. While the cyclic nature of solar activity has long been documented at a decadal time scale (e.g. 11-year Schwabe and 22-year Hale cycles) the identification of centennial scale solar periodicities is still controversial. The scientific literature reveals that centennial periodicities of solar activity, studied both in long sequences of the production rates of the cosmogenic radionuclides ^{14}C and ^{10}Be and in sunspot activity series, show an important heterogeneity in time that may be explained by the non-stationary nature of these proxies. Thus the centennial periodicities of solar activity should not correspond to fixed values, as they may vary within different time-intervals of the series. For this reason identifying sun-climate relationships in palaeoclimate proxies is a difficult task. For example, OGURTSOV *et alii* (2002) demonstrated that the DeVries-Suess cycle shows a variation within a period of 170-260 years, while the Gleissberg cycle is even more complex presenting a wide frequency band with a double structure that consists in 50-80 year and 90-140 year periodicities. Also the ^{14}C and ^{10}Be production rate records, which are among the most reliable solar activity indicators for the Holocene, may be affected by various factors that further complicate the assessment of solar variability, such as geomagnetic fields and precipitations. In addition, the Carbon cycle may affect the atmospheric ^{14}C content (MUSCHELER *et alii*, 2000).

The cyclic variations observed in the vegetation development of the pollen record of Lago Salso, a coastal site of the Tavoliere Plain (south Adriatic coast of Italy) (Fig.1), appear to be consistent with the centennial-scale variations ascribed to solar activity (DI RITA, 2012) (Fig.2). This observation stimulates a discussion on the possible influence of solar activity on the extent of a coastal salt-marsh in order to contribute to a better understanding on the sun-climate relationships in the central Mediterranean area.

Lago Salso was an extensive basin located at the margin of the Tavoliere Plain, one of the most arid areas of Italy (<500 mm mean annual precipitation), just south of the Gargano headland (Fig.1). The plain is a very flat area characterized by remarkably gentle slopes both inland and in the submerged part of the Manfredonia Gulf. The climate of the plain is arid and the landscape is deforested, although the natural steppe vegetation has been progressively replaced by widespread cultivations of cereals. During the Holocene the coastal side of the Tavoliere Plain was characterized by the presence of a lagoon (Laguna di Salpi) that during the periods of maximum extension occupied a wide area 40 km long (Fig.1). Since the middle Holocene this coastal basin underwent successive modifications, leading to the formation of several coastal lakes (e.g. Lago Salso), which were dried out at the beginning of the 20th century. At present, the original lagoonal environment and its brackish vegetation are still preserved in the protected areas of Palude Frattarolo and Saline di Margherita di Savoia, two remnants of the extinct Salpi lagoon (Fig.1).

The pollen record from Lago Salso shows regular fluctuations of halophilic vegetation (*Salicornia* type and *Ruppia maritima* type) between 6350 and 4000 cal years BP (DI RITA *et alii* 2011). In order to detect possible periodicities of these fluctuations a Wavelet analysis was applied to the percentage values of

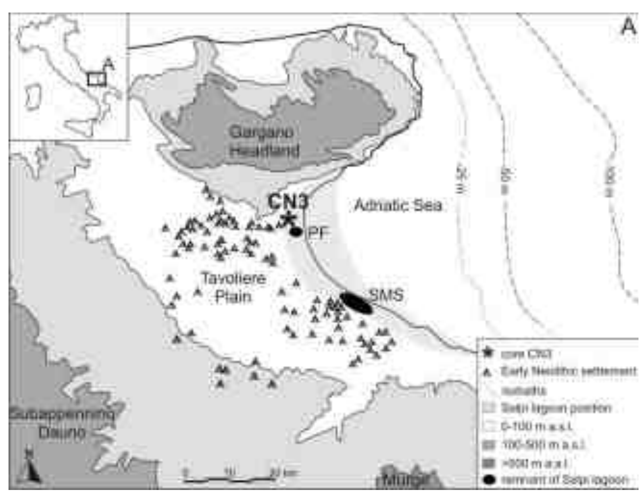

Fig. 1 – Study area showing the localization of the CN3 core and the remnants of the Salpi lagoon (PF=Palude Frattarolo; SMS=Saline di Margherita di Savoia) (modified from DI RITA, 2012)

(*) Dipartimento di Biologia Ambientale "Sapienza" Università di Roma

Salicornia type pollen. Two significant periodicities, corresponding to ca 250-260 years and 130-140 years respectively, consistent with cyclicities recognized in the bandwidth of the solar activity periodicities were found. The *Salicornia* type and *Ruppia maritima* type records of Lago Salso were also compared with the ^{10}Be GISP2 curve (FINKEL & NISHIIZUMI, 1997), on the basis of their respective independent chronologies (Fig.2).

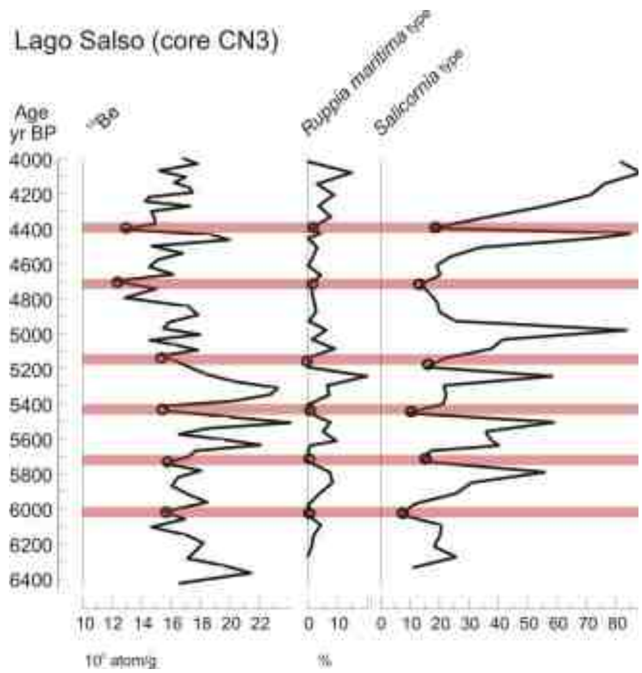

Fig. 2 – Comparison between ^{10}Be from GISP2 ice core (FINKEL & NISHIIZUMI, 1997) and salt-marsh vegetation indicators from CN3 core (modified from DI RITA, 2012)

The comparison reveals a strong visual correlation, indicating that minima of salt-marsh percentages correspond to minima of the ^{10}Be curve (Fig. 2). These minima represent solar activity maxima, associated with warm and arid phases at the middle latitudes. Thus, the salt-marsh appears to have contracted during the arid/warm phases associated to maxima of solar activity and to have expanded during the wet/cold phases of solar minima. This pattern may have been determined by solar activity through a control on: a) regional atmospheric circulation, which influences the localization, migration and stability of the atmospheric systems (GRAY *et alii* 2011); b) minor sea level fluctuations, determined by sea circulation processes that in the Adriatic Sea appear to be strongly related to the solar magnetic activity variations (FERRARO & MAZZARELLA, 1998; ZANCHETTIN *et alii*, 2009). The combination of variations in regional atmospheric circulation and sea level fluctuations may have had an important influence on the development of the Salpi Lagoon and on the extent of its salt-marsh, with effects exacerbated by the very flat topography and arid climate of the area that is particularly sensitive to even minor hydrological changes. Geological studies in the area document that, between 6000 and 4000 cal BP, the Salpi lagoon experienced desiccation phases, testified by the production of evaporitic formations (gypsum minerals) pointing to semi-desert sabkha-type environments (BOENZI *et alii*, 2001). Interestingly the contractions of the salt-marsh, documented by pollen and evaporitic sediments, match the chronology of grand solar maxima proposed by USOSKIN *et alii* (2007). According to the study of USOSKIN and co-authors, the period between 6000 and 4000 cal BP would represent a phase of major and frequent maxima of solar activity. This evidence further supports the pattern of the solar activity in the evolution of coastal Tavoliere Plain, although also the influence of other factors should not to be totally ruled out. Tidal rhythms, overall sea level rise, and geomagnetic field activity may have played some role in the modulation of the salt-marsh fluctuations, but their action in the past is difficult to be assessed because of the scarcity of data (DI RITA, 2012).

The environmental changes determined by solar activity may have also been responsible for the abandonment of the human coastal settlements of the Tavoliere Plain so influencing the cultural evolution of one of the most important archaeological districts of Italy. Geological evidence and archaeological finds suggest that environmental changes related to desiccation phases followed by flood events forced local Neolithic human populations to repeatedly abandon the coastal sites of the Tavoliere Plain during the Neolithic (BOENZI *et alii*, 2001; CALDARA *et alii*, 2002 and references therein), although times and modes of these dynamics are not fully constrained. The possible influence of solar activity adds new elements to this still open issue.

Morphological changes of calcareous nannofossils during Oceanic Anoxic Event 2

GIULIA FAUCHER (*) & ELISABETTA ERBA (*)

Key words: *Oceanic Anoxic Event 2, calcareous nannofossil , adaptations.*

The Cenomanian - Turonian Oceanic Anoxic Event 2 (OAE2) is one of the most pronounced perturbations of the Cretaceous that induced major changes in the marine environment and severe disturbances of the biosphere. It is thought to be linked to extensive volcanism and particularly to the emplacement of a Large Igneous Province (LIP) that acted as a natural source of excess CO_2. Particularly, OAE2 seems to be strictly connected with the formation of the Caribbean Plateau, which triggered a chain of events leading to enhance ocean fertility, accelerated organic carbon burial, widespread ocean anoxia, and acidification.

Calcareous nannoplankton is sensitive to chemical - physical - trophic changes and must have reacted to the OAE2 extreme environmental conditions. Indeed, nannofossil data show that they experienced a turnover, a general decrease in species richness and locally a decline in abundance of the fertility indicator species.

In this study we present new results of a detailed morphometric analysis of 4 nannofossil species during OAE2 from two different areas: the Mediterranean area (Novara di Sicilia section, North-eastern Sicily) and the Sussex area (Eastbourne section, United Kingdom). These sections have been chosen based on integrated high-resolution stratigraphy: the C isotopic anomaly is taken as primary tool of dating and correlation of OAE2 events. Furthermore the Novara di Sicilia section represents only the lower portion of OAE2, whereas the Eatsbourne section, covering the entire OAE2 interval, provides the opportunity to characterize changes before, during and after the paleoenvironmental perturbation.

In analogy to the work of (ERBA *et alii*, 2010) on the Early Aptian OAE1a, biometric analyses were performed at high resolution on *B. constans, D. rotatorius, Z. erectus* and *W. barnesiae* in order to evaluate the influence of paleoenvironment on coccolith size and morphology. Size measurements of calcareous nannofossils were carried out on smear slides with a light microscope: in each sample 30 specimens of *B. constans, D. rotatorius*, *Z. erectus* and 50 specimens of *W. barnesiae* have been measured by using the Qcapture Pro suite.

Morphometric analyses highlight that:

1. In both sections dwarf coccoliths are present even before the OAE2 onset.
2. There is a species - specific response in both section: *B. constans* displays the most pronounced reduction in size, *D. rotatorius* records a well express reduction in size too as opposed to *Z. erectus* which diminishes in size to a lesser extend.
3. In both sections, the mean size of *W. barnesiae* is within the holotype and normal range size
4. In the Novara di Sicilia section dwarf coccoliths record the strongest reduction in size relative to Eastbourne samples.
5. Pronounced dwarfism is observed in discrete intervals before and within the carbon isotope excursion.
6. During OAE2 coccoliths return to normal sizes around the carbon isotopic peak “A”.

Comparison of morphometric analyses through OAE1a (ERBA *et alii*, 2010) and OAE2 shows analogies and differences. During OAE1a dwarfism and malformation are restricted to the onset of the carbon isotopic anomaly, in the core of the negative shift coeval with most profound paleoenvironmental perturbations. In the OAE2 interval dwarfism is most pronounced in the last part of the C isotopic anomaly, and coccolith deformation is negligible. During the two major Cretaceous OAEs, the ocean experienced extreme CO_2 concentrations, acidification and an increase in fertility. Coccolith dwarfism suggests a link between nannoplankton calcification and high pCO_2, although enhanced fertility and/or presence of toxic metals in seawater might have been instrumental as well. We speculate that during OAE1a and OAE2 excess CO_2 played a fundamental role in ruling nannoplankton calcification efficiency, and that coccolith dwarfism might be a proxy of ocean acidification. Different patterns and degree of dwarfism and malformation during OAE1a and OAE2 suggest unequal volcanic CO_2 emissions (rates, pulses, amount). We conclude that analogous causes (LIPs emplacement) have induced partially similar response at different times.

The Early Toarcian anoxic event and shale gas potential: the case history of the Marne del Monte Serrone Formation (Central Italy).

GUGLIOTTI L. (*), CIRILLI S. (*), BURATTI N. (*)

Key words: *Basin, geochemical, organic matter, shale gas.*

The Early Toarcian facies enriched in organic matter represent a significant target for oil exploration as source rocks and in particular as shale gas as testified by recent studies (CURTIS, 2002; JARVIE *et alii*, 2007; BUSTIN *et alii*, 2008). While shale gas production in the USA began in 1821 in contrast the European shale gas exploration is still in progress, being the Early Toarcian organic rich shale currently tested for their shale gas potential. This organic rich facies (black shales) are related to the Early Toarcian anoxic event occurred more or less synchronously in several European basins (JENKYNS *et alii*, 1986, 1988; ERBA, 2004; VAN DE SCHOOTBRUGGE *et alii*, 2005; MAILLIOT. *et alii*, 2006; DERA *et alii*, 2009; SUAN *et alii*, 2010) including the S-W Germany Basin, where the lower Toarcian Posidonia Shale is a well-known example of shale gas formation (ROHL *et alii*, 2001; HORSFIELD *et alii*, 2011; BERNARD, *et alii*, 2011). This widespread event has been linked to a global perturbation of the carbon cycle and marine biological change, these coincide with a marked global transgression and increase in organic carbon burial (BODIN *et alii*, 2009, MATTIOLI *et alii*, 2009; ERBA *et alii*, 2010). In the Central Northern Apennine the Marne del Monte Serrone Formation, represents one example of Early Toarcian deposits enriched in organic carbon. The formation mostly consists of organic rich shale, marly-clay and marly-limestones, deposited in a low oxygenated basin (PIALLI, 1969; JENKINS *et alii*, 1988; ORTEGA-HUERTAS, *et alii*, 1993; BUCEFALO PALLIANI *et alii*, 1998; SABATINO *et alii*, 2009). Previous studies (PARISI *et alii*, 1996; BUCEFALO PALLIANI *et alii*, 1998) document a strong variations in TOC from place to place within the same basinal environment. These differences reflect also in the type and preservation degree of accumulated organic matter which in turn influence the shale gas potential of these facies. The main aim of this study is to define how the physiography of the sedimentary basin controls the amount, typology and preservation of organic matter and its dilution within the mineral fraction in order to provide the main tools to predict the potentiality of shaly deposits to be shale-gas. To reach this target several examples from different palaeogeographic domain will take in consideration. In the present contribution the preliminary results from the case history of Marne del Monte Serrone Formation will be presented.

This formation deposited in a basinal environment characterized by an articulated physiography and bathymetry consisting of structural highs and subsiding basins, inherited from the break-up and drowing of the Early Jurassic Calcare Massiccio carbonate platform. An integrated study, based on organic and sedimentary facies, geochemical ($\delta^{13}C$) and calcimetric analysis ($CaCO_3$ contents) has been performed to reconstruct the relationships between the total sedimentation rate, the organic sedimentation rate and basin physiography. The Marne del Monte Serrone Formation has been measured and sampled in several portions of the Umbria-Marche basin, both on outcrops and core (Colle d'Orlando, Pozzale, Valdorbia, Pale, Fonte Cerro, Monte Serrone), spanning from *Tenuicostatum* and *Serpentinus* ammonite zones, where resulted that lithofacies and organic facies show marked differences..

Preliminary results show that the lithofacies deposited in the basinal areas developed on the previous structural highs are characterised by low TOC % (0.1-0.3), against the higher values reached in the successions deposited in the deepest portions of the basin. In the first ones the total organic matter never reaches high percentage and it is dominated by terrestrial derived organic debris, mostly composed of palynomacerls, frequently oxidized woody fragments and rare sporomorphs. The marine organic content is always very low, mostly represented by dinoflagellate cysts and Tasmanaceae algae. Amorphous organic matter and framboidal pyrite occur, with moderate percentage, at rare stratigraphic levels. The organic facies distribution show a good correspondence with the $\delta^{13}C$ curve which dysplays an anomalous $\delta^{13}C$ positive trend to a minimal value at an organic rich layer at the base of the Formation (Monte Serrone area, type locality) where amorphous organic matter and framboidal pyrite are relatively abundant.

In the deepest portions of the basin (e.g. Valdorbia, Colle D'orlando, Pozzale), the black shale facies within the *Tenuicostatum* ammonite zone are characterized by $\delta^{13}C$ negative shifts correlable with higher TOC% (0.3-2.6) (Parisi *et alii*, 1996, Sabatino *et alii*, 2009). The organic matter is mostly composed by a mixture of continental organic debris and marine components such as dinoflagellate cysts, foraminifera linings and Tasmanaceae algae.

The preliminary data suggest that the physiography and bathymetry of the Early Toarcian Umbria-Marche basin strongly controlled the type, the accumulation and the preservation rate of the total organic matter. The sediment supply from landmasses, including organic matter and clay, was probably rather constant while variable subsidence rates linked to tectonic-eustatic processes generates differences in organic matter composition, as well as in black shale facies distribution.

(*) Dipartimento di Scienze della Terra, University of Perugia (Italy)

In the shallowest areas of the basin the organic matter was readily oxidized within the water column and at marine bottoms. Periodically increases of continental water run-off and high terrestrial sediment supply from landmasses caused water stratification and temporary reducing conditions at sea bottoms. On the contrary in the deepest areas of the basin there were the right conditions to assure the deposition and preservation of large amount of sedimentary organic matter, by the combination of high primary productivity and permanent low dysoxic to anoxic conditions at the marine bottoms, lying well below the oxygen minimum. In such conditions the organic rich facies well developed only in the deeper portion of the basin where they reach the best shale gas potential both for abundance and type of organic matter.

Which relationship between the development of forest vegetation and the sapropel layers in the Mediterranean Basin?

DONATELLA MAGRI (*) & LUCILLA CAPOTONDI (**)

Key words: *interglacial, Mediterranean Sea, pollen, precession, sapropel.*

INTRODUCTION

The relationships between the formation of Mediterranan sapropels and monsoon regime (ROSSIGNOL-STRICK, 1983), freshwater contributions (OSBORNE *et alii* 2003), and precession-induced insolation maxima (ROSSIGNOL-STRICK, 1985) have been discussed in a number of papers, but there are still many unsolved questions that form the subject of lively discussions in the scientific community (e.g., TZEDAKIS, 2007; RUDDIMAN, 2006).

In this paper we compare the forest development in central Italy with the age of the Mediterranean sapropels in the time interval 0-200 ka BP, with the aim of suggesting new elements to the ongoing discussion.

POLLEN-SAPROPEL-PRECESSION COMPARISON

The long pollen record from Valle di Castiglione (FOLLIERI *et alii*, 1988, 1989), a crater lake 20 km east of Rome, presents two features that make it especially suitable for a comparison with the age and the development of the Mediterranean sapropels: (i) its pollen concentration represents fairly well the changes in plant biomass that have occurred during the last two glacial–interglacial cycles (MAGRI, 1994), and (ii) its chronology is supported by a close relation between vegetation phases and orbital configurations, showing that components of vegetation have responded systematically to insolation forcing associated with specific orbital geometries (MAGRI & TZEDAKIS, 2000).

In Fig. 1 the arboreal pollen concentration from Valle di Castiglione is compared with the curve of precession (BERGER, 1978) on the basis of their independent chronologies. The comparison shows that (i) situations with perihelion (point in the Earth's orbit closest to the Sun) with the northern Hemisphere in winter (pink bands in Fig. 1) always correspond to significant contractions of tree populations; in these conditions no sapropels were documented in the Mediterranean Basin; (ii) peaks in forest biomass were always associated with perihelion during northern autumn (yellow bands in Fig. 1); in these situations there were no sapropels; (iii) the start of forest development, often characterized by thermophilous taxa, such as *Olea* and evergreen *Quercus*, always occurred with perihelion occurring in northern summer. All Mediterranean sapropels were found in this orbital configuration (green bands in Fig. 1).

DISCUSSION

The comparison between the pollen record from Valle di Castiglione, the age of Mediterranan sapropels and the precessional term suggests possible relationships between the contraction of forests and the absence of sapropels, as this coincidence is repeated all the times when perihelion occurs in northern winter. In this orbital configuration, tree populations are always much reduced and the vegetational landscape is dominated by steppe and grasslands. From the climatic point of view, these vegetational formations indicate a generally dry climate, which is also consistent with the lack of sapropels.

At Valle di Castiglione, the maximum density of forests is always found in the second half of the interglacial cycles, when climate was generally cool and wet, and soils were well developed. Forest generally consisted of mesophilous trees, with significant expansions of deciduous *Quercus* and *Carpinus*, often accompanied by increases in *Fagus* and *Abies*. This forest composition indicates water availability and abundant precipitations also in summertime. All such cases were associated with perihelion in northern autumn and never corresponded to sapropel formation, suggesting that water availability and high rainfalls, which are considered one of the necessary features for sapropel formation, were not a sufficient factor.

All sapropels occurred with the perihelion in northern summer, when more or less thermophilous forests developed in central Italy. Climate conditions for this vegetation type include a moderately wet climate, with a mediterranean rainfall regime and relatively high temperatures, which are generally encountered in the first half of the interglacial periods. Also at more northern latitudes in Europe, the vegetation features point

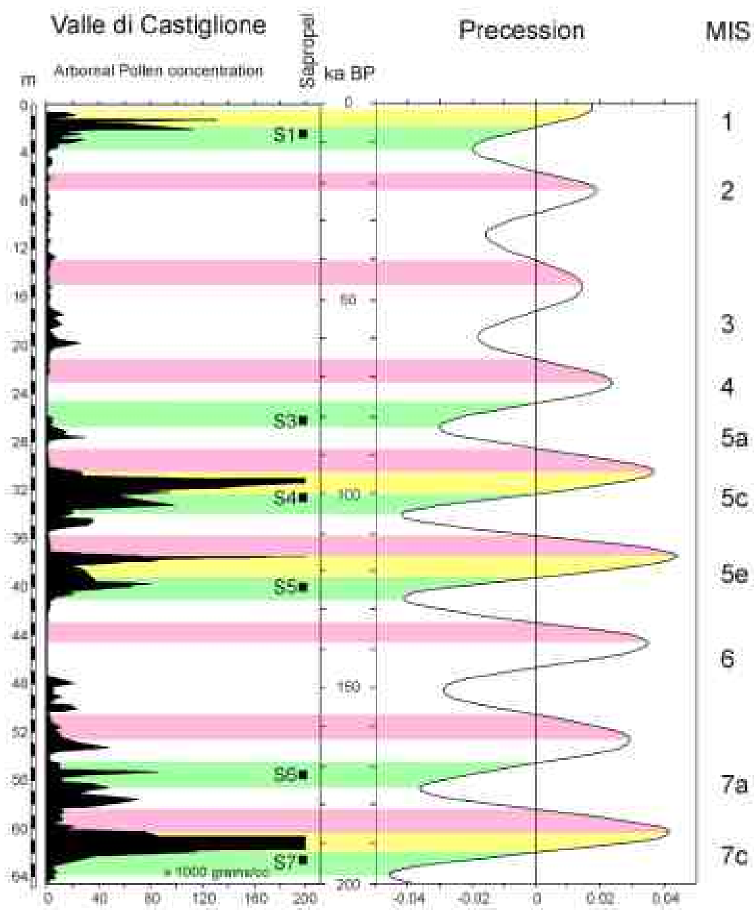

Fig. 1 – The Arboreal Pollen concentration diagram from Valle di Castiglione (FOLLIERI et al., 1988) and the climatic precession (BEGER, 1978) are compared with the age of the Mediterranean sapropels (KROON *et alii*). Shaded bands indicate the times when perihelion occurred in northern winter (modified from MAGRI & TZEDAKIS, 2000).

to wet climate, generally warmer than in the second half of the interglacial, suggesting that much of the freshwater input into the Mediterranean Basin might have been from the European regions.

Interestingly, the orbital configurations with perihelion occurring in autumn did not always produce forest expansions, and the situations with perihelion in summer did not always produce sapropel formation. Theses discrepancies are on the one hand really puzzling, and on the other hand stimulate deeper insights into the effects of atmosphere and ocean circulations on the continental and marine ecosystems of the Mediterranean Basin. A specific case is the lack of both important forest expansions and sapropels during Marine Isotope Stages (MIS) 4, 3 and 2. Pollen records from numerous European sites provide evidence for multiple intervals of relatively warm and humid conditions during the last glacial, which promoted the establishment of open boreal forest in central western Europe and the Alpine region, and open temperate forest in southern Europe (FLETCHER *et alii*, 2010). A millennial-scale variability is also evident, by and large corresponding to the Dansgaard–Oeschger cycles in Greenland ice core records (DANSGAARD *et alii*, 1993). This variability is one possible explanation for the lack of extensive forests during the favourable orbital configurations of the last glacial period. Tree populations slowly increased as climate conditions were suitable for them, but were soon disrupted by changing conditions, so that they could never attain high densities. The same mechanisms may be envisaged for the formation of sapropels in the Mediterranean Basin.

Carbonate platform evidence of ocean acidification at the onset of the early Toarcian oceanic anoxic event

MARIANO PARENTE (*), ALBERTO TRECALLI (*), JORGE SPANGENBERG (**), THIERRY ADATTE (°) & KARL B. FÖLLMI (°)

Key words: *Ocean Acidification, Toarcian Oceanic Anoxic Event, Apennine Carbonate Platform, carbon isotope stratigraphy, paleophysiology.*

The early Toarcian oceanic anoxic event (Early Jurassic; ~183 Myr ago) is associated with one of the most prominent negative carbon isotope excursions (CIE) in the whole Phanerozoic. Estimates of the magnitude and rate of CO_2 injection in the ocean-atmosphere system are compatible with a scenario of ocean acidification.

A sharp decrease in the abundance of heavily calcified nannofossils during the T-OAE (the so-called schizosphaerellid crisis) and the concurrent reduction in size of some species have been interpreted as evidence of a biocalcification crisis in the shallow ocean . However, attribution to ocean acidification is problematic because it is very difficult to disentangle the effects of concurring paleoenvironmental stressors, like high fertility, low salinity and rapid temperature changes.

Even if the hypothesis of ocean acidification needs confirmation by independent geochemical proxies of seawater carbonate saturation, it is tempting to test it by looking at the record of carbonate platforms and their shallow benthic calcifiers across the early Toarcian event.

Many Tethyan platforms drowned during the Pliensbachian as the result of extensional tectonics linked to the opening of the western Tethyan ocean. For those platforms that continued growing, the terminal drowning close to Pliensbachian-Toarcian boundary is seen as the combined effect of tectonics, accelerated sea-level rise and paleoenvironmental deterioration.

Some resilient platforms continued growing in shallow-water across the Pliensbachian-Toarcian boundary and the T-OAE (Trento Platform; Apennine Platform; Adriatic-Dinaric Platform; Pelagonian platform). These platforms offer the unique possibility of studying the response of shallow-water benthic calcifiers to an episode of massive and geologically rapid release of CO_2 into the ocean-atmosphere system.

In this paper we test the hypothesis of surface water ocean acidification by looking at the record of a resilient carbonate platform: the Apennine Carbonate Platform of southern Italy.

The studied sections document a dramatic shift of the carbonate factory from massive biocalcification to chemical precipitation. Lithiotis bivalves and calcareous algae (Palaeodasycladus mediterraneus), which were the most prolific carbonate producers of Pliensbachian carbonate platforms, dissappear at the onset of the early Toarcian event. We discuss the local vs. supraregional significance of this shift and propose a scenario envisaging abrupt decline of carbonate saturation, forced by CO_2 release at the onset of the early Toarcian CIE, followed by a calcification overshoot, driven by the recovery of ocean alkalinity. Attribution of the demise of carbonate platform hypercalcifiers to ocean acidification is supported by paleophysiology and reinforced by experimental data on the detrimental effects of ocean acidification on extant shellfishes and calcareous algae.

Dynamics at the sicilian strait and mediterranean sapropels

SPROVIERI M.(1), SANNINO G. (2), AGATE, M. (3), SABATINO N. (3), INCARBONA A. (3), SPROVIERI R. (3), RIBERA D'ALCALÀ M. (4), ARTALE V. (2) & MAZZOLA S. (1)

A number of OGCM experiments were run to explore processes at work during deposition of sapropels and organic rich layers in the eastern and western Mediterranean basin for the last 3.5 million years. Sapropels and organic rich layers recovered from ODP Sites during Leg 160 and 161 were precisely tuned to the La2004 insolation curve and synchronized to precession minima. New mid-resolution paleogeographic maps of the basin, with a detailed reconstruction of paleobathymetry at the Sicily Strait, were generated to capture the impact on the 3D dynamic circulation of the basin.

SST (EMEIS *et alii*, 2003) and SSS (VAN DER MEER *et alii*, 2007) values, of sediments deposited before and during the one of thickest anoxic layers, Sapropel S5 (124-119 ka), were used as reference parameters to investigate the sensitivity of the 3D dynamics of the Mediterranean Sea during sapropel and non-sapropel conditions, in different paleogeographic settings. Water properties and 3D circulation of both eastern and western Mediterranean Sea during the Plio/Pleistocene appear to be significantly conditioned by the bathymetric control at the Sicilian sill. Also, thermal and salinity changes modulate density values of Intermediate Waters during sapropels/organic rich layers deposition and consequently determine buoyancy properties of eastern and western Mediterranean Deep Waters.

Bathymetric changes at the sill and dynamics of Intermediate Waters directly influence horizontal and vertical spreading patterns of Eastern Mediterranean Deep Water at the bottom of the basin with relative and deposition of anoxic sediments. It is worthy to note that benthic fauna in the western Mediterranean ODP 654 and 653 sites documents crucial changes in ventilation of bottom sediments in key intervals of bathymetric changes in the Sicily Channel and testifies reduced Intermediate Water outflow to the western Mediterranean.

Key words: *Cretaceous, carbon cycle, Oceanic Anoxic Event.*

INTRODUCTION

Cretaceous sedimentary records from the alpine Tethys serve as archives of chemical and physical oceanography and of climate. Pelagic sedimentary facies is used as proxy for oxygenation state of deep water and as source of information on changing surface water conditions, including ocean acidification and varying nutrient loads. Sedimentation rates, condensation levels and stratigraphically identified sedimentary gaps inform on sediment reworking, on current intensity, on winnowing of sediment and on distribution of drift deposits. The carbonate carbon isotope record established in pelagic carbonates provides information on changing carbon cycling, on changing atmospheric CO_2 levels and hence on climate. This study focuses on impact of global climate change on chemical and physical oceanography and hence on sedimentation in pelagic and shelf settings during times of Cretaceous greenhouse and coolhouse climate.

Pelagic, white limestones of earliest Cretaceous age mirror stable oceanography and climate with oligotrophic surface waters, a stable thermocline and rare evidence for current-induced erosion. Few chert layers can be interpreted as evidence for upwelling episodes resulting in nutrient enriched surface waters and in radiolarian blooms. Carbon isotope values reflect stable climate persisting into the Valanginian. In the Valanginian, darker limestones with irregular intercalated black shales form the upper part of the Maiolica Formation followed by variegated green, black and red foraminifera marlstones of Aptian and Albian age. These pelagic sediments mirror less stable Tethyan oceanography, which is also reflected in the carbon isotope record. A first major positive C-isotope excursion in the Valanginian marks the transition to less stable Valanginian to Cenomanian climate and oceanography. While low amplitude fluctuations in the C-isotope are controlled by long-term eccentricity cycles (SPROVIERI *et alii*, 2006, GIORGIONI *et alii*, 2011), high-amplitude C-isotope excursions of Valanginian and Aptian age represent major perturbations of global carbon cycle and climate probably triggered by volcanism. A comparison of the Early Aptian C-isotope event corresponding to Oceanic Anoxic Event (OAE) 1a with the Valanginian C-isotope event shows differences but also some remarkable similarities .The Aptian positive C-isotope excursion is preceded by a negative carbon isotope spike recording an extreme perturbation of the carbon cycle, related to volcanic degassing and/or to methane bursts. A negative spike is not recorded before the Valanginian C-isotope excursion. The Aptian positive C-isotope excursion following the negative spike records the response of the global carbon cycle to the initial perturbation triggered by volcanism or methane degassing. The Valanginian C-isotope excursion was tentatively linked to Parana Continental Flood Basalt formation even if a negative C-isotope spike is not observed. Parana volcanism as a trigger of the Valanginian perturbation is under debate because new radiometric dating is in disagreement with current chronology of the carbon-isotope anomaly in the Valanginian. Even if the trigger of the Valanginian C-isotope anomaly is unknown the response of Valanginian oceanography and climate is similar to Aptian response pattern. Changes in hydrological cycling, in weathering, and in quartz sand shedding are recorded in Valangininan and Aptian archives. The Valanginian C-isotope event was accompanied by anoxia, limited to the Atlantic and few restricted basins in western Tethys. The Aptian C-cycle perturbation triggered more widespread anoxia (OAE1a) observed in the Atlantic and western Tethys and on submarine highs in the Pacific but not in the eastern equatorial Tethys. Drowning of carbonate ramps and choking of biocalcification is observed in both Valanginian and Aptian selective neritic and pelagic carbonate settings. Biocalcification crises seem to be characteristic for rapid volcanically driven C-cycle perturbations while orbitally driven low amplitude changes in carbon cycling were not accompanied by choking of carbonate production.

Changes in Valanginian to Albian oceanography are not only recorded in unstable C-isotope record and in changing sedimentary facies of pelagic sediments, they are also documented in a change from continuous to discontinuous sedimentation in Tethyan basinal settings and on submarine highs. Sedimentary gaps, omission surfaces, seafloor mineralizations (phosphorites) are common in Valanginian to Albian/Cenomanian pelagic successions and corresponding drift deposits can be found in certain basinal settings. These changes in sedimentation suggest that intermediate and deep

(*) Department of Earth Sciences, ETH Zürich, Switzerland

Lavoro eseguito con il contributo finanziario della Swiss Science Foundation

water current intensities were at least episodically high affecting sediments in water depths of 1000 meters or more. Evidence for episodically intensified currents is also found in shelf successions of the Northern Tethys. Phosphoritic hardgrounds were repeatedly formed on drowned carbonate ramp deposits of the Northern alpine Tethys during times of major carbon cycle perturbations (e.g. Valanginian, Aptian). Widespread condensation and repeated high-productivity black shales (OAEs) are both signatures of a predicted circumequatorial current system (HOTINSKI & TOGGWEILER, 2003), which can be described as a "greenhouse mode" circulation system. These ocean circulation simulations predict strong wind-driven circum-equatorial surface water currents, with intense upwelling along the Tethys Seaway during Cretaceous. According to the model by HOTINSKI & TOGGWEILER (2003), the Tethys upwelling system was coupled with strong deeper water currents reaching velocities of several cm/s in water depths of 1000m or more. Greenhouse climate conditions could have enhanced the proposed circulation pattern recorded in pelagic and shelf settings. Cooler climate seems to have favored more stable surface water conditions and weakened current intensities. This "coolhouse" mode of the earliest Cretaceous was possibly coupled with lower sea level and altered equatorial-polar circulation patterns not yet recognized in available circulation simulations.

Digital 3D modeling by laser scanning technique of Lepidocyclina limestone (Bolognano Formation, Majella)

BRANDANO M. (*,°°), GUARINI G. (**), PETRUNGARO R. (**), VELOCCI L. (**), MELONI D. (*), MASCARO G. (*) & LIPPARINI L. (°)

Key words: *Laser scan, submarine dune, Oligocene, Majella, carbonate ramp*

To study a sedimentary structures the prerequisite is the availability of 3D outcrop. Sedimentary structures reproductions may be based on drawings, supplied by photographs. However drawings and photographs present and cause different problems, for examples the accuracy of drawings as well as photographs are dependent on the direction and intensity of light.

Laser scanners produce a "point cloud" giving an accurate and precise three dimensional representation of a considered target. Terrestrial laser scanner has been used in order to obtain a model of the trampled area taking in account that terrestrial laser scanner allows a highly detailed geometric characterization also on target situated at distances up to tens of meters. The acquisition has been performed with Riegl VZ 400 laser scanner from a distance of approximately 90 m, setting a mean point to point spacing of 0,005 m . The 3D digital modelling was performed on the sedimentary structures of the Chattian Lepidocyclina limestone of Majella (Formazione di Bolognano) along a 200 m long transect.

The Lepidocyclina Limestones of the Majella area were deposited in the oligophotic and aphotic zones of a carbonate ramp (BRANDANO *et alii* 2012). The taphonomic analysis implies a parautochthonous origin for an important part of the sediments in a middle ramp environment, and an increase with depth of autochthonous sediments in the outer ramp.

In the Lepidocyclina Limestone, sediment sorting is not directly related to a decrease in water energy linked to increasing water depth. Instead, sediment-sorting is attributed to the effect of uni-directional currents. Grainstones dominate the middle ramp environment. Palaeocurrent patterns suggest the occurrence of a strong, generally north–west directed flowthat affected the middle ramp environment. It is believed that this basinward-flowing current led to the development of a wide (10×15 km), downslope-migrating dune field. It is proposed that the combined effects of coastal set-up and strong return currents caused by storms and winds were able to produce basinward migrating bedforms

In this work it will be presented the result of the 3D modelling of the sedimentary structures of the sigmoidal cross-bedded grainstone that represent the record of submarine dune migration in the middle ramp environment.

Middle Triassic carbonate platform-basin system from Sicily. New evidence from the Madonie Mountains

PIETRO DI STEFANO (*), CHRISTOPHER MCROBERTS (**), PIETRO RENDA (*), ANGELO TRIPODO (*), GIUSEPPE ZARCONE (*)

Key words: *Triassic, Ladinian, Sicily, Diplopora, Daonella.*

INTRODUCTION AND GEOLOGICAL SETTING

New findings of Middle Triassic shallow and deep-water carbonate sediments from the Madonie Mountain confirm the presence of an originally pre-Carnian sedimentary substrate in the Panormide and Imerese paleogeographic units (DI STEFANO *et alii*, 2012, in press). The tectonostratigraphic setting and the preliminary sedimentological and stratigraphical data collected from these sediments are here summarized.

The studied area is located in the southern zone of the Madonie Mountains near the village of Petralia Sottana along the eastern slope of Monte San Salvatore (Fig. 1). The structural setting of this area consists of a complexly deformed thrust pile which is the result of the Neogene compressional and transpressional stacking of a Mesozoic carbonate platform-basin system (known as the Panormide Platform and the Imerese Basin) and its Cenozoic, mostly terrigenous, covers (RENDA et al. 1999). Neo (or Alpine) Tethyan-derived allochtons known as Sicilidi units (OGNIBEN 1960) are also involved in the collisional complex.

In the Monte San Salvatore area several thrust sheets that are considered to be derived from the slope between the Panormide Platform and the Imerese Basin outcrops (RENDA et al. 1999).

The stratigraphy of these thrust-units consists of Carnian calcilutites and marls (Mufara Fm.) overlain by slope dolostones (known as the Quacella Formation, CERETTI & CIABATTI 1965). Numidian Flysch sediments follow on a deep erosional surface. The Numidian sediments contain thick intercalations of platform-derived carbonate megabreccias (Wildflysh di Monte San Salvatore, OGNIBEN 1960).

Fig. 1 – Structural sketch of the Central Mediterranean area showing the location of the Madonie Mountains.

THE SANT'OTIERO SUCCESSION

The Middle Triassic sediments occur at the base of a thrust sheet with a similar sedimentary succession in the Sant'Otiero locality near Petralia Sottana (Fig. 2).

The studied section exposes from the base about 60 m of dark grey coarse calcareous breccias with centimeter to decimeter-sized angular pebbles surrounded by a calcilutite matrix. The breccia outcrops along the nearly vertical slope of the Sant'Otiero peak and is followed upward by about 50 m of thick parallel-bedded dark-grey calcilutites. Between the calcareous breccias and the calcilutites a détachement surface can be observed. The lowermost part of the calcilutitic zone, consists of wedge-shaped beds with pebbly mudstones. Upsection, beds of thin-shelled bivalve lumachella are irregularly intercalated to the calcilutites.

Christopher.McRoberts@cortland.edu

This research was supported through the MIUR-COFIN 2008 project on "Upper Triassic carbonate systems from Sicily: Stratigraphic architecture, depositional dynamics and paleogeographic setting" (grants to P. Di Stefano).

Fig. 2 – Outcrop view of the calcare di Sant'Otiero. The section shows the brecciated zone (right) and the overlying well bedded calcilutites.

Upward the dark gray calcilutites are overlain by the typical Mufara sediments consisting of alternations of brown clays and platy calcilutites. They are in turn overlain by the Quacella dolomites and by the Numidian Flysch containing thick megabreccia intercalations.

The microfacies analysis of samples collected along the section shows that the elements of the megabreccia consists of different microfacies types such as dasycladalean grainstone with *Diplopora annulatissima* Pia, peloidal grainstone with *Tubiphytes and benthic foraminifers,* algal boundstone with the problematic *Zornia obscura* Senowbari-Daryan & Di Stefano. Additionally among the elements pelagic wackestones with calcispheres and filaments are found.

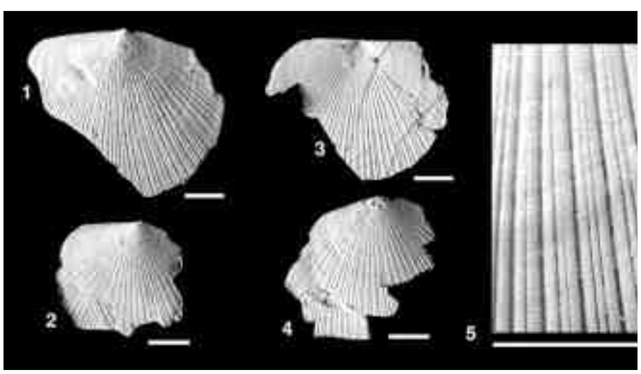

Fig. 3 – Daonella tyrolensis Mojsisovics, 1874 from calcare di Sant'Otiero, Sant'Otiero section, Monte San Salvatore, Sicily.

The upper part of the Sant'Otiero section shows mud-dominated microfacies types such as dark-gray mudstone or wackestone with thin-shelled bivalves and rare calcispheres. In places a shelter porosity can be observed that increases in the lumachella beds. Among the thin shelled bivalves *Daonella tyrolensis* Mojsisovics, 1874 has been recognized (Fig. 3).

DISCUSSION

The carbonate megabreccias with *Diplopora annulatissima, Zornia obscura, Tubiphytes* and benthic foraminifers in the lower part of the calcare di Sant'Otiero, support a provenance from the dismantling of an Anisian? or early Ladinian carbonate shelf. The micritic matrix with thin-shelled bivalve fragments between the elements indicate a deep-water (slope or toe-of-slope) environment for the megabreccia accumulation. Moreover, the presence of lithoclastic grains with the same microfacies, suggests the presence in the source areas of already litified pelagites.

The age of the overlying *Daonella* beds is well constrained by the presence of *D. tyrolensis*. This species is among the most widely distributed Ladinian *Daonella* in Alpine Europe and is a well-established biostratigraphic marker of the early late Ladinian *Protrachyceras longobardicum* ammonoid zone (BRACK & RIEBER 1993; SCHATZ 2004; MCROBERTS 2010). An early late Ladinian age for the *Daonella* beds requires that the megabreccia emplacement took place in the early Ladinian or to the earliest late Ladinian.

CONCLUSIONS

The finding in the Madonie Mountains from Sicily of a Ladinian *lumachella* with daonellids including *Daonella tyrolensis*, associated with a megabreccia formed by neritic elements with *Diplopora annulatissma*, provide new data permitting a more precise reconstruction of the pre-Carnian sedimentary basins of Sicily during the early-Alpine stage. The presence of pelagic limestones of Ladinian age and their tectonostratigraphic location, reinforce previous data on the existence of a Middle Triassic carbonate platform to basin system which more or less corresponds to the Panormide and Imerese paleogeographic zones.

Progradational geometries and early rifting-related extension in the Calcare Massiccio formation (Northern Apennines)

SIMONE FABBI (*) & MASSIMO SANTANTONIO (*)

Key words: *Jurassic, clinoforms, rifting, progradation.*

INTRODUCTION

The Umbria-Marche Domain is a vast depositional system that was characterized by dominantly pelagic sedimentation through most of its Jurassic to Oligocene/Early Miocene history. The pelagic succession is underlain by Hettangian shallow-water carbonates (Calcare Massiccio Fm.), constituting a regional carbonate platform that was subjected to tectonic extension due to rifting of the Adria/African Plate in the earliest Jurassic (Fig. 1). Rapid tectonic subsidence was the cause of platform drowning in hangingwall blocks, that is seen through a change to pelagic or pelagic/turbiditic sedimentation around the Hettangian/Sinemurian boundary (MARINO & SANTANTONIO, 2010; SANTANTONIO & CARMINATI, 2011). On the other hand, the final switch to pure pelagic condensed sedimentation on structural highs is interpreted as due to environmental stress in a post-rift regime, and is correlated with an event that left a geochemical signature in the middle Carixian across the Western Tethys (MORETTINI *et alii*, 2002). During the earliest phases of syndepositional faulting, the carbonate factories of footwall blocks were temporarily able to occupy a part of the accommodation space produced by the normal faults, prograding into the incipient basins. We report herein for the first time a low-angle clinoform bed package within the Calcare Massiccio, interpreted as documenting an ephemeral phase of lateral growth of the carbonate platform during these early rift phases. Due to continued tectonic subsidence along the normal fault bounding the local structural high, the clinoform slope facies was replaced by deeper water turbidites and pelagic deposits.

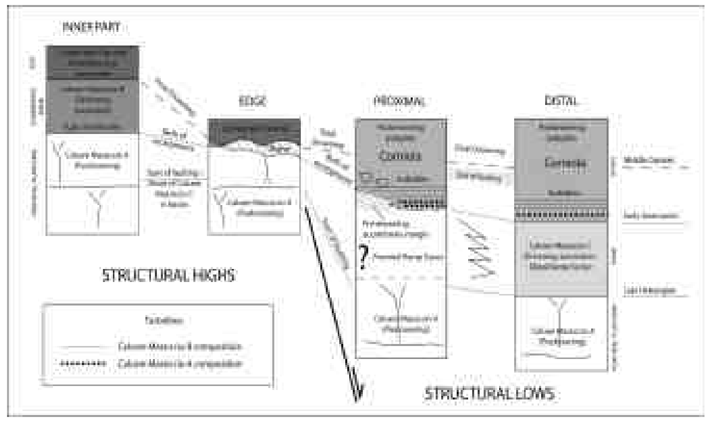

Fig.1 – Sedimentation and rifting in the Early Jurassic.

DATA AND DISCUSSION

Near Pioraco (MC), the Early Jurassic succession crops out at the core of the Mt. Primo anticline, deeply incised by the Potenza river; the river follows here the WSW-ENE trend of the Early Jurassic normal fault that separated the Mt. Primo structural high from the Mt. Gemmo basin. The studied interval (?latest Hettangian/earliest Sinemurian in age) represents the lowest part of the hangingwall-block succession, and is followed by a thick (> 0.7 km; FABBI, 2008) pelagic succession. The Pioraco section is ~60 m thick. The lower ~25 meters are made of thick beds of coarse skeletal grain/packstone, alternating with very thin fine peloidal packstone levels. This interval is topped by a thin peloidal packstone containing sponge spicules, and is followed by alternating thick clinoform bed packages and thinner clusters of thin tabular beds, ~20 m thick (Fig. 2). The thickness of each clinoform set exceeds 5 m. The thinner intervals are up to 2 m thick, and consist of 30-50 cm-thick beds made of micropeloidal wackestones. The clinoforms are largely composed by up to very coarse graintones (rarely rudstones). Above the youngest clinoform, bedding becomes dominantly tabular and chert makes its first appearance. The chert-bearing tabular beds are graded and form the upper ~15 m of the section with beds up to several decimetres thick.

THE CLINOFORMS

The incomplete nature of the outcrop makes it difficult to fully describe the Pioraco clinoforms along with the depositional system they were part of, as their updip continuation has been eroded away by the Potenza River and the area was subjected to

(*) Università degli Studi di Roma "La Sapienza"- Dipartimento di Scienze della Terra.

multiple phases of faulting.

In order to tackle the subject of clinoform dip, two assumptions must be made: 1) we take the thin inter-clinoform tabular beds as the best approximation to the paleohorizontal; 2) while bed attitude cannot be directly measured due to outcrop accessibility issues (*i.e.* our figures are technically apparent dips), we note that the natural cut revealing them has a ~N-S orientation, which should roughly correspond to the local dip of the slope when a platform-bounding paleofault striking ~E-W to WSW-ESE is considered. We therefore consider the observed dip (values corrected for the paleohorizontal) as being actually close to true dip. Also, any post-depositional bed-dip steepening due to differential compaction should be negligible here as our section must be underlain by downthrown Calcare Massiccio, and not by a buried paleoescarpment tract (CARMINATI & SANTANTONIO, 2005). In addition, the grain-supported nature of the slope sediment, coupled with common evidence for early lithification (*e.g*. syntaxial cements around echinoderm fragments), would have made them less prone to compaction. With this in mind, dip angles are seen to range from 5° to 8-10°, while the overlying turbidites would originally have had a nearly horizontal to very low-angle (<1°-2°) attitude.

The relatively low angle of our clinoforms might theoretically be compatible with an "oblique" (planar) slope, since what is observed is only the tip of the clinoforms downlapping the basin floor and KENTER (1990) mentions, from the Triassic platforms of the Dolomites, angles varying between 1.4 and 20° along the concave, lower one-third of slopes that dip 30-45° in their upper two-thirds. That said, however, an updip decrease in declivity is instead clearly observed with clinoforms of the second set (Fig. 2), and this is incompatible with a typical "oblique" high-relief slope, which typically represents, as in the Alpine Triassic, a mature stage. In our interpretation, the Pioraco clinoforms were part of a sigmoidal prograding wedge, and their geometries, notably general scale, updip continuation into sub-horizontal beds and slope height, are those of a low-relief slope in the shallow-water environment, as described by QUIQUEREZ & DROMART (2006). Although the field outcrop is only partial, out of the three clinoform shapes proposed by QUIQUEREZ & DROMART (2006), the "oblique" and "exponential" ("concave-upward" slope in ADAMS & SCHLAGER, 2000) types must be clearly ruled out. Within the remaining "sigmoidal" category, a "perfect" fit is found neither with the "symmetrical" nor the "asymmetrical" shapes, as they have a concave toe, while the Pioraco clinoforms show an abrupt downlap contact with the underlying bed. The reasons for a non-asymptotic toe might in our view be: 1) mud-poor nature of clinoform sediment; the angular unconformity is due to the angle of repose of grainy sediment; 2) we are seeing the lateral termination of a lobe-shaped bed so, partially in contrast with one of our assumptions above, the natural cut of the exposure is not subparallel to dip, and/or dip has a fan-like rotation across the exposure.

Our interpretation implies that the paleotopographic relief (=slope height) existing between the platform/ramp top and the basin had to correspond to the observed section thickness spanned by each sigmoid, that is a few (<5-7) meters. Also, hydrodynamics (*e.g.* storm waves), rather than gravity, would play a major role in determining the very existence and geometry of each individual clinoform, along with *in situ* carbonate production (QUIQUEREZ & DROMART, 2006).

An interpretation of the Pioraco clinoforms as shallow-water deposits implies that the slope had to be a carbonate factory. Their composition is very close to that of the typical pre-rift Calcare Massiccio, due to the relative abundance of tubular Cyanophyceae (*Cayeuxia* sp.) and *Thaumatoporella* (algae?). The very common occurrence to dominance of microproblematica like *Lithocodium-Bacinella* in the clinoforms (and in the turbidites, see below) however, is especially worth noting. The Pioraco occurrences suggest that *Lithocodium*/microbial communities promptly colonized the platform-break environment soon after its tectonics-induced birth. They conceivably had a role in stabilizing the bottom sediment, but also contributed intraclasts to be found in the lower slope sediments, as *per* our sampling stations. We speculate that their development could be directly related here to the severe environmental turmoil that occurred with early rifting. The flooding of downfaulted corridors by proto-oceanic waters, and the regionally diffuse switch from inner-platform to platform-edge conditions that must have taken place along the strike of rift faults dissecting the parent carbonate megabank, generated a wealth of brand-new ecologic niches over areas which, prior to this, constituted a vast lagoon/tidal flat complex. The proliferation of *Lithocodium* and allied forms might then have been fostered by the alteration of key physical/chemical environmental parameters linked with changed seawater circulation.

The clinoforms are interpreted as representing a phase of platform progradation, following the facies backstepping marked by deposition of the fine-grained tabular packstone, which represents here the downlap surface. This progradation occurred in discrete pulses, as the two observed clinoform bed bundles are separated by a thin set of finer-graned tabular beds similar to those found at their base. This punctuated pattern of accretion was the likely result of tectonic and/or sea-level control over sediment production and dispersal patterns across the depositional system, the former being the more probable candidate here in the light of the syn-faulting regime. Accommodation space for this lateral accretion of the Mt. Primo platform was provided by tectonic subsidence along a synsedimentary fault generating the Mt. Gemmo basin (CENTAMORE *et alii*, 1971) to the north. Our field mapping data indicate the paleofault had to be a mere couple hundred meters away from the clinoforms .

The moderate angles of the Pioraco clinoforms reflect the low relief initially existing between the platform top and the embryonic basin, when the basin-generating fault was still blind.

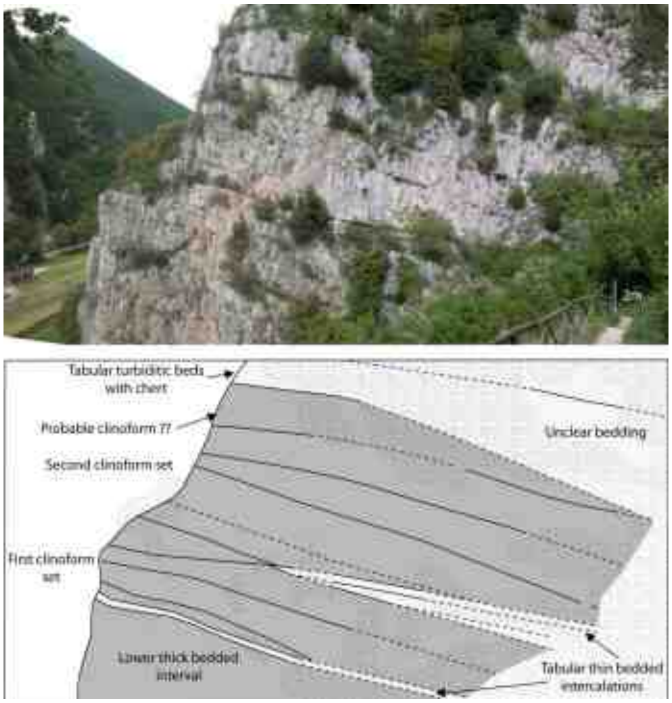

Fig. 2 – The Pioraco section.

The sudden change to turbidites suggests rapid deepening of the basin, due to fast tectonic subsidence of the hangingwall, exposure of the pre-rift substrate along a submarine paleoescarpment, and consequent halt of lateral accretion of the platform. The turbidite-rich bed package is interpreted as a bypass wedge changing laterally to typical pelagic Corniola facies. It is notable that the composition of the turbidites is very similar to that of the clinoforms, The main differences lie in the presence of lithoclasts of mud/wackestone with sponge spicules, and the appearance of calcareous sponges. This indicates that during the initial stages of basin deepening the structural high was still productive. Its later evolution would see development of a drowning succession in the late Sinemurian to early Carixian (Calcare Massiccio "B"), and eventually drowning in the middle Carixian, with onset of a condensed pelagic succession (MARINO & SANTANTONIO, 2010).

CONCLUSIONS

The Early Jurassic succession exposed at Pioraco (Marche, Northern Apennines) documents the earliest stage of platform/basin differentiation, which occurred across the Umbria-Marche region as a product of rift tectonics. The succession is interpreted as having been developed across the platform/embryonic basin transition zone during the initial phases of hangingwall subsidence along a synsedimentary normal fault. The clinoforms document ephemeral phases of platform progradation in an overall facies backstepping scenario. Lateral growth was initially favoured by healthy carbonate production, making use of the accommodation space generated by hangingwall subsidence. The tip of the last clinoform physically documents the termination of slope growth due to subsidence exceeding sedimentation rates, marking the change to turbidite-pelagic cherty limestone.

Middle-Upper Jurassic stratigraphic evolution of basinal carbonates of Eastern Sardinia (European passive margin)

JADOUL FLAVIO (*), CASELLATO CRISTINA EMANUELA (*), LANFRANCHI ALESSANDRO(**)

Key words: *Middle - Late Jurassic, nannofossil biostratigraphy, hardgrounds, Eastern Sardinia*.

Eastern Sardinia represents the southernmost part of Middle-Late Jurassic European passive margin, directly facing the Alpine Tethys (FOURCADE *et alii*,. 1993). Thus it may play a crucial role for (a) understanding the evolution of such passive margin and (b) correlate events between european and intra-Tethys carbonate platforms. To accomplish this, a refined biostratigraphic framework is required and new biostratigraphic analysis (calcareous nannofossils) has investigated emipelagic limestone from intraplatformal basins that were located north (Cala Gonone, Mt. Tuttavista, Mt. Albo, Casellato et al., submit,) and south (Baunei-Pedra Longa, JADOUL *et alii*, 2010) of a carbonate high (Urzulei, Cala di Luna).

In the northern basin (S'Adde Limestone, Fig.1) calcareous nannofossil are generally rare to few and poorly to moderately preserved. Nevertheless, few bioevents have been recognized and confirm that emipelagic sedimentation started in the Late Bathonian (DIENI & MASSARI 1966, 1985). At Mt. Albo (S'Adde valley), emipelagic sedimentation ceased in the Early Tithonian whilst at Mt. Tuttavista it continued up to the latest Tithonian. In the southern Orosei Gulf, emipelagic sedimentation started in the Late Callovian-Early Oxfordian age (lower Baunei Fm.), and continued up to the Early Tithonian (upper Baunei Fm., uppermost Tului Fm.) and locally up to Late Tithonian (Upper Pedralonga Fm., lowermost Bardia Fm.) (Fig.1) when prograding carbonate slopes reached the distal part of the southern basin (JADOUL *et alii*, 2010; LANFRANCHI *et alii*, 2011). Stratigraphic and facies analysis of the studied successions permit to distinguish three lithozone in the S'Adde Fm., two in the Baunei Fm. and to evidence a regional shallow ramp carbonate progradation (locally with reefal facies) during the latest Kimmeridgian-Early Tithonian and locally during the Oxfordian (Fig1). The Late Kimmeridgian basinal limestones everywhere are characterized by frequent black chert nodules.

This study points out that the Middle Jurassic succession shows different degrees of condensation (Fig1). In the northern Basin (M.te Albo, Siniscola, Posada) the first ooidal shoals (Dorgali Fm.) are capped by a condensed carbonate succession (a few decimetres up to ten metres) with marly-silty, quartz-rich litharenites, calcarenites interbedded with two Fe-hardgrounds of Late Bathonian-Late Callovian\Early Oxfordian age (DIENI & MASSARI, 1966; CASELLATO *et alii*, submitted). The hardgrounds are centimetre\decimetre thick, characterised by Fe-oxides/hydroxides, phosphatised crusts associated with lithoclasts, macrofossils (crinoids, belemnites, and ammonoids), Fe-ooids with quartz nucleus (original Fe-silicates ooids?), as well as skeletal grains of open marine benthonic and planktonic biota (i.e. *Globigerina* sp., *Bositra* sp., echinoids, lagenids). Low sedimentation rates are also registered in the Oxfordian portion of S'Adde Limestone (less than 10 metre thick) by faint carbonate bioturbated hardgrounds, pelagic oncoids (Massari & Dieni 1983).

In the southern Baunei-Jerzu basin Fe-hardgrounds occur in the same chronostratigraphic positions and also in the Early Tithonian\uppermost Kimmeridgian middle-outer ramp carbonates below the thin bedded basinal calcilutites of Pedralonga Fm. (Fig.1).

The regional distribution of Fe-P rich condensed succession at the base of the S'Adde succession (Mt. Tuttavista, Mt. Albo-Siniscola-Posada) along with (a) renewed terrigenous quartzose-feldspatic input from the Paleozoic basement, (b) local sharp lateral transition of the condensed lithofacies association and (c) a few east-dipping sedimentary dikes with pelagic internal sediments, reworked Fe-hardgrounds in the overlying pelagic carbonates (Siniscola), suggest a tectonic controlled sedimentation. A small scale tensional block faulting, active from the Late Bathonian until the early Oxfordian, controlled the development of a swell-to-basin system (half-graben).

The Middle Jurassic swell of Sardinia passive margin was characterized by a gentle slope and was likely located in the north-eastern part of Mt. Albo (present day N-S Siniscola-Posada alignment).The half-graben geometry of Eastern Sardinia basins favored Oxfordian to Early Tithonian progradation of shallow-water carbonates along hanging wall gentle slopes (Tului Fm. carbonate ramp depositional system, Fig.1).

The Eastern Sardinia passive margin evolution, in particular the condensations and starving phenomena during the Late Bathonian-Callovian and Oxfordian intervals display affinities with the South European margin, which is characterized by a

pronounced reduction of sediment production (Iberian carbonate platform, Portugal, Hungary) and mirror a serious restriction of the carbonate budget (JENKYNS *et alii*, 2002; WEISSERT & ERBA 2004), possibly due to sudden cooling, global sea-level fall (DROMART *et alii*, 2003), as well as climate changes (ABBINK *et alii*, 2001).

Stratigraphic setting of a segment from the Eastern margin of the Apennine platform (Monte di Viggiano, Southern Apennines)

LECHLER M. (*), FRIJIA G. (**), MUTTI M. (**), PALLADINO G. (*) & PROSSER G. (*)

ABSTRACT

In this study the carbonate succession of the Monte di Viggiano, situated about 30km South of Potenza (Southern Italy), has been investigated in detail for the first time. Three sections have been selected and a high resolution sampling was carried out. Integrated fabric and facies analyses supplemented with biostratigraphic observations have been used to evaluate the depositional environments and ages of the investigated deposits. Palaeontological assessment indicate a deposition within a subtropical inner shallow platform environment. This allow us to associate the limestones to the tectonic unit of Alburno-Cervati that represent the internal realm of the Apennine platform. Palaeontologic analyses give us a Late Liassic age for the lowermost section. The other two profiles show shallow-water limestones evolving from the Valanginian to the Early Cenomanian. This sedimentary record is, however, affected by frequent episodes of breccia sedimentation. At least four brecciation processes could be distinguished throughout this time span. The breccias originated probably from periodic emersion of some parts of the platform due to relative sea-level changes and were deposited in the close vicinity to where they were generated.

Miocene quartzarenites have been found for the first time on the Monte di Viggiano, unconformably lying over the Mesozoic deposits.

Key words*: Val d'Agri, Alburno-Cervati tectonic Unit, Paleogeography, Mesozoic shallow-water limestones.*

INTRODUCTION

The Southern Apennine chain is a complex fold- and thrust belt created from the Oligocene to the Early Pleistocene, after the inversion of the Mesozoic continental margin of Apulia. Different models tried to explain the paleogeography and the evolution of the mountain chain. Reconstructions and correlations of the paleogeographic elements are hampered by several difficulties as, for example, the definition, distinction of the depositional environments and the association to tectonic units of all of the outcropping deposits. Consequently, some areas are still poorly known and have been associated to tectonic units and depositional environments without detailed studies.

The Monte di Viggiano (Fig. 1) borders to the Northeast the Val d'Agri (Basilicata region). The mountain is made of Mesozoic subtropical carbonates, generally referred to the Apennine platform, but no detailed studies have been performed yet. Thus, its exact depositional setting and its association to a specific tectonic unit within the Southern Apennine belt is still unclear. Due to its external position within the mountain chain, BONARDI *et alii* (1988) interpreted the limestones of the Monte di Viggiano to have been deposited on the slope of the platform (Monti della Maddalena Unit). MENARDI NOGUERA & REA (2000), on the other hand, indicated that the rocks are subtropical shallow-water carbonates, deposited in an inner-platform realm (Alburno-Cervati Unit). In the 1:50 000 geological map of the Val d'Agri (CARBONE *et alii*, 1991) the limestones of the Monte di Viggiano are described as a continuous succession deposited during Mid-Late Liassic to Neocomian (Early Cretaceous). The upper part of the mountain is, according to the authors, composed of carbonates Hauterivian-Barremian, Aptian and dubiously Danian in age. Nevertheless, they do not link the deposits to any tectonic unit or a specific depositional environment.

Fig. 1 – Panoramic view of the uppermost part of the Monte di Viggiano. View towards NE.

This study aims to investigate in detail the Mesozoic platform carbonates of the Monte di Viggiano in order to define the depositional environment and to refer them to a specific tectonic unit. In the study area three sections have been sampled in extreme detail for facies and biostratigraphic analyses. The results of this study could act as reference for correlations of similar deposits in the area and may help to understand the paleogeography and the structural evolution of the Southern Apennines.

(**) Institut für Erd- und Umweltwissenschaften, Universität Potsdam.

RESULTS AND DISCUSSION

Due to the presence of striking faults and discontinuous outcrops we were forced to choose three continuous profiles at different elevations. They are all situated on the SW slope of the mountain. Identified from base to top: Scarrone la Macchia, La Laura, Il Monte.

The limestones of the Scarrone la Macchia section are 190 m thick. The rocks consist mainly of wackestone-packstones to grainstone textures. The amount of organic matter increases towards the top where they are replaced by a m-thick oolitic grainstones. Due to the fossil assemblage, especially the presence of *Palaeodasycladus mediterraneus* (Fig. 2C), *Pseudocyclammina liassica* and Lithiotis bivalves, the rocks of this section can be referred to the Liassic (Pliensbachian to Toarcian) and they were deposited in a subtropical shallow-water environment.

The deposits of the La Laura section are 141 m thick. Within the sequence, abundant breccia bodies containing angular clasts (Fig. 2A) are intercalated with wackestone-packstone and boundstone textures. The extent of the bodies is not always clear due to a general high degree of amalgamation. Occasionally, mudstones with fenestral structures (Fig. 2B) are capping the breccias passing upward to wackestone-packstone textures with *Protopeneroplis ultragranulata* (Fig. 2D), *Trocholina alpina*, *Palorbitolina sp.* and *Radiolitidae* rudists. This fossil assemblage infers a deposition from Valanginian to Late Aptian on a subtropical shallow-water carbonate platform.

The carbonates of the last profile, Il Monte, are 205 m thick. Like in the former section, the sequence, mainly made of wackestones-packstones to bioclastic grainstones, is embedded with several breccia bodies containing angular clasts (Fig. 2A) but with a reduced degree of amalgamation. The fossil assemblage of *Salpingoporella turgida*, *Mesorbitolina texana*, *Spiroloculina cf. cretacea*, *Orbitolinopsis cf. aquitanica*, *Conicorbitolina conica* (Fig. 2E) and rudists, suggests an age comprised between the Late Aptian to the Albian-Cenomanian boundary in a shoal-water setting of a subtropical carbonate platform. However, biostratigraphic data suggest that the sediments referring to the Albian are very thin if not absent.

In few spots quartzarenites cap unconformably the youngest shallow-water limestones. Nevertheless the deposits do not contain any fossils, they are the equivalent of the Numidian sandstones described in literature (PATACCA *et alii, 1992*) of Late Burdigalian age.

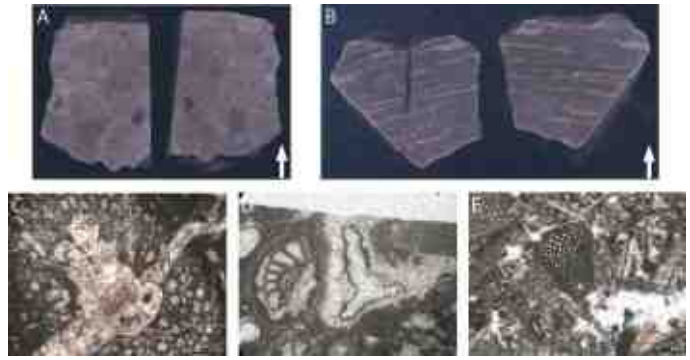

Fig. 2 – Typical facies and fossils of the Monte di Viggiano limestones. (A) Carbonate breccia containing angular clasts. (B) Mudstones with fenestral fabric. (C) *P. mediterraneus* of the profile Scarrone la Macchia. (D) *P. ultragranulata* of the section La Laura. (E) *C. conica* of the profile Il Monte.

CONCLUSIONS

The facies type and their fabrics in the studied profiles indicate an inner-platform depositional environment due to the widespread presence of dasyclads, benthic foraminifera and mudstones with fenestral structures. Moreover, no features related to a slope environment, such as slumping or planktonic foraminifera, have been observed. These considerations allow to refer the deposits cropping out in the area of the Monte di Viggiano to the Alburno Cervati Unit.

Coral-sponge-microencruster-microbialite associations in the Upper Jurassic reef: quantitative characterization of a case study from Eastern Sardinia (Italy)

RICCI C.*., JADOUL F.**, LANFRANCHI A.***, RUSCIADELLI G.*, DELLA PORTA G.**, LATHUILIÈRE B.****, BERRA F.**

Key words: *Upper Jurassic reef, Corals, Microbialite, Microencrusters, Sponge, Eastern Sardinia.*

INTRODUCTION

The Late Jurassic records one of the largest reefal expansions of the Phanerozoic, with major diffusion and differentiation in the Tethys realm (WOOD, 1999; KIESSLING, 2002; CECCA *et alii*, 2005). Several depositional and compositional models about Upper Jurassic reef types (see INSALACO *et alii*,1997; LEINFELDER *et alii*, 2002, 2005; RUSCIADELLI *et alii*, 2011 for a revision) have been published but little knowledge is available about the Eastern Sardinian reefs. This study focuses on the compositional and sedimentological characterization of the Upper Tithonian reef complex presently exposed in the area of Cala Gonone (Orosei Gulf) (Fig.1).

The Upper Jurassic carbonate succession of Eastern Sardinia consists of three Bathonian-Callovian to Berriasian (DIENI & MASSARI, 1985; JADOUL *et alii*, 2010 and references therein) carbonate depositional systems developed on the southern Europe passive margin (Fig.1): 1) the first (Dorgali Fm.) is characterized by ooidal grainstone, accumulated above wave base on structural highs (Variscan basement), capped by an Upper Bathonian-Callovian condensed succession with a few Fe-phosphatic hardgrounds; 2) a low-angle Oxfordian-upper Tithonian depositional system: the shallow ramp deposition (Tului Fm.) is characterized by basal oolitic facies overlain by prograding coral-stromatoporoid reefs, interfingering with outer ramp-basinal peloidal packstone-wackestone (S'Adde and Baunei Fms.); 3) the third depositional carbonate system (Bardia Fm.) developed after an Early Tithonian regressive trend, locally marked by carbonate breccias indicative of subaerial exposure. The lower part of the Bardia Fm. (upper Tithonian) is locally characterized by gentle slopes (3-15°) with bioclastic-coral-sponge facies associations (LANFRANCHI *et alii*, 2011). This progradational unit is followed by up to 400-500 m of back reef and inner platform shallow water carbonates.

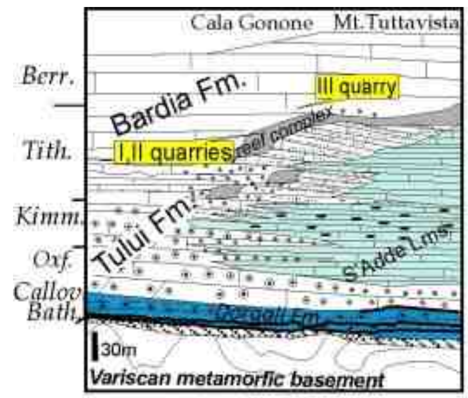

Fig.1 Stratigraphy of the studied Upper Jurassic carbonate succession.

REEF COMPONENTS AND FACIES

Compositional and sedimentological analysis of the Bardia reef has been carried out through the combination of "macroscopic" (outcrop-scale) and "microscopic" (microfacies-scale) observations on exceptionally exposed saw-cut quarry walls, over a surface of a few hundreds square metres in three different locations. The external surface of each macroscopically detectable component has been emphasized on the quarry walls (fig.2). The areal distribution of each portion has been stored as vector images, defining frequency, density and area occupied by the reef components. Microfacies and paleontological analyses have been performed on 280 thin sections.

Reef components were grouped into three broad categories: 1) macroscopically detectable organisms (mainly corals, sponges, bivalves, gastropods, echinoderms); 2) microscopically detectable components (microencrusters and microbialites); 3) fine- to coarse bioclastic debris and mud-supported facies. Corals show different degree of reworking, from in life-position skeletons more than 2.5 m^2 in size to centimetre-sized rubble. The 49 recognized genera of corals have been classified

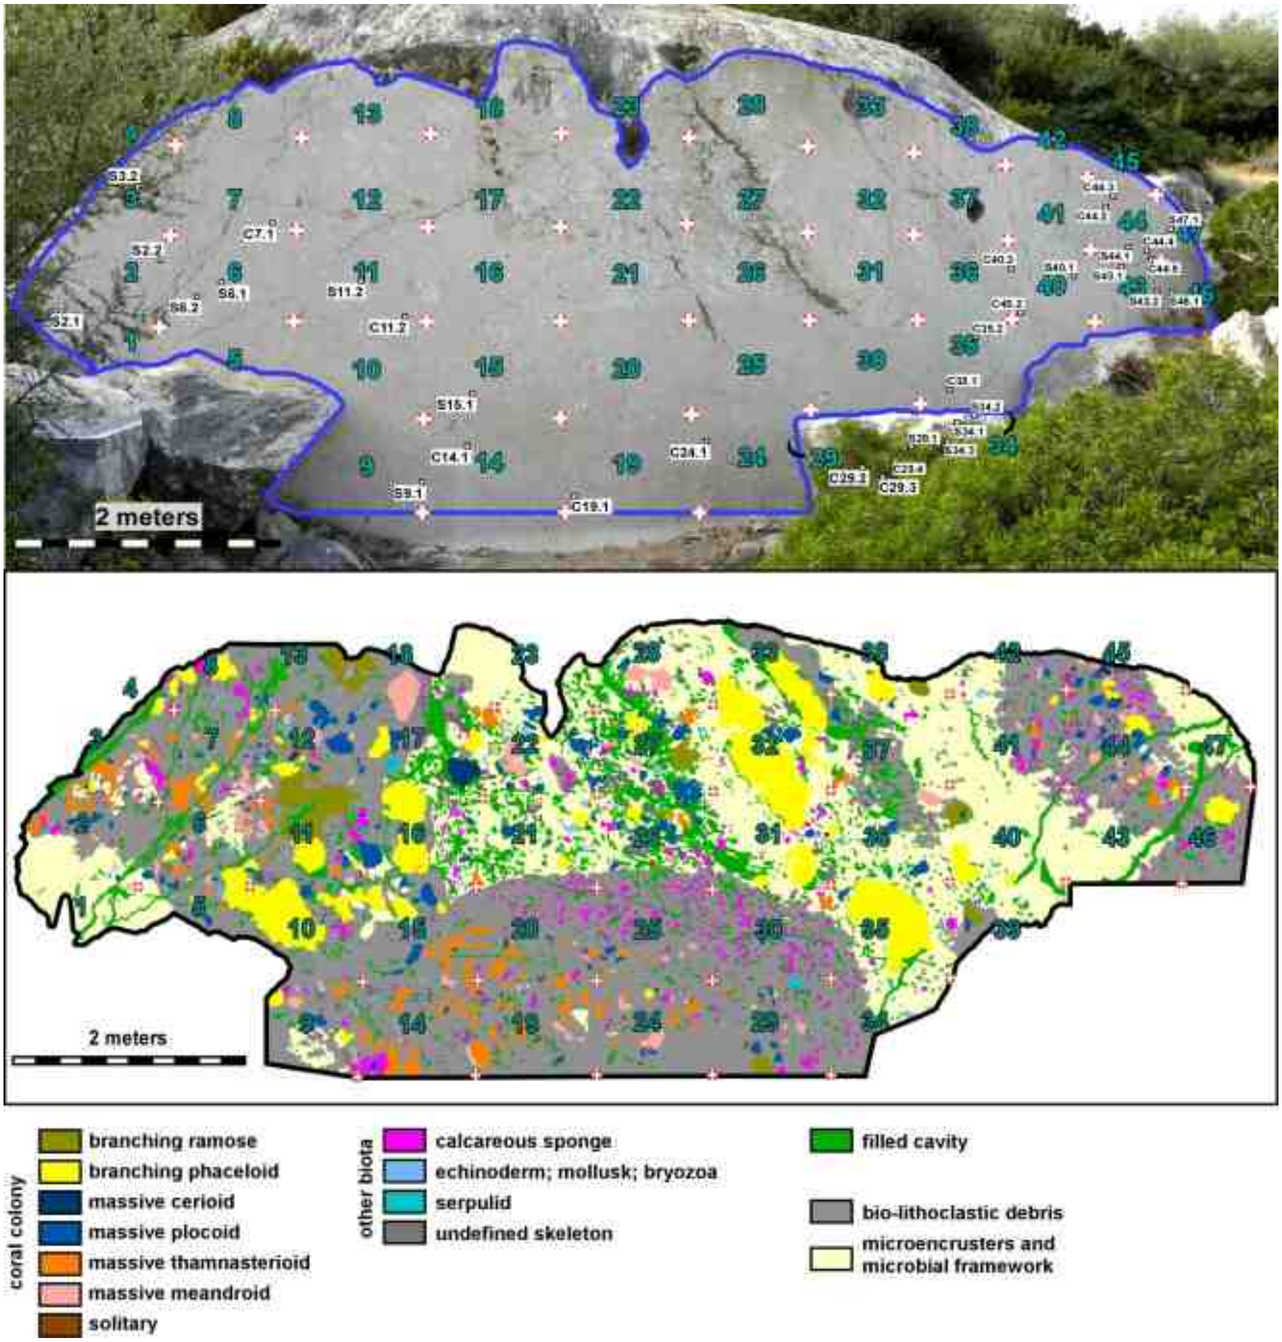

Fig. 2 – Example of studied quarries at Cala Gonone (Eastern Sardinia). Quarry 1. Outcrop condition and line-drawing of the macroscopically recognized reef components.

according to external morphology and corallite type.

Calcified sponges (Stromatoporoids) are a few centimetres to tens of centimetres in size, occurring as isolated specimens and in densely-packed assemblages. Siliceous sponges and spiculae are replaced respectively by precipitated automicrite and calcite spar. Microbialite and microencruster organisms form domal, columnar or irregular accretionary crust, few millimetres to several centimetres in thickness. Frequently, crusts bind neighbouring skeletons of large biota, developing metre-scale bioconstructions.

These components combine in various proportions within and among quarries, reflecting abrupt lateral and vertical changes of environmental conditions. Quarry 1 is characterized by large branched and massive coral colonies partially or totally encrusted by centimetre thick microencruster crusts and well-washed bioclastic facies, indicating sediment reworking in a high–energy environment. This facies abruptly passes laterally into a densely packed massive microsolenid coral and calcareous sponge assemblage and microbialite and microencruster (*Tubiphytes*. and other nubeculariids) boundstone. Microsolenid assemblages are commonly interpreted to have formed in deeper water (Lathulière & Gill, 1995; Gill *et alii*, 2004) or alternatively related to poorly illuminated shallow-water cave environments, and adapted to low-sedimentation, low-energy and nutrient-rich conditions (INSALACO, 1996; DUPRAZ & STRASSER, 2002). Quarry 2 is characterized by progressive vertical variations from facies dominated by densely packed platy and flat coral colonies (microsolenids and others) to facies dominated by calcareous sponges and loosely packed phaceloid coral colonies. Microbialite and microencrusters (*Tubiphytes* and other nubeculariids) envelope and bind large biota. Platy growth forms are generally interpreted as a response to poor illumination (INSALACO, 1996). Consequently the whole association seems to be compatible with poorly illuminated water, low sedimentation rate in a low energy environment. Quarry 3 records large scale bedding (from 1 m to several metres) defined by six intervals dominated respectively by 1) bivalves; 2) dasycladacean algae; 3) reworked massive thamnasterioid coral colonies; 4) thin phaceloid coral and calcareous sponges in growth position; 5) branched ramose coral colonies and calcareous sponges; 6) reworked massive plocoid coral colonies and gastropods. Large biota within intervals 3, 4 and 5 are largely encrusted by different microencrusters such as *Koskinobulina*, *Thaumatoporella*, light-dependent *Lithocodium-Bacinella*, and microbial accrectionary crust. Coral assemblages and microencruster association reveal a progressive increasing of the energy regime and sediment reworking in well-lit waters (INSALCO, 1996; SCHIMD & LEINFELDER, 2002), while the presence of bivalve, algae and gastropod floatstone represents the temporary shifting to "peri-reefal" environments.

Despite variability of facies associations in the three quarries, a paleoecological evolution from quarry 1 to quarry 3 emerges, reflecting the change from moderate energy environment with more protected, poorly illuminated cave environment (quarry 1), through a low energy, poorly illuminated environment characterized by low sedimentation rate (quarry 2), to a high energy, well illuminated environment, characterized by high sedimentation rate and reworking (quarry 3). The relative position of the studied quarries along an ideal depositional profile remains speculative, although a medium-scale progradational trend, from distal to proximal setting, seems to be compatible with the long-scale stratigraphic trend of the Bardia Fm.

Spectacular outcrop conditions, amount of data collected, biota taxonomic classifications and the observed stratigraphic evolution provide the solid base for paleo-biogeographical comparisons with other Upper Jurassic Tethyan reef complexes.

Mid-Cretaceous evolution of the Ernici Mountains carbonate successions (Latium-Abruzzi, Central Apennines)

MAURIZIO SIRNA (*) & HAMED HOOSHMAND KOOCHI (*)

Key words: *biostratigraphy, Central Apennines, Cretaceous, facies analysis.*

INTRODUCTION

The classic "greenhouse state", or even "hothouse" (KIDDER & WORSLEY, 2010, 2012) period of the Earth, is represented by the environmental conditions of the Cretaceous Period, with sea level rising, flooding about 1/3 of the continental area and creating extensive seaways. The Tethys closure produced small short-lived marginal sea basins and complex inter-ocean passageways. Emplacement of Large Igneous Provinces (LIPs) (LARSON, 1991; COFFIN & ELDHOLM, 1994) increased greenhouse gas concentrations and ocean fertility (SINTON & DUNCAN, 1997).

Different proxies have been used to decipher the Cretaceous conditions and palaeoclimatology. However, shallow-water carbonates have generally received little attention for biostratigraphical dating and are poorly understood with regard to palaeoenvironmental conditions; this is due to the stress conditions especially during the mid-Cretaceous and therefore, dominance of low-diversity and long-lasting, stress-resistance faunal assemblages. The shallow-water carbonates of the Ernici Mountains have been recorded an almost complete succession of the mid-Cretaceous and we have tried to review biostratigraphy contents of this succession in sake of using this framework for paleoenvironments reconstructing and defining the spans and borders of different stages of the mid-Cretaceous.

APTIAN

The early Aptian is strongly transgressive and the basal part is commonly condensed. It marks the commencement of almost continuous overall sea-level rise which continued into the Late Cenomanian. This period likewise recorded a remarkable climate perturbation as the Selli episode and development of organic-rich mud and shales usually in deep marine settings of the North Atlantic and Tethyan oceans (FÖLLMI, 2012). Shallow- water environments also underwent large changes and drowning facies developed on the northern Tethyan platforms (SKELTON & GILI, 2012). Benthic and planktonic foraminifera, rudists, calcareous nannoplankton, ammonites and belemnites experienced an extensive evolutionary change (CECCA, 1998; MUTTERLOSE, 1998; ERBA *et al.*, 2010; DI LUCIA, 2012; SKELTON & GILI, 2012).

In the Ernici Mountains, the Aptian interval lithologically consists of dark hazel-brown to grey well-bedded limestones alternate with upward-decreasing saccharoidal dolomites. Moreover, thin pelitic greenish intercalations are rare at the base and being almost constant to the top. The lower boundary is marked by diffusion of *Salpingoporella dinarica* in laminated mudstones and wackestones that alternate with thick levels of microcrystalline dolomites. The richest micropalaeontological assemblage of this part of the succession contains algae (*Salpingoporella dinarica*, *Thaumatoporella parvovesiculifera*) and benthic forams (*Praechrysalidina infracretacea*, *Cuneolina camposauri* and *C. laurentii*). Moreover, an intercalation of discontinuous green marly clay horizon rich in characeae and ostracods with smooth carapax ("2nd level with Charophyta and ostracods" of DEVOTO, 1967) marks this part of the succession. Generally, this remarkable clay level is always present in the Simbruini Mountains, in the north, and becomes thinner and finally disappears toward the south. *Salpingoporella dinarica* also could be found in this microfossiliferous assemblage, while Orbitolinae, whose diffusion horizon is coeval with these brackish episodes, are either rare or absent. In the Ernici Range, on the contrary, the thin clayey intercalations become more frequent and could be found in limy levels associated with *Salpingoporella dinarica*, rare characeae and high presence of Orbitolinae.

Above this interval, thin bedded mudstones and wackestones with many millimetric laminae that are often dolomitized are present. These limestones contain many benthic foraminifera among which *Archaeoalveolina reicheli* and *Dictyoconus algerianus*.

ALBIAN

The early Albian in evidenced by continuing environmental change and the Paquier episode of organic-rich shale deposition as one segment of OAE 1b in the Atlantic basin (FÖLLMI, 2012). The period during which the Paquier level was

(*) Dipartimento di Scienze Ambientali – Seconda Università di Napoli – Via Vivaldi, 43 – 81100 Caserta.

deposited has been interpreted as a warm, humid period, with considerable freshwater flow into the ocean, decreasing its surface salinity (WAGNER *et al.*, 2008). Facies changes along the northern Tethyan margin associated with the drowning unconformities indicate sea-level lowering during the earliest Albian (FÖLLMI, 2012). The Middle and Late Albian represents a time with a greenhouse climate meaning higher temperatures especially at middle and high latitudes and the absence of polar ice caps and the poleward expansion of rudist-dominated carbonate platforms.

In the terrigenous sediments of the northern hemisphere it is documented by northward migration of low-latitude, relatively arid flora. A shallow seaway between the South Atlantic and the western Tethys developed during the Late Albian. These basins received a large clastic input from the land, documenting the weathering conditions on the surrounding land masses. (FENNER, 2001).

In the Ernici Mountains, the Albian interval consists of dolostones with dark and fetid thin laminae and limestones with rare macrofossils towards the top of the interval. Before the appearance of Alveolinidae these intervals contain small requieniae and nerineae, embedded in the limestones, with a rich assemblage of algae and forams. *Orbitolinidae* are common in the foraminiferal assemblages. Furthermore, *Bacinella irregularis* (as out of balance and stress-determined facies – HUCK *et al.*, 2010) as well as rare Charophyta are present.

CENOMANIAN

The Cenomanian continued the period of overall sea-level rise and five progressively onlapping third-order sequences can be recognized across Europe (GALE, 2004). This period is characterized by two small black shale depositional events occurred in the middle Cenomanian and are known as middle Cenomanian events (MCE) 1a and 1b (GALE *et al.*, 2008). Sediments are characterized by relatively high total organic carbon (TOC) and minor faunal and floral turnovers. However, in case of planktic foraminifera and radiolaria the mid-Cenomanian turnover is considered high and is coincident with rapid sea-level fluctuations (PAUL *et al.*, 1994).

In the all Ernici Range Cenomanian is characterized by the widespread "Alveolinidae horizons" The first one is constituted by mudstones to grainstones, often reddened and containing centimetric intraclasts with various colors (yellow, pink, gray). The microfossiliferous assemblages of the first horizon are evidenced by the presence of *Sellialveolina viallii* (sometimes accompanied by *Ovalveolina maccagnoae*).

Above this interval, well-bedded grainstones and mudstones alternating with laminated dolomites and breccias, sometimes with rounded black clasts, are present. The microfaunal content records the presence of *Cisalveolina lehneri*, associated with other benthic forams like *Cuneolina pavonia parva* and *Pseudorhapydionina dubia*. The last "Alveolinidae horizon" consists of packstones and grainstones containing *Cisalveolina fraasi* with a rich benthic foraminiferal association among which most remarkable are *Chrysalidina gradate* and *Pseudolituonella reicheli*. *Cisalveolina fraasi* level is often represented by a thick rudist-rich bank of limestone (Requienidae and Radiolitidae with *Sauvagesia nicaisei*).

TURONIAN

The latest Cenomanian/early Turonian was the warmest interval of the past 200 million years (MILLER *et al.*, 2011) and is remarked by one of the profound climate perturbation as the OAE 2 that is associated with 1 – widespread burial of marine organic matter; 2 – carbon isotope excursion; 3 – marked drop in $^{87}Sr/^{86}Sr$ isotopic values that has been attributed to submarine volcanism (TURGEON & CREASER, 2008; SETON *et al.*, 2009) as well as; 4 – positive excursion of Nd isotope (MARTIN *et al.*, 2012).

Elevated rates of seafloor spreading and subduction are implicated by the volume, thickness, and extent of ash fall deposits (bentonites) through the Cenomanian/Turonian boundary interval in the Western Interior Sea of North America (KAUFFMAN & CALDWELL, 1993). Additional supporting evidence for increased hydrothermal activity comes from elevated levels of trace metals in marls and organic-rich mud rocks of the southern part of the Western Interior Sea as tropical water masses invaded the seaway with rising sea level (JONES & JENKYNS, 2001).

In the Ernici Mountains, *Cisalveolina fraasi* limestones are overlaid by light hazel to whitish and white limestones, poorly dolomitic interbeds and frequent greenish clayey thin intercalations. At various levels, brecciated horizons with sharp edge and black grains in a greenish dolomitic matrix are present. The limestones are including fine mudstones containing Miliolidae and Ostracoda (overall) and *Montcharmontia apenninica* toward the top. Rudists (*Durania arnaudi*, *Sauvagesia* cf. *sharpei*) levels that are often very rich in macrofossils are present at the top of these deposits, immediately below the *Accordiella conica* and *Rotorbinella scarsellai* limestones.

So the Aptian-Turonian carbonate successions of Ernici Mountains record the presence of episodes characterized by muddy lithofacies, often very dolomitized, containing poor and insignificant fossiliferous associations. On these deposits often rest coarser lithofacies with fossiliferous associations increasingly rich and differentiated. The first ones could be connected with stress events maybe correlated with the Oceanic Anoxic Events, well documented in mid-Cretaceous basinal areas, the last ones could mark the spreading of paleoenvironmental conditions favorable to the development of more and more blooming benthic communities.

Karstic overprint of Upper Triassic peritidal cycles: the example of the Panormide Carbonate Platform at San Vito lo Capo (Sicily)

SIMONA TODARO (*), GIUSEPPE ZARCONE (*), ANDREA MINDSZENTY (°) & PIETRO DI STEFANO (*)

Key words: *Triassic, carbonate platform, karstic dissolution, carbonate porosity, Sicily.*

INTRODUCTION

One of the aspects of present day and ancient karstic systems in platform carbonates is the extraordinary complexity of features such as caves and little cavities. These features are the results of multiphase dissolution events affecting shallow-water limestones in vadose, phreatic or marine-meteoric mixing zone environments and it is often difficult to establish the sequence of events that has controlled their formation (James et al. 1988, Back et al. 1986, Smart et al. 1988, Bacete et al. 2001).

This study presents a preliminary report on the wide range of paleokarstic dissolution patterns recorded by Triassic peritidal cycles in westernmost Sicily. Also the interpretation of these structures is attempted in the light of well known karstic carbonate platform morphologies.

GEOLOGICAL SETTING

The study area is located in the Custonaci "marble" district (westernmost Sicily) where a polychrome limestone known as "Libeccio Antico" was quarried extensively during the Baroque Age. The old quarries of this ornamental stone are concentrated along the northern slope of Monte Sparagio, an E-W striking ridge that represents a major structural unit of the Maghrebian fold and thrust belt in the southern part of the San Vito Lo Capo Peninsula (Fig.1). The Libeccio quarries are aligned along a narrow stratigraphic interval in the topmost zone of a thick Upper Triassic succession of peritidal carbonates, belonging to the Panormide Platform. The studied section is exposed along the walls of one of these quarries in Contrada Cocuccio.

The succession consists of about 450 m of thick and parallel bedded, whitish-grey, dolomitized limestones of Late Triassic age that can be ascribed to the Sciacca Formation.

.

Peritidal facies, namely megalodont limestones, stromatolitic limestones and green and reddish marls, are cyclically arranged along the succession. The uppermost beds of this succession can be assigned to the Rhaetian on the basis of the common occurrence of *Triasina hantkeni* MAJZON.

A discontinuity surface (paraconformity) overprinted by karstic dissolution, separates the Triassic strata from the overlying succession that consists of peritidal carbonates of Lower Jurassic age (Inici Formation). This change is marked by the disappearance of large Megalodonts, and of *Triasina hantkeni* and the appearance of rare *Aeolisaccus* sp. and valvulinids associated to *Thaumatoporella parvovesiculifera* (RAINERI).

KARST MORPHOLOGIES

The Upper Triassic succession shows an extensive development of dissolution cavities with a very variable shape and dimensions that are associated in places with collapse breccias. Several paleokarst micro- and macroporosity types can be identified:

a) Microkarst

Millimetre scale dissolution that suggests a slight meteoric influence has been observed particularly in loferitic limestones. This type of dissolution creates the enlargement of the fenestral porosity or micro-cavities filled by vadose silt and sparry calcite forming typical geopetal structures.

b) Moldic

The lagoonal facies of some cycles show the dissolution of megalodont shells. Moulds are filled up by radiaxial calcite and/or by reddish silt. Values of stable isotopes are indicative of seawater. The dissolution of aragonite shells and precipitation of low-Mg calcite is possible in areas occupied by seawater that is (or was) undersaturated with respect to aragonite but supersaturated with respect to calcite. This can be the response to a transient interaction with marine phreatic and meteoric vadose phreatic diagenetic fluids probably recording multiple episodes of sea level fluctuations.

c) Spongy-like

Concentrations of centimetre-scale irregular cavities are commonly observed in the lagoonal facies of the cycles, namely in Megalodont - *Triasina* wackestones and packstones. This type of dissolution pattern is well comparable to the "swiss cheese" or "spongy-like dissolution" of Smart et al., 1988a, and Bacete et al., 2001 and appears as a dense network of interconnected cavities, of about 3-5 cm in diameter, filled by calcite cements and reddish silt. In some of these cavities small crystals of dolomite occur. This network of cavities develops along extensive, bed-parallel, layers about 1 m thick (Fig. 2).

Fig. 2 – Megalodont and *Triasina* wackestone pervaded by spongy-like dissolution. The part below is filled by reddish silt while the part above by cements. Quarry A at Monte Sparagio, near Custonaci.

Fig. 3 – Coarse, collapse breccias that fills a decametre-sized cavern with a cylindrical shape. Among the elements are common angular fragments showing the sponge-like dissolution (arrow). Quarry A at Monte Sparagio, near Custonaci.

d) Cavern

This type of porosity consists of decametre-scale caverns that cut across the peritidal cycles. Their shape varies from more or less cylindrical to elongate, with an irregular roof. They are filled up by clast-supported collapse breccias constituted by heterometric, angular elements of megalodont- and stromatolitic limestones that clearly indicate their provenance from the host peritidal carbonates. The matrix between the clasts is reddish, greenish or, sometimes, yellowish silt that renders this material most appreciated for ornamental purposes. Additionally the presence in the collapse breccias of clasts with "spongy" porosity filled-up by calcite cements (Fig. 3) confirms that the cavernous porosity is related to a different (later) dissolution event.

e) Sinkhole

A decameter scale, v-shaped, cavity has been observed on the topmost zone of the Triassic succession. It is filled up by reddish, laminated silt with occasional angular clasts of peritidal limestones and silt-size dolomite (Fig. 4). This structure overlies a cylindrical cavity filled up by collapse breccias well comparable to the breccia pipes described by Choquette & James (1988).

DISCUSSION AND CONCLUSIONS

The presence of extensive karstic porosity in the studied carbonate platform is controlled by more or less prolonged subaerial exposures of the platform. The formation of microkarst can be related to low amplitude, high frequency sea level fluctuations of short duration and not to a long-lasting karstification (D'Argenio et al., 1997).

.

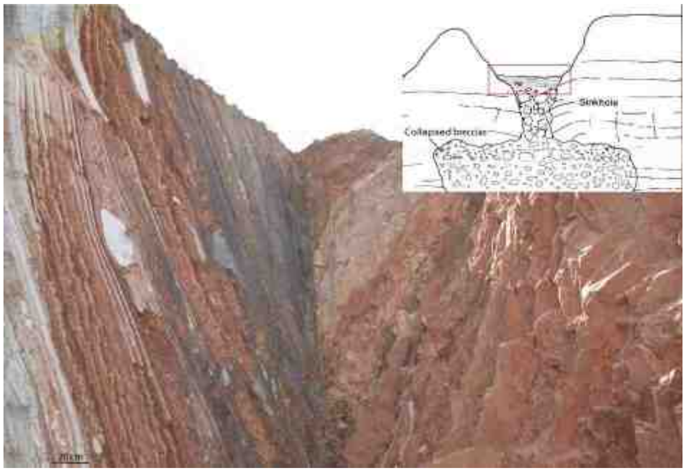

Fig. 4 – Laminated reddish silt as filling of a paleosinkhole on top of the Rhaetian peritidal cycles. Fragments of white limestones from the host rock are also present. Quarry A at Monte Sparagio, near Custonaci.

The origin of spongy-like cavities is interpreted as result of dissolution by especially corrosive waters in a phreatic-marine mixing zone (Back et al., 1986, Smart et al., 1988) as supported also by our preliminary isotopic data from radiaxial fibrous calcite cements. At San Vito the spongy-like dissolution levels are concentrated close to the Raethian/Hettangian boundary and are associated with peritidal cycles capped by particularly thick paleosoils. These features could reflect sea level fluctuations of longer duration and higher amplitude when compared to the underlying cycles.

The large caves and related collapse breccias were clearly controlled by a major sea level fall subsequent to the cycle-related sea-level oscillations and they are superimposed on the previous karstic features. Also in this case most of the dissolution is linked to the presence of corrosive mixed waters. That the collapse breccia-filled caves postdate the cycle-related karst episodes is supported by fragments, derived from the spongy dissolution horizons, occurring in the cave-fills (Fig. 3). The record in the Panormide Platform of a tectonically-enhanced high amplitude sea-level fall close to R/H boundary has been recently related to the effect of rifting in the Alpine Tethys (Zarcone & Di Stefano, 2010).

Depositional geometry and fabric types of hydrothermal travertine deposits (Albegna Valley, Tuscany, Italy)

BARILARO FEDERICA (*), DELLA PORTA GIOVANNA (*) & CAPEZZUOLI ENRICO (**)

Key words: *Albegna Valley, hydrotermal travertines, Tuscany.*

ABSTRACT

Travertines are continental calcium carbonate deposits precipitated by warm to hot water (from 20 up to 80 °C) supersaturated with calcium bicarbonate degassing CO2 while out-flowing from a tectonically controlled hydrothermal vent.

Several mechanisms of mineral precipitation have been proposed to explain travertine formation, and these vary from abiotic to biogenic processes.

The abiotic physicochemical control on mineral precipitation is driven by CO2 degassing and evaporation of water outflowing from the spring. Nevertheless, precipitation is not purely a consequence of physical degassing, due to the fact that calcium carbonate precipitation might be biologically influenced by the presence of microbial biofilms, common in such high temperature environments.

Travertine deposits are widespread in different geographic areas, in particular in the Mediterranean region. Hydrothermal-spring travertine deposition in Central Italy is considered mainly to be related to the magmatic and hydrothermal activity linked to the Plio-Pleistocene extensional tectonics developed during the opening of the Tyrrhenian Sea, following the Miocene Apennine thrust sheet belts propagation. Central Italy has extensive travertine accumulations all younger than 400 kyrs that include present-day deposits.

In the Neogene Albegna Basin, southern Tuscany (Central Italy), travertines are present in several deposits, distributed along faults and fractures. They are from about 20 m up to 700 m a.s.l and some deposits are still active.

The internal architecture of a fossil travertine body (Late Pleistocene-Holocene?) is well exposed within an active quarry located on the Manciano Sector of the Neogene Albegna Basin (Saturnia Travertine Quarry). The travertine deposit has an approximate maximum thickness of 40 m and it is laterally exposed for about 350 m.

Three decametre-scale travertine units of different ages (Unit I, II, III;) separated by two claystone beds were identified in the Saturnia Travertine Quarry; these units exhibit terraced slope, smooth slope and flat pond depositional environments.

Several carbonate fabrics at the centimetre-scale were distinguished on the outcrop. Petrographic analysis shows that travertines are essentially composed of a mixture of micrite, microsparite and sparite calcite crystals.

The wide range of travertine fabrics can be essentially distinguished into three categories:

1) Travertine Boundstone s.l. in which the original components are directly precipitated from hydrothermal water that includes: a) dendritic boundstone; b) crystalline crust dendritic boundstone; c) fine crystalline crust dendritic boundstone;d) laminated boundstone; e) raft boundstone; f) coated gas bubble boundstone; g) micrite/ microsparite boundstone.

2) Encrusting Travertine Boundstone s.l. in which original components (acting as substrate) are directly encrusted by carbonate precipitated by hydrothermal water that includes carbonate coated reeds (reed boundstone);

3) Carbonate grain packstone/grainstone to floatstone/rudstone formed by intraclasts of already lithified travertine precipitates and lithoclasts eventually associated also with skeletal fragments such as ostracodes and gastropods.

Pore space is an important component of travertine fabrics. Travertine fabrics show a wide range of depositional porosity (inter-dendritic form, channelled, non connected intra-bubble, inter-raft, inter-laminae, shelter, intraskeletal) and secondary porosity (biomoldic, vuggy meteoric dissolution, fractures). This porosity can be partially or totally occluded by a secondary cement (meteoric or related to a subsequent circulation of hydrothermal water).

Dissolution and aggradational neomorphism combined with cementation are the main diagenetic processes that can alter the fabric appearance. Cementation and aggradational neomorphism are in inverse proportion to the age of these travertines.

Petrographic and XRD diffraction analyses confirm that travertines are composed predominantly of calcite with minor amounts of aragonite (in raft boundstone fabric). Acicular to fibrous morphology of a significant amount of the calcite suggests that transformation of aragonite into calcite might have occurred.

(*) Dipartimento di Scienze della Terra "Ardito Desio"- Università degli Studi di Milano. Presenter e-mail: federica.barilaro@unimi.it

(**)Dipartimento di Scienze della Terra "Ardito Desio"- Università degli Studi di Siena

The large variety of growth fabrics reflects their origin (by interplay of biotic and abiotic processes), depositional environment (fast vs. slow flowing thermal water). A relationship. between fabric types and velocity/turbulence and discharged volumes of the flowing water is suggested. The travertine fabrics can be subdivided between those occurring in fast flowing water areas (crystalline crust and fine crystalline crust dendritic boundstone) and those precipitating in slow flowing water areas (dendritic boundstone, laminated boundstone; raft boundstone; coated gas bubble boundstone; micrite/ microsparite boundstone). In addition fabrics that occur in low energy areas might be more biologically influenced than fabrics occurring in fast flowing dipping surface for which the abiotic processes of physical degassing might prevail.

This study suggests also that an interplay between abiotic and biotic processes (biologically induced by microbial metabolic process or simply influenced by nucleation on microbial biofilm substrate) is involved in the precipitation of travertine. Many fabrics represent transitional forms of a continuum between the two end-members of purely abiogenic and microbially mediated precipitation.

Imaging of subsurface alluvial stratigraphy: an electro-stratigraphic traverse across the Po plain in Lombardy

RICCARDO BERSEZIO (*,**), MAURO MELE (*) & MAURO GIUDICI (*,°)

Key words: *Alluvial depositional systems, electro-stratigraphy, hydrostratigraphy, Lombardy, Po plain, VES-ERGI.*

FOREWORD

Alluvial depositional systems are relevant components of hydrostratigraphy of sedimentary basins. Hence, hydrogeological applications require comprehensive models of alluvial architecture, inclusive of 3-D images of the shape of the sedimentary bodies, of the hierarchic arrangement of depositional units and of the characterization of their internal heterogeneity. The geophysical imaging of subsurface stratigraphy is currently used to assist the procedure of hydrostratigraphic modeling. Owing to the exceeding cost of seismic exploration, the most common tools utilized at this purpose are geo-electrical methods (VES, ERGI), in combination with GPR, MASW, TDEM and rarely HRS. Specifically, VES (1-D resistivity soundings) and ERGI (2-D resistivity imaging) provide a cost-efficient tool for the elaboration of images of subsurface alluvial architecture.

During the last decade we refined a method to calibrate the VES-ERGI electrostratigraphic images to the traditional stratigraphic reconstructions based on correlation of borehole data, obtaining multidisciplinary, integrated stratigraphic-geophysical models of alluvial architecture (BERSEZIO *et alii*, 2007; MELE, 2008; MELE *et alii*, 2012) and introducing a modified concept of "electro-stratigraphic unit (EsU)". The application of this method to the study of the Quaternary Po plain alluvial fill allowed to ameliorate the resolution of the technique, to elaborate multi-scale integrated models and to collect a relevant amount of new data about the glacio-fluvial, alluvial and transitional depositional systems of the Po basin fill in Lombardy.

Here we present the first approach to the elaboration of a continuous electrostratigraphic image along a N-S traverse across the Po basin fill, N of the present-day Po river course (Fig. 1).

THE ELECTRO-STRATIGRAPHIC TRAVERSE

The Quaternary continental depositional systems of the Lombardy Po plain sit above the interference zone between the S-verging Southern Alps (North) and the N-verging Northern Apennines (South). The marine Upper Pliocene fine-grained

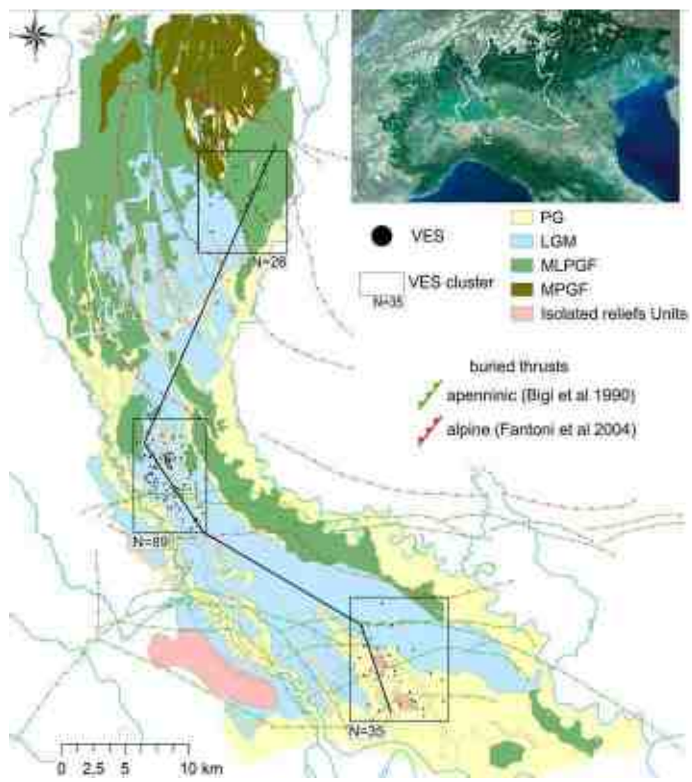

Fig. 1 – Data-set for the Po plain electro-stratigraphic traverse West of the Adda River, based on 150 VES data-points clustered into three type areas (N: number of VES for each area). Isolated Relief Units: undifferentiated Mio-Pleistocene sediments uplifted by Apennine ramp anticlines; MPGF: Middle p.p. Pleistocene Glacio-Fluvial to alluvial sediments; MLPGF: Middle p.p. - Late Pleistocene Glacio-Fluvial to alluvial sediments; LGM: Late Glacial Maximum sediments; PG: Post-Glacial to recent alluvial sediments. The three VES clusters are located into the satellite image.

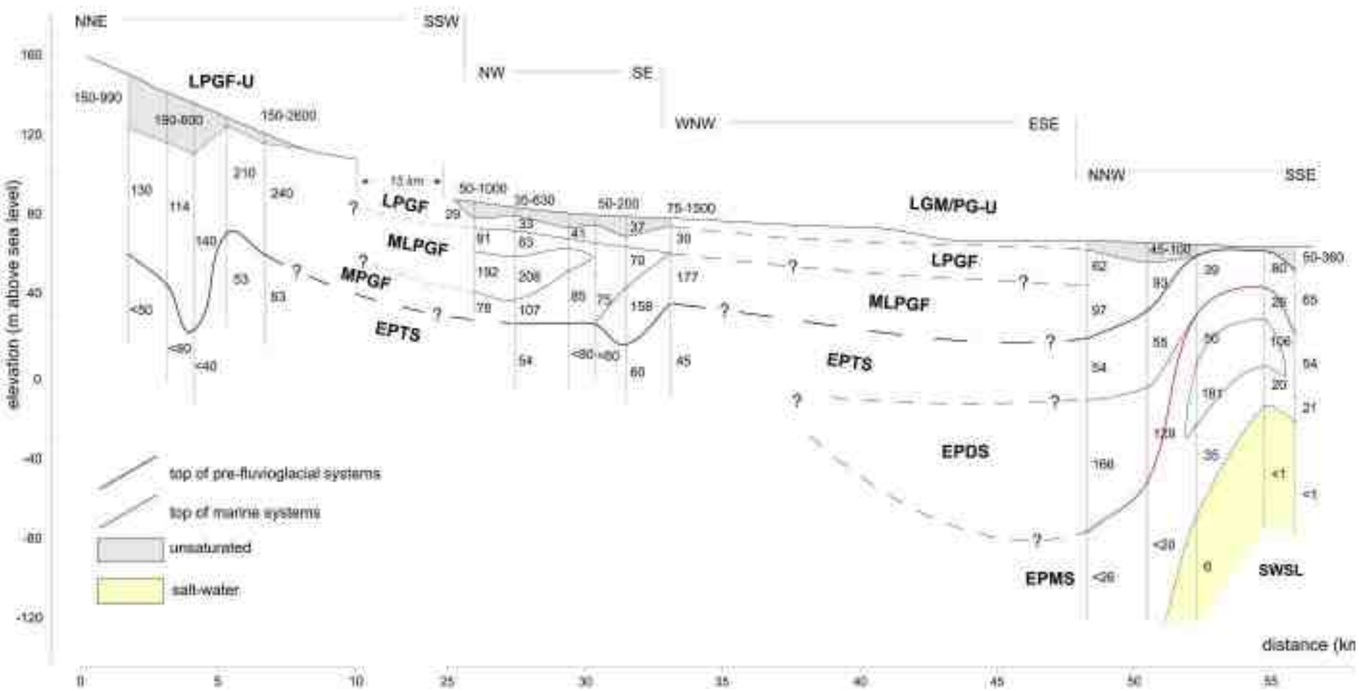

Fig. 2 – A simplified 2-D image of the electrostratigraphic traverse (location in Fig. 1). SWSL: salt-waterlogged sediments; EPMS: Early Pleistocene marine sediments; EPDS: Early Pleistocene deltaic systems; EPTS: Early Pleistocene transitional systems; MPGF: Middle p.p. Pleistocene glacio-fluvial systems; MLPGF: Middle p.p. – Late p.p. Pleistocene glacio-fluvial systems; LPGF: Late p.p. Pleistocene glacio-fluvial systems; LPGF-U: unsaturated Late p.p. Pleistocene glacio-fluvial systems; LGM/PG-U: unsaturated Late Glacial Maximum and Post-Glacial systems. Grey vertical lines identify the selected constraining VES data –points. Numbers refer to modeled electrical resistivity (Ωm). Note the high vertical exaggeration.

sediments of the Pedealpine Homocline (PIERI & GROPPI, 1982) are cut by deep incised valleys filled by pre- to syn-glacial alluvial (North) to deltaic and shallow marine units (South) of Early Pleistocene age; this stratigraphy is cut and covered by the terraced units of the glacio-fluvial sandur (Middle – Late Pleistocene) that correlate with alluvial plain depositional systems moving towards the Southern end of the traverse, close to the post-glacial to recent Po river valley (BINI, 1997; BAIO *et alii*, 2004; 2009; BERSEZIO *et alii*, 2004; BINI *et alii*, 2004).

During the Quaternary the depositional systems along the N-S traverse responded to: i) progradation and uplift of the buried Apennines' thrusts to the South, ii) consequent flexural uplift and faulting of the Southalpine crust to the North, iii) glacial advances and retreats to the North and consequent relative changes of local and regional base-levels and of location and elevation of the glacial mouths, iv) isostatic rebounds at the Southalpine side, v) glacial-interglacial climate, discharge and sediment input changes.

As a consequence of this evolution, the architecture of the alluvial depositional systems is expected to hold relevant textural and geometrical heterogeneities that can be detected and resolved by geo-electrical methods at different scales: i) the lower boundary between the Pleistocene alluvial and transitional depositional systems and the Plio-Pleistocene shallow marine shales; ii) the lens shape of the fining-upwards fills of the incised valleys (including conglomerates); iii) the coarsening upwards trend of the Middle – Late Pleistocene coarse-grained Northern sandur systems, iv) the regional Southward-fining trend along the Pleistocene depositional systems; v) the contrast between the Northern and Southern sectors of the traverse (amalgamated gravel-sand sandur and braided river systems vs. interfingered coarse-grained and fine-grained alluvial plain and fluvial systems); vi) the contrasts between fining, coarsening and stationary genetic units that build the different depositional systems.

At present the traverse consists of three clusters of 150 VES data-points (Fig.1). The clusters allow for 3-D imaging of the subsurface of three key-sectors of the Lombardy plain: 1) the Northern hinge between the uplifted Pleistocene sandur and the Southern alluvial depositional systems, 2) the central area where the transition between braided and terraced alluvial plain systems occurs and 3) the Southern area where uplift of the Apennine thrusts conditioned deposition of both the alluvial systems fed from the North and the axial alluvial system (Middle – Late Pleistocene "Po" system). Fig. 2 shows a simplified 2-D image of the traverse, based on the 3-D imaging of the three areas and constrained to selected VES data-points.

RESULTS

The electro-stratigraphic architecture has been obtained defining the electro-stratigraphic units (EsU) as volumes of sediments characterized by: i) a specific mode of electrical conduction (electrolytic vs. "shale"), ii) contrasting electrical resistivity with respect to the surrounding volumes, iii) a polarity of this contrast that is preserved along the boundary (i.e. conductive vs. resistive or vice-versa). These features make the concept of EsU comparable to the concept of "stratigraphic unit" (either litho- or allo-stratigraphic or genetic units)

Calibration to borehole and water-well stratigraphic logs was used to validate the electro-stratigraphic architecture, accounting for the most influent litho-textural factors: i) Coarse-grained/Fine-grained sediments ratio (C/F), ii) thickness distribution of the litho-textural associations, iii) water saturation, iv) water salinity.

In extreme summary, the simplified traverse of Fig. 2 shows the top boundary of the lowermost marine shales, that is cut to the North by the alluvial incised valley fills. The same surface depicts a gently S-wards dipping monocline that is folded and uplifted by the Apennine structures at the Southern end of the traverse. In the central VES cluster, the transition from the amalgamated gravels and sands of the terraced sandur and braided river depositonal systems to the clay-rich alluvial plain and fluvial meandering systems is shown. The prograding-retrograding Middle – Late Pleistocene large-scale cycle is clearly depicted along the traverse, in the sector North of the southernmost VES cluster. In this southernmost sector the syn-depositional growth of the Apennine structures is portrayed by the shape of the involved electro-stratigraphic units, as well as by the onlap and seal features of the Late Pleistocene post-tectonic fluvial systems.

The 3-D images obtained for each VES cluster, assisted by ERGI surveys, permitted to draw several local images of the depositional systems that are by far more detailed than the very generalized traverse here presented, showing that different kinds of genetic units, nested within the high order stratigraphic units, can be recognized by this method. Hence, from a general point of view, we can state that electro-stratigraphic surveys can provide multi-scale images of the alluvial subsurface, that can be interpreted in terms of: i) large-scale and high-order stratigraphic trends and cycles; ii) regional vs. local tectono-sedimentary features; iii) transitions among different depositional systems; iv) low-rank genetic units within the depositional systems.

The Holocene infill of the Adwa Valley (Tigray, Northern Ethiopia): preliminary results

BIANCHI V. (*), BILLI P. (°), CORNAMUSINI G. (**), FEDI M. (§), GHINASSI M. (*), IELPI A. (**), SANDRELLI F. (**)

Key words: *East Africa, Holocene, climatic changes, landscape degradation, aridification, valley-fill.*

INTRODUCTION

In East Africa, well-documented Holocene climatic changes have a demonstrated effect on landscape modification (COHEN *et alii*, 1997; BENVENUTI *et alii*, 2002; DRAMIS *et alii*, 2003), mainly as alternation between landscape aggradation and degradation (MACHADO *et alii*, 1998). Nevertheless, the strict correlation between these repeated fluctuations and Holocene climate are currently a matter of discussion (MAYEWSKI *et alii*, 2004, GASSE, 2000), which aims at unravel the effects of climate variability on different environments. The morphologic stability of alluvial areas surrounding lakes is strictly related to the lacustrine level and erosion is expected to take place during lake retreat following the onset of arid conditions. By contrast, the nature of landscape degradation drivers in areas unrelated to a lacustrine base level is still controversial though it appears related to a dynamic equilibrium between the rate of vegetation growth/depletion (soil protection factor) and the increasing vs. decreasing rainfall, i.e. runoff, trends (soil erosion factor). In the Tigray region (Northern Ethiopian Highlands) Holocene land degradation and soil erosion are well-documented (BRANCACCIO *et alii*, 1998) and stem out from a strict interaction between soil protection and soil erosion factors (DRAMIS *et alii*, 2003).The present study focuses on the Holocene alluvial, valley-fill deposits exposed in the Adwa surroundings (*Tigrai* region) and aims at investigating the effects of climatic changes on landscape aggradation.

GEOLOGICAL AND GEOMORPHOLOGICAL SETTING

In the Adwa area, located about 30 km East of Aksum, a widespread precambrian basement complex comprising low-grade metamorphic rocks (MOHR, 1962) is overlain unconformably by detrital rocks of Permo-Triassic age (Adigrat group). This succession is overlapped by Tertiary basalt flows (Trap series) which present, together with the Adigrat Group deposits, a subhorizontal structure. The most important geological event for the geomorphic evolution of the area was the rifting and uplift which involved the Horn of Africa since the Oligocene. Many geomorphological features are the result of erosional processes induced by uplifting of the Ethiopia Plateau. The general physiography of the area consists of few scattered hills with steep to subvertical slopes standing on a high plain cut by small ephemeral streams. Climate is characterized by interannual variability of rain ranging from 600 to 800 mm/yr. The main. Seasonal contrasts in precipitation correspond to the annual fluctuation of the Intertropical Convergence Zone (ITCZ) over the Horn of Africa. The main rainy season is middle June through September and it follows an unpredictable small rain from mid March to mid May. Mean annual temperature is around 18 C° with low seasonal variability but great diurnal range.

THE ADWA SUCCESSION

The study succession is exposed in natural outcrops forming the flanks of two main gullies located about 2 km NE from Adwa. This succession is about 10 m thick and is divided into four main unconformity bounded units (AD1, AD2, AD3 and AD4), which can bear internal minor unconformities. Unit AD1 is scarcely exposed and is made of two sub units (labeled as AD1a and AD1b) separated by a minor erosional surface. Sub unit AD1a consists of a blackish vertisol, whereas sub-unit AD1b is made of reddish, well-stratified alluvial gravels. Unit AD2 is up to 4 thick and consists of a basal gravelly interval grading upward into sandy to muddy deposits. The basal gravels are channelized and well-stratified, and contain abundant blackis mudclasts. The upper sandy to muddy deposits are affected by pedogenic processes and bear a well-developed soil at the top. Unit AD3 consists of two sub-units (AD3a and AD3b) separated by a minor erosional surface. Sub-unit AD3a is up to 1 m thick and is clearly nested within deep incisions. These deposits consist of massive to poorly stratified silty sand. Sud-unit AD3b is up to 1.5 m thick and fills the same depressions hosting sub-unit AD3a. This sub-unit is made of cross-stratified, oxidized sand and subordinate massive silt. Unit AD4 is made of sub-units AD4a and AD4b, and covers a sub-horizontal erosive surface. Sub-units AD4a and AD4b consist of horizontal bedded gravel and sand and are 2.5 and 1 m thick respectively. Preliminary data (radiocarbon datings) suggest units AD2 and AD3 were accumulated about 6000 and 4000 yrs BP respectively, when the East Africa was affected by important phases of aridification (MAYEWSKI *et alii*, 2004; MACHADO *et alii*, 1998; GASSE, 2000). Although a more detailed chronological framework is required, such a preliminary model would suggest that aridification promoted sediment storage in vallive segments, probably because of a significant increase in slope-fed sediment due to decrease in soil protection factors (i.e. vegetation depletion). If such a model will be validated by forthcoming investigations, it will be able to highlight how these alluvial systems are out of phase with respect those surrounding lakes, where aggradation is expected to take place during lake rises following the onset of humid conditions.

The Plio-Pleistocene fluvial deposits of the Ambra valley (Tuscany, Italy): an example of tectonically-controlled valley fill succession

BIANCHI V. (*), GHINASSI M. (*), ALDINUCCI M. (°), BOAGA J. (*), DEIANA R. (*)

Key words: *non-marine valley-fill, epeirogenic movements, Northern Appennines, alluvial sedimentation.*

INTRODUCTION

Most of the incised-valleys preserved in the stratigraphic record have been cut and filled in response to downstream relative sea/lake-level changes. Nevertheless, few Authors highlight the importance of tectonic and climatic upstream control on valley-fill aggradation (SHANLEY AND MCCABE, 1994; HOLBROOK, 2001; BLUM AND TORNQVIST, 2000) beyond the influence of relative sea-level. In a fluvial realm decoupled from marine or lacustrine influence, the occurrence of sin-sedimentary tectonic warping can control erosion or aggradation, with associated modification of fluvial patterns and development of heterogeneous valley-fill architectures. The effects of sin-sedimentary tectonic warping are known in a modern setting (SCHUMM, 1986) or laboratory experiments (OUCHI, 1985), whereas study cases from fossil record are almost missing.

The present study focuses on a fluvial, valley-fill succession (Ambra River valley) exposed along the Northern margin of the Chianti Mounts (Northern Apennines) and aims at defining the effects of sin-sedimentary tectonic warping on the aggradation of a valley-fill succession in an alluvial realm which was not influenced by marine or lacustrine oscillations.

GEOLOGICAL SETTING

The Plio-Pleistocene deposits of the Ambra River valley, located across the Chianti Ridge (Central Tuscany, Italy). This ridge separates the Siena and Upper Valdarno Basin, two tectonic depressions belonging to the external sector of an articulated basin complex that characterizes the Northern Apennines hinterland and resulted from the post-orogenic collapse of an over-thickened orogen (Martini and Sagri, 1993). The paleo-valley trends almost N-S and developed across the modern watershed between the Siena and the Valdarno Basin. The valley was cut both on pre-neogene bedrock (northern valley reach) and Pliocene marine to transitional deposits of the Siena Basin (southern valley reach) as consequence of a Middle Pliocene regional forced regression (ALDINUCCI *et alii*, 2007). Paleo-transport was from N to S. The valley fill represents a striking example of a fluvial valley-fill uninfluenced by relative sea-level changes (ALDINUCCI *et alii*, 2007). It consists of two main intervals separated by an erosive surface. The upper interval is cut in the lower one in the northern and southern part of the study area, whereas they are offset in the central part. The lower interval is almost 40 m thick, consists mainly of gravelly deposits and has been the focus of previous studies (ALDINUCCI *et alii*, 2007), which emphasized the role of tectonic and climate in controlling accumulation of the alluvial deposits. The upper interval, which is the focus of the present study, is about 35 m thick and deposited across a sin-sedimentary normal fault. This lineament, NW-SE trending (i.e. almost transverse to the valley axis) dips toward NE (i.e. upstream) and is still affected by intense CO_2 emissions (BROGI *et alii*, 2002).

RESULTS

The upper valley-fill interval can be divided into two segments, located downvalley and upvalley of the normal fault respectively.

The deposits forming the downvalley segment are relatively well-exposed and consist of cross- to plane-parallel stratified gravels with subordinate sands. These deposits are commonly organized into form set (2-4 m thick) of large scale inclined beds, as also highlighted by GPR (Ground Penetrating Radar) images. These deposits are interpreted as channel bars developed in a gravel-bed river setting.

The correlative deposits forming the upvalley segment are poorly exposed and have been mainly analyzed through integration of ERT (Electrical Resistivity Tomography) lines and well-core data. These deposits consist of organic-rich mud containing isolated, erosive-based sand bodies (2-4 m thick), which are interpreted as the active infill of fluvial channels.

DISCUSSIONS AND CONCLUSIONS

The significant change in fluvial facies across the fault zone highlights a sin-depositional activity of the normal fault. This is also in agreement with the occurrence of tectonic deformations in the gravels forming the lower valley-fill interval. The fault activity is thought to be the main cause of the SE shift of the

(°)Weatherford Petroleum Consultants AS, 5147 Bergen, Norway

valley axis, which produced the offset of lower and upper valley-fill deposits in the central part of the study area. In particular, the change in fluvial transport capability recorded by the studied deposits across the fault area is thought to represent the response of the river systems to tectonic movements. Specifically, tectonic upwarping caused a decrease in transport capability in the upstream reaches of the paleovalley, manifested by the aggradation of poorly-drained floodplain deposits. In contrast, a significant increase in bedload grain-size and fine-sediment bypass is recorded by the gravelly rivers downstream of the upwarping area, where aggradation was promoted by the increase in sediment supply from the erosion of the uplifted area.

The present case of study highlights the role of tectonic movements on aggradation of valley-fill succession in areas which are commonly decoupled from the influence of marine or lacustrine oscillations.

Palaeoenvironmental and vegetational changes from the Pleistocene lacustrine sediments of the Trasimeno area (Central Italy): evidences from palynofacies and pollen analysis

BURATTI N. (*), BARCHI M. R. (*), BERTINI A. (°), CIRILLI S. (*), GASPERINI L. (^), MARCHEGIANO M. (*), & PAZZAGLIA F. (*)

Key words: *paleoenvironment, paleoclimate, palynofacies, pollen analysis, Pleistocene, Trasimeno.*

The aim of this study was to reconstruct vegetation changes within the Trasimeno lake catchment area and to identify the relative contributions of the different sources of organic debris delivered to the lacustrine sediments.

Sediments are the product of lake life and can be regarded as a bank of information about environmental changes occurring in both the water body and in the catchment area (DE VICENTE *et alii*, 2006). The primary source of organic matter to lake sediments is mainly from the particulate detritus of plants, degraded to various degrees, and deriving from both autochthonous and allochthonous sources (MEYERS & LALLIER-VERGÈS, 1999). As the plant life in and around lakes change, the composition and amount of organic matter delivered to lake sediments changes.

In the frame of a multidisciplinary project, aimed to reconstruct the palaeoenvironmental and paleoclimatic evolution of Trasimeno lake during the Pleistocene, one core (175 m long) was drilled along the south-eastern coast of the lake, by the Regione Umbria Geological Survey. Optical examination of palynofacies, coupled with a preliminary pollen analysis was performed. Although a careful interpretation of the results will require a comparison with sedimentology, complete pollen record and a well-constrained sediment chronology, some reliable conclusions can be achieved.

The Trasimeno lake (Umbria, Central Italy) is a meso-eutrophic, shallow (<6 m deep) lake with a large extension (~120 km^2), characterized by a water balance strongly affected by the pluviometric regime (DRAGONI, 2004). As is common in shallow-water ecosystems, climate change plays a fundamental role in their evolution and functioning. Today the hydrological, thermal and hydrochemical regime of Trasimeno lake are deeply influenced by climatic variations (LUDOVISI & GAINO, 2010). Most of the organic production originates from the macrophyte community, which mainly consists of submerged plants, distributed from the shore to the center of the lake and subordinately of semi-emerged plants, growing around the lake.

The lake is located between two extensional basins, the Valdichiana to the west and the Valtiberina to the east. Its onset probably started in the Early Pleistocene, as evolution of a lateral branch of the Valdichiana basin. Seismic reflection data (GASPERINI *et alii*, 2010) show below the lake floor almost 600 m of sediments overlying a deeply eroded Miocene bedrock.

The geological data of the surrounding area (BARCHI & MARRONI, 2007; ARUTA *et alii*, 2004) and the lithology of the core suggest an Early Pliocene deposition of marine clays and sands in the Valdichiana basin and a Pleistocene deposition of (fluvio?)-lacustrine clays and sandy clays in the Trasimeno basin.

Quantitative analysis of organic constituents was carried out in Trasimeno sediments, within a palynologically productive interval, comprised between 15 m and 30 m. Palynofacies types were identified on the basis of visual evaluation of the relative abundances of organic constituents and then integrated by cluster analysis, in order to test group consistency.

Three main palynofacies assemblages (A, B, C) and three sub-assemblages (A1, B1, C1) were recognized. Palynofacies A was dominated by poorly preserved woody remains, partially degraded in aerobic conditions (soil) before deposition, associated with relatively abundant translucent, well preserved woody remains, still maintaining tracheidal structure and cuticles. The rest of the palynofacies was composed by highly diversified pollen assemblages, gelified debris, accessory fungal remains, and framboidal pyrite. Much of the organic matter characteristic of palynofacies A was represented by fluvially or wind transported allochthonous remains. The relative abundance and good preservation of this material, which comprises numerous centimeter-size plant remains, imply short transport distances. The organic matter would thus originate from higher plants that grew within the basin or in its immediate vicinity, as testified by the great sporomorphs diversity in palynological residues.

Palynofacies B has a transitional nature between A and C. It was characterized by an analogous contribution from both allochthonous and authocthonous organic debris. As in palynofacies A, very low amount of amorphous organic matter revealed a good oxygenation of the depositional environment.

Palynofacies C was almost completely composed of gelified debris, relatively abundant framboidal pyrite and amorphous organic matter. This palynofacies was dominated by an

Lavoro eseguito nell'ambito del progetto "Ricostruzione paleoambientale e paleoclimatica del Lago Trasimeno", in collaborazione con il Servizio Geologico e Sismico della Regione Umbria e il CNR-ISMAR di Bologna.

authocthonous organic fraction, produced in the lake itself. Gelified material could represent the result of submerged and semi-emerged macrophyte degradation within the water column (SIFFEDINE *et alii*, 1995; MARTÍN-CLOSAS *et alii*, 2005). Low percentages of the allochthonous fraction could suggest a reduced plant cover and /or a very low land supply. The occurrence of dark brown, amorphous organic flakes and framboidal pyrite suggested reducing conditions in the depositional environment.

Data obtained from the study of sedimentary organic matter will be integrated by organic geochemistry analysis (TOC, $\delta^{13}C$, $\delta^{15}N$, C/N), providing additional valuable information on organic matter sources and paleoproductivity.

Pollen analysis revealed a vegetation landscape considerably different from the present one, for the presence of a number of taxa today extinct in Europe (e.g. *Carya*, *Pterocarya*, *Tsuga*), living in North America and Asia (BERTINI, 2003, 2010; MAGRI, 2010).

An interglacial cycle marked by the presence of a mixed-oak forest (mainly deciduous *Quercus*, *Ulmus*/*Zelkova*, *Carpinus*, *Corylus* and *Fagus*) followed by Juglandaceae (*Carya*, *Pterocarya* and *Juglans*) and then by conifers (*P. diploxylon*-type, *Cedrus*, *Abies*, *Picea*, *Tsuga*, and Cupressaceae) has been detected in the central portion of the succession. At its base the end of a glacial is testified by the pollen of grasses and other herbs. At its top an interglacial/glacial transition as well as the start of a new glacial phase are expressed by the increase respectively of altitudinal coniferous taxa and *Artemisia*, Poaceae and Chenopodiaceae typical taxa of steppe phases.

Such pollen record is significant to discuss the stratigraphical position of this part of the Trasimeno core (from 19 m to 21,5 m) in absence of chronological constrains. In fact the peculiar floral composition as well as the evaluation of the relative percentages of each pollen taxon (e.g. presence of *Carya*, *Pterocarya*, *Tsuga* and *Cedrus*; absence of *Taxodium* type, *Liquidambar*) permit to attempt a correlation with the Glacial/interglacial cycles within the Early/ Middle Pleistocene transition.

Pollen analyses though still in progress seem to represent a valuable starting point for biostratigraphic correlations with other Italian palynological records (starting from the geographically closer ones) and for adding new information about the distribution and disappearance of the “exotic” elements in Central Italy during the Early-Middle Pleistocene.

Preliminary observations on continental carbonate clasts in alluvial/volcanoclastic deposits (Pleistocene, Venosa Basin, southern Italy)

C. CARUSO (*), P. GIANNANDREA (**) & E. PERRI (*)

Key words: *alluvial and volcanic Quaternary deposits, continental carbonates, rhizolith, Melfi Synthem, southern Italy, Venosa Basin.*

GEOLOGICAL SETTING AND STRATIGRAPHY

The fluvial-lacustrine middle Pleistocene in age succession of the Venosa basin (southern Italy), represents the sedimentary filling of a palaeovalley, within the Pliocene-Pleistocene foredeep deposits of the Bradanic Trough, located between the Vulture volcano and the Murge massif (Apulian foreland) (Fig. 1). The sedimentary-stratigraphic variations of the foredeep deposits are related to the Pliocene to Pleistocene tectonic evolution of the chain front, and to the Apulian platform subsidence. In fact, the Apulian platform, in the studied area, is affected by a lithospheric transfer fault (Vulture Fault; SCHIATTARELLA *et alii*, 2005), which, during the Middle Pleistocene, produced the tectonic uplift of the area between Monte Vulture and the Murge, and caused the magma ascent through the Vulture volcano (SCHIATTARELLA *et alii*, 2005). In this framework, strike-slip faults systems, oriented N110° ± 5°, N130°, and east-west, have driven the formation of the hydrographic pattern of the Venosa Basin, including the Venosa River, (GIANNANDREA, 2009): firstly with the formation of alluvial terraces, and later with the deposition of the Venosa sedimentary succession, of about 35-80 m thick, that consists of volcanic sediments, deposited in alluvial, and secondarily lacustrine, environments. Subordinately, primary volcanic beds, due to pyroclastic flows and fall from the Vulture volcano, are also present.
Stratigraphic discontinuities, angular unconformities, and thick paleosols, divide the epiclastic succession into three units which are the Foggianello, Barile and Melfi Synthems (687±8 ka - 530±22 ka), belonging to the volcanic succession of the Vulture Mount area (GIANNANDREA *et alii*, 2006; GIANNANDREA, 2009).
Near Masseria della Mezzana Locality (Fig. 2) an alluvial succession, referring to the Barile Synthem, crops out; it is composed of decimetric ash and lapilli beds, cross and horizontal stratified, with intercalation of massive ash beds and three layers

(**) Dipartimento di Scienze Geologiche, Università degli Studi della Basilicata, Potenza. paolo.giannandrea@unibas.it

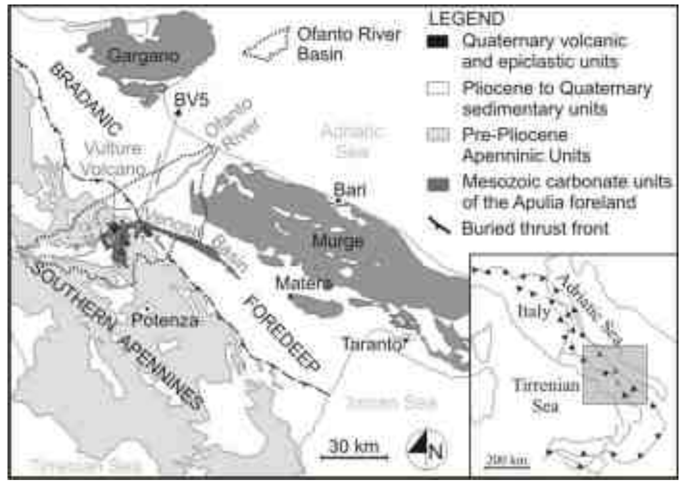

Fig. 1 – Geological sketch map of the southern Apennines, and location of log BV5.

of pumice fall. A low maturity paleosol, 1.18 cm thick, overlies this deposits, followed by 2.30 m of fall pumices, massive ash and lapilli deposits (attributed to the Melfi Synthem by GIANNANDREA, 2009) at the top of which the studied carbonate clasts were discovered. These clasts are randomly dispersed into decimetric beds, composed of massive or graded detrital medium-coarse ash, with or without lapilli (debris flows) (Fig. 3A).
The sequence ends at the top with a thick paleosol, with carbonate crusts at the bottom.

CARBONATE CLASTS TEXTURE AND POSSIBLE ORIGIN

The carbonate clasts are found as separate, isolated and non-branched elements, arranged randomly in three stratigraphic layers at the top of the studied succession (Fig. 3A). The shape is irregular, even if sub-cylindrical forms are common. Some elements are straight, with smooth outer edge, while others are weakly curved and having slight protuberances on the outer edge. An axial hole is present in almost all samples (Fig. 3B).
The dimensions are variable: elements of a few millimeters in width and length, associated with others of about 1 cm in width and 3 cm in length, have been found in the same stratigraphic interval.
The colour of these carbonate clasts is roughly similar to the sediment around, in particular, by means of the Munsell Tables,

Fig. 2 – Field view of the Masseria della Mezzana stratigraphic section, and Log (BV5) with the position of carbonate clasts (*).

the following values are been distinguished: 2.5Y 6/3; 2.5Y 7/2; 2.5Y 7/3; 7.5YR 4/6.

Thin section observations (Fig. 3 C-D) show that the most common petrographic components of these carbonate clasts are micrite (anhedral mostly opaque crystals <5 µm diameter) and minor microspar (subhedral to euhedral clear crystals between 5 and 15 µm) with spar or pseudospar (euhedral clear crystals >15 µm). Micrite and microspar are often associated with four types of fabric: peloidal to aphanitic, laminar and dendrolitic. The peloidal fabric consists of anhedral brown micrite crystals that constitute aggregates of 20 to 30 µm in size with sub-rounded to irregular shapes. Rarely, these micritic aggregates are surrounded by an isopachous rim of microspar. The peloidal fabric locally passes to a more homogeneous texture (aphanitic micritic fabric). Laminar fabric mainly consists of the same brown micrite organized into thin, even to crinkly laminae, 8 to 10 µm thick, forming layers up to *ca* 40 µm, alternating with microsparitic laminae of similar thickness. Dendrolitic fabric is seen as broadly filamentous, in some cases branching micrite and/or microsparite.

Sparry calcite can occur in layers composed of isolated to coalescent fan-shaped crystals forming, respectively, botryoids of 100 to 150 µm in size or continuous crusts *ca* 100 µm thick. These crusts frequently form multi-layer structures alternating with thin laminae of brown micrite, generating a laminar fabric. Laminae can also originate by the alternation of several types of fabric.

Sub-millimetre carbonate crusts seem grow around organic substrates, possibly woods, leaves or roots, inferred from the shape of the axial voids that rarely contain relicts of probably mineralized plant tissues

These carbonate clasts could originate through two bio-mediated mechanisms: 1) these tubular elements grew around living plant roots; in this case they are rhizoliths, thus trace fossils; the specific type could be defined "root tubules" which are cemented cylinders, or "rhizocretions *s.s.*", which are pedodiagenetic mineral accumulations (KLAPPA, 1980). The rhizoliths may have multilayer arrangement of isodiametric carbonate cements (KLAPPA, 1980; HASIOTIS, 2002). Furthermore, the fact that the root systems of plants are constituted by roots of a diameter gradually lower, fits with the variable in size assemblage of the rhizoliths in the deposits. The ichnoassemblage is composed by fragmentary or incomplete elements, which seem to be eroded, so presumably they were transported. This is one of the rare examples in which trace fossils are not *in situ*.

A diverse origin of these carbonate clasts could be related to the microbial-mediated precipitation of carbonate crusts around not-living plants remains (leaves, woods, *etc*.) - because of the developing of a biofilm - similarly to tufa/travertine deposits near a water spring or along a river. The microfacies assemblage of our clasts results very similar to that seen in modern tufa deposits (cf. MANZO *et al*. 2012). Moreover, the clasts, which are probably autochthonous in origin, were eroded and included in the alluvial sediments; and/or they can be even allochthonous in origin in the form of pisoids, as these grains are common in those sedimentary environments.

Late Carboniferous to Permian volcano-sedimentary successions in SW Sardinia: a sedimentological, mineralogical and petrographical review

LUCA G. COSTAMAGNA (*), GABRIELE CRUCIANI (*) & MARCELLO FRANCESCHELLI (*)

Key words: *Carboniferous, Permian, red beds, limnic successions, petrography, sedimentology, SW Sardinia.*

INTRODUCTION

The post-Variscan Late Carboniferous to Permian successions outcropping in SW Sardinia were reviewed for sedimentological purposes and then sampled in detail for petrographic and geochemical analysis. The investigated outcrops are Tuppa Niedda (Arburese), San Giorgio (Iglesiente) and Guardia Pisano (Sulcis) (Fig. 1).
Generally the Sardinian Variscan molassic succession (CASSINIS & RONCHI, 2002) may be split in two parts, separated by the Saxonian unconformity: that is roughly located between the Carboniferous/Permian boundary and the Early Permian. The parts are: a dark grey to blackish lower part, built of limnic deposits; and a purplish upper part, made up by red bed deposits.

DESCRIPTION AND INTERPRETATION OF THE INVESTIGATED SUCCESSIONS

The Upper Carboniferous Tuppa Niedda outcrop (Fig. 1, 2) (BARCA et al., 1994; COSTAMAGNA & BARCA, 2008) is 14 m thick. It pertains to the limnic successions and is made of immature conglomerates and rare sandstones. The conglomerates are polygenic and made of rounded pebbles and cobbles from the metamorphic basement. The sandstones are litharenites. A significant microflora level has been found. The succession is built by debris- passing to stream flows and it has been referred to an alluvial fan environment.
The Upper Carboniferous San Giorgio succession (fig. 1, 2) (COCOZZA, 1966; BARCA & COSTAMAGNA, 2003) is 45 m thick. It is a limnic succession made of terrigenous coarse cobbly to sandy immature deposits with minor alternations of locally bioturbated carbonate sediments connected with times of scarce or no terrigenous input. The conglomerates are polygenic and made of rounded pebbles and cobbles from the metamorphic basement. The petrographic analysis of the sandstones allowed to classify them as litharenites and rare sublitharenites: rarely calclitites have been found. Micro- and macroflora are abundant in scattered levels of the succession (DEL RIO, 1973). At the base of the succession also tetrapod footprints (FONDI, 1979) has been found. The depositional environment can be ascribed to prograding to retrograding alluvial fan lobes built by stream and debris- flows interdigitated with low-energy lacustrine-palustrine environments in which microbial mats and organic matter may accumulate.

Fig. 1 – Localization of the investigated outcrops.

The Guardia Pisano succession (PITTAU *et al.,* 2002; BARCA & COSTAMAGNA, 2006) (fig. 1, 2) is formed by 10 meters of limnic succession aged Late Carboniferous to Early Permian (297±5 Ma, radiometric age) (Fig. 4) followed unconformably (Saxonian unconformity) by nearly 100 m of Permian red bed sandstones (Fig. 5). The lower limnic succession is made of alternation of siltites, fine sandstones, sandstones, epiclastics, pyroclastics and autoclastic lavas. Scattered limestone layers are present. The sandstones are litharenites and very rare arkoses. A rich micro- and macrofora level has been found. The depositional environment has been referred to a lacustrine-palustrine context with wandering channels and interested by tectono-magmatic

(*) Dipartimento di scienze Chimiche e Geologiche, Via Trentino 51, 9127 Cagliari (Italy) – lucakost@unica.it, gcrucian@unica.it, francmar@unica.it

Lavoro eseguito con fondi 60% (L.G. Costamagna, M. Franceschelli)

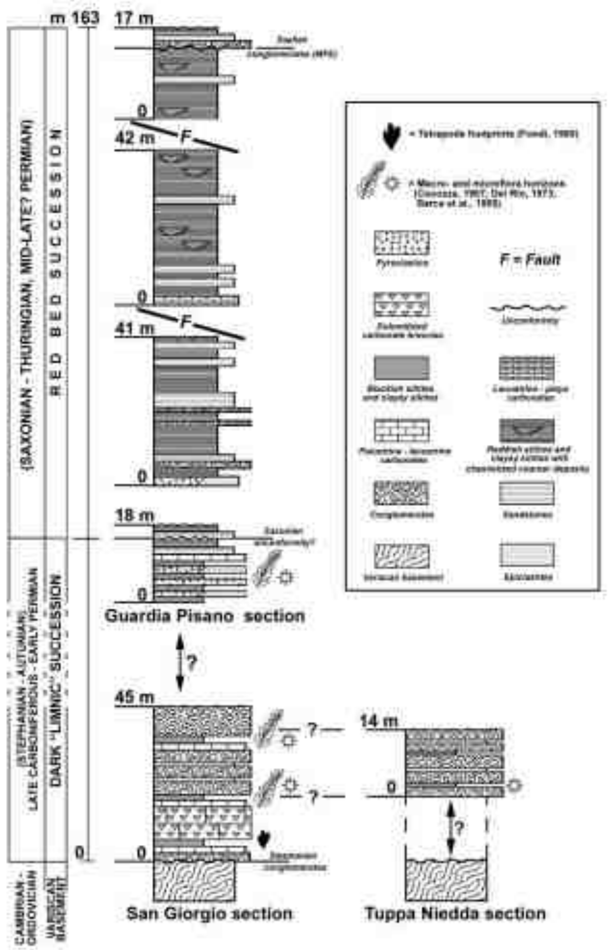

Fig. 2 – Stratigraphic columns of the investigated outcrops.

activity under an hot-humid climate. The upper red bed succession starts with reddish pelites frequently containing tree trunks of decimetric size. It is made of alternations of siltitic clays, siltites, fine sandstones, sandstones and minor conglomerates. Also here rare limestone beds may be observed. The conglomerates are polygenic and made of subangular to subrounded pebbles from the metamorphic basement and from the Permian volcanics: those latter tends to vanish upwards. The petrographic analysis of the sandstones allowed to classify them as litharenites and minor subarkoses: arkoses are rare. Scarce volcanic products (tuffs) and epiclastics crops out close to the base of this red bed succession. The coarser depositional bodies are lens-shaped. Stream flow are dominant. Calcretes are present as interalations in the finer laminated deposits. Rare bioturbation may be observed here and there. At the top of the red bed succession another unconformity, marked by coarse conglomerates and perhaps related to the Saalian phase (tectono-magmatic Middle Permian Episode: DEROIN & BONIN, 2003), has been evidenced. In those conglomerates the volcanic clasts reappear again. The depositional environment can be supposed to be a sub(?)arid alluvial plain crossed by an ephemeral fluvial network with seasonal features: permanent channel were rare.

The volcanic products change their serial affinities passing from the limnic to the red bed succession: they are initially rhyolithes-riodacites passing upwards to andesites.

The pelitic rocks of the limnic succession consist of quartz, K-feldspar, calcite, dolomite and phyllosilicates. The phyllosilicates, identified by X-ray diffractometric analyses, are kaolinite, illite, smectite and interstratified illite-smectite. The arkoses consist of quartz, K-keldspar, abundant phyllosilicates, in particular biotite. In the arkoses from the red bed succession the mica and K-feldspar content strongly decreases. The pelitic and siltitic rocks of the red bed succession consist of the same minerals in different modal proportions. They are characterized by high amount of hematite and sporadic occurrence of plagioclase. Worthy of note is the lower K-feldspar content and the lack of smectite and interstratified illite-smectite in the Upper Unit. Chemical analysis on some selected sandstone and pelite samples yielded the following composition: Sandstones SiO_2 = 28-78 wt%; Al_2O_3 = 5-20 wt%, Fe_2O_3tot = 1-5 wt%, Na_2O = 0.04-0.75 wt%, K_2O = 0.75-3.3 wt%; Pelites SiO_2 = 57-72 wt%; Al_2O_3 = 10-20 wt%, Fe_2O_3tot = 1-6 wt %, Na_2O = 0.1-0.3 wt%, K_2O =1.5-2.7 wt%.

So, also the chemical and mineralogical data suggest a progressive drying of the Guardia Pisano succession depositional environment from bottom to top.

Presently, elaborations of the geochemical data are in progress to evidence the geotectonic signature of the sandstone deposits.

Alluvial, aeolian and tidal deposits in the Triassic Buntsandstein of NW Sardinia (Italy)

LUCA G. COSTAMAGNA (*)

Key words: *Wadi systems, Aeolian system Tidal flat, Buntsandstein, Trassic, NW Sardinia.*

INTRODUCTION

In NW Sardinia, investigations of the Lower(?)-early Middle Triassic Verrucano Sardo Fm of the "Buntsandstein" Group evidenced that this unit was deposed in rapidly evolving variable continental to transitional-shallow marine environments under a prevalently arid to sub-arid climate. The Verrucano Sardo Fm is composed of two lithofacies separated by an erosive surface that is probably referable to a ravinement. The lower Conglomerato del Porticciolo Lithofacies may be mainly referred to a wadi braided system with limited aeolian sediments close to the coastline. The wadi system passes upwards to a narrow sandy aeolian coastal system with frequent ephemeral marine ingressions reworking the aeolian deposits. The upper Arenarie di Cala Viola Lithofacies represents the start of the Triassic marine transgression, advancing over mainly aeolian deposits through a progressively flooded tidal flat with an increasing degree of energy; the tidal cycle is repeated twice before the transition to the Muschelkalk carbonate shelf. The early tidal influence on this "Buntsandstein", which is different from other similar contexts of the European mainland, may be due to the Sardinia location, posed during Early to Middle Triassic times close to the developing Western Neo-Tethys European margin. Affinities with some coeval European successions are also briefly discussed.

PALEOENVIRONMENTS OF THE VERRUCANO SARDO FM

The Verrucano Sardo Fm was deposited in an arid to sub-arid environment, passing rapidly from a wadi system with subordinated aeolian deposits to a coastal

aeolian low-dune field that was ultimately transgressed by a tidal flat. Limited and ephemeral tidal influences (due to spring-tide incursions) may have been present from the very start.

The wadi system was formed by ephemeral channels featured by a braided pattern of thin gravel bars due to a flashy discharge (lower interval of the Conglomerato del Porticciolo Lithofacies); in times of limited or no alluvial deposition, the bars were partially reworked at the top by aeolian processes, thus developing deflation lags and desert pavement, as well as a limited cover of aeolian sandstones. The aeolian sandstones increase upwards, suggesting the taking over of the aeolian processes and the development of a small low-dune field located in between the wadi system and the transitional-marine environment; this may rarely transgress early and ephemerally over the dune field, leaving behind rare tidal structures (sandy layers with tidal cross-bedding, reactivation surfaces, neap-spring cycles: upper interval of the Conglomerato del Porticciolo Lithofacies). The ephemeral, flashy stream regime and the unchannelized character of the flows may be linked to the Early Triassic arid to semi-arid climate with hard storm events. The prevalence of rounded pebbles suggests reworking due to a long period of transport. Although massive events may be present, tractional stream flow deposits dominate.

For the upper interval of the "Conglomerato del Porticciolo" succession, a fluvial meandering environment has also been proposed (GHINASSI *et al.*, 2009). Nonetheless, this hardly fits in with the mainly bipolar current trend revealed by the sedimentary structures. Moreover, the Triassic dominant arid to semi-arid climate does not usually support a meandering fluvial pattern. Finally, the total absence of pelites is difficult to explain in terms of such a pattern.

The Arenarie di Cala Viola Lithofacies, which was laid down over an erosive (ravinement?) surface, marks a marine ingression. The absence of any weathering connected with this surface points to a very brief, or no, depositional hiatus. Accordingly, a transgressive tidal environment developed, as evidenced by the growing energy related to the passage from the inner muddy to the outer sandy tidal flat. The tidal cycle is duplicated, possibly due to a minor drop in sea level, and is terminated by tidal bar carbonate sandstones that pass suddenly upwards to cavernous carbonates, suggesting a restricted, shallow carbonate shelf environment.

A terminal fan environment (CASSINIS *et al.*, 2003; DURAND, 2006), or even meandering channels (GHINASSI *et al.*, 2009), have previously been suggested for this lithofacies, but this is in contrast with the tidal evidence observed (e.g. paleocurrent bipolarity) and the coarsening-upwards trend of the succession that is typical of tidal transgressive conditions. Conversely, the terminal fan model is characterized by an overall fining-upwards succession, also developing in the meandering channel pattern.

(*) Dipartimento di scienze Chimiche e Geologiche, Via Trentino 51, 9127 Cagliari (Italy) – lucakost@unica.it,

Lavoro eseguito con fondi 60% (L.G. Costamagna)

Based on the previous paleogeographic reconstructions (SCIUNNACH, 2001), the tidal ebb-flow (oriented southwards) prevails all along the Verrucano Sardo Fm.
Overall, the Monte Santa Giusta, Cala Viola-Torre del Porticciolo and Cala Bona areas are the only thin remains of the "Buntsandstein" deposition in NW Sardinia. BUZZI *et al.* (2008) synthesized a large array of data from the Permian-Triassic Nurra basin and proposed a general tectonic scheme, suggesting a half-graben setting with a structural high in the Monte Santa Giusta area. Based on the sedimentological and stratigraphic features, as well as the reduced thickness of the Cala Bona Permian-Triassic successions, COSTAMAGNA (2011) proposed that the Cala Bona area represents a southern structural high and possibly the southern edge of the NW Sardinia basin. On this basis, a full-graben structure cannot be excluded. In this framework, the "Buntsandstein" successions are thinner on the graben sides (Monte Santa Giusta, Cala Bona). Consequently, the subordinated lithofacies, like the aeolian one, tend to disappear or be very limited, especially in the Conglomerato del Porticciolo, where they represent a minor facies.

EUROPEAN FRAMEWORK

Desert systems were described in the Central European "Buntsandstein" during the Lower Triassic. Recently, erg

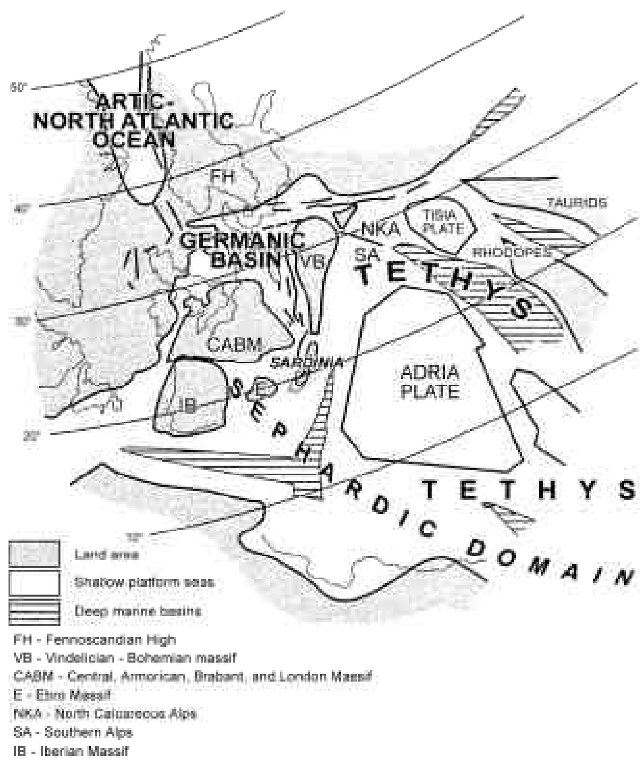

Fig. 1 – Paleogeographic sketch map of the Mediterranean area during early Middle Triassic times (modified from SZULC, 1999).

systems of the same age in the Iberian chain (Spain) have been suggested. Accordingly, the presence of wadi and aeolian deposits in the Early-early Middle Triassic of Sardinia, linked to the Iberian Microplate up to the Oligo-Miocene times, further confirms this picture.

In the typical Germanic Triassic of Central Europe, the passage from the "Buntsandstein" to the "Muschelkalk" takes place through transitional coastal facies, where the tidal influence appears to be negligible. This could be due to the setting of the Triassic Germanic basin as a closed sea (fig.1), which is similar to the present-day Mediterranean sea; here, the tidal influence was minimized by narrow gateways (Carpatian, Silesian and Burgundian gates (SZULC, 1999; DERCOURT *et al.*, 2000), with discontinuous communication with the Arctic-North Atlantic Ocean northwards or the Tethys Ocean eastwards. Otherwise, the location of the Iberian sub-plate area, of which Sardinia formed the SE part, was wide open in front of the rising Neo-Tethys Ocean (DERCOURT *et al.*, 2000) (fig. 1), and so was probably prone to tidal effects. Locally, such tidal effects may even have been enhanced by coastal morphological features such as embayments or even straits.

In the Iberian area, a tidal influence has previously been suggested in the upper part of the "Bunsandstein". At the very least, transitional coastal areas, with evidence of both continental to marine processes, have been accepted. In the Alpine "Buntsandstein" area, which is probably a more peripheral eastern facies with respect to the typical "Buntsandstein", a significant tidal influence during the passage to the marine environment has been evidenced. Accordingly, the tidal influences may gradually have become stronger southwards in Early Triassic Paleo-Europe. The evidence of a siliciclastic tidal system in the upper part of the Sardinian "Buntsandstein" confirms these statements as well as the previous location of the Corsica-Sardinia block in front of the rising Neo-Tethys Ocean, providing significant tides during the Triassic. Consequently, the tidal deposits of NW Sardinia, along with similar tidal deposits described in Haute-Provence, represent peculiar areas that have to be considered in the Early Triassic paleogeographic setting of the Western Mediterranean domain.
The low thickness of the Sardinian "Buntsandstein" Group, which is rather steady along all of the island (from 20 to 30 m), is referable to its location; it was probably deposited on a structural high, serving as a stable area with a low subsidence rate between Western Europe, Central Europe and the Tethyan basins.

The Plio-Pleistocene fluvio-lacustrine Upper Valdarno Basin (central Italy): stratigraphy and basin fill evolution

MASSIMILIANO GHINASSI (*), FRANCESCO FIDOLINI (**), MAURIZIO MAGI (**), MAURO PAPINI (**) & MARIO SAGRI (**)

Key words: *Northern Apennines, Upper Valdarno Basin, Plio-Pleistocene.*

INTRODUCTION

The Upper Valdarno Basin to stand out from the numerous Neogene-Quaternary basins of the Northern Apennines (MARTINI et alii, 2001) for its outstanding fossil mammal record, along with the good quality of natural and artificial outcrops and the peculiar tectono-stratigraphic framework. The well-preserved fossil mammals collected since the Renaissance, were studied by many researchers since 1800. The spectacular exposures located along the NE margin of the basin, locally known as "balze", fascinated Leonardo da Vinci and provided to Nicholas Steno a noteworthy base in formulating the basic principles of the modern stratigraphy. The Upper Valdarno Basin has been also used as key case to formulate new hypotheses on the latest phases of the Apenninic chain evolution and formation of the Neogene-Quaternary intermontane depressions. Although the basin has been extensively investigated during the past decades (SAGRI & MAGI, 1992; ALBIANELLI et alii., 1995; NAPOLEONE et alii., 2003; GHINASSI et alii., 2004), an exhaustive summary of the basin stratigraphy along with a detailed analysis of the spatial distribution of the main sedimentary units is still missing. The presents study summarizes the main results stemming out from a detailed mapping of the whole basin at 1:10.000 scale. This work, which was carried out in the frame of the Carta Geologica della Regione Toscana (scala 1.10.000) aims at describing the spatial distribution of the main sedimentary units and discussing the main steps of basin fill development. The basin stratigraphy is outlined using the principles of physical stratigraphy, identifying and tracing the most representative key surfaces (e.g. unconformities) at the basin scale.

GEOLOGICAL OUTLINES

The Upper Valdarno Basin is located 35 km SE of Florence between the Chianti Mountains and the Pratomagno Ridge (Fig. 1). It is a 15 km wide asymmetric tectonic depression elongated for 35 km in a NW-SE direction and drained from SE to NW by the Arno River. This depression has been filled up by 550 m of alluvial and lacustrine deposits during the Plio-Pleistocene. The basin substratum consists Oligo-Miocene sandy turbidites, locally covered by deep-marine, muddy Ligurian units Cretaceous to Eocene in age.

SEDIMENTARY SUCCESSION

The basin-fill succession is subdivided into four synthems, which are, from bottom up: Castelnuovo dei Sabbioni (CSB), Montevarchi (VRC), Fosso Salceto (OLC) and Torrente Ciuffenna (UFF) synthems. Synthems CSB, VRC and UFF occur in the Upper Valdarno Basin (Fig. 1), whereas synthem OLC was deposited in the Palazzolo sub-Basin (Fig. 1) and is almost coeval with the upper part of the VRC Synthem (FIDOLINI et alii, in press). The CSB Synthem (Late Pliocene) is exposed along the Chianti margin and shows a maximum thickness of about 200 m. It consists of basal fluvio-deltaic gravel and sand (CSBa in Fig. 1), grading upward into lacustrine mud with lignite levels (CSBb in Fig. 1), in turn overlain by fluvio-deltaic sand (CSBc in Fig. 1). The VRC Synthem (Late Pliocene-Early Pleistocene) consists of two parts separated by a minor unconformity surface which passes into a conformable surface moving from the Chianti margin to the basin. The lower part (Late Pliocene-Early Pleistocene) crops out only along the SW margin, where is at least 40 m thick. This part is made of alluvial fan gravels (VRCa in Fig. 1) grading upward into aeolian-reworked alluvial sand (VRCb in Fig. 1), which grades into mollusc-rich alluvial sand (VRCc in Fig. 1). The upper part is exposed at the basin scale and is about 30 m thick along the Chianti margin and thickens moving toward NE, reaching at least 100 m at the toe of the Pratomagno Ridge. This part is made of axial fluvial sand and mud (VRCd, VRCe and VRCf in Fig. 1) interfingering with gravelly alluvial fans (VRCg in Fig. 1) sourced from the margins

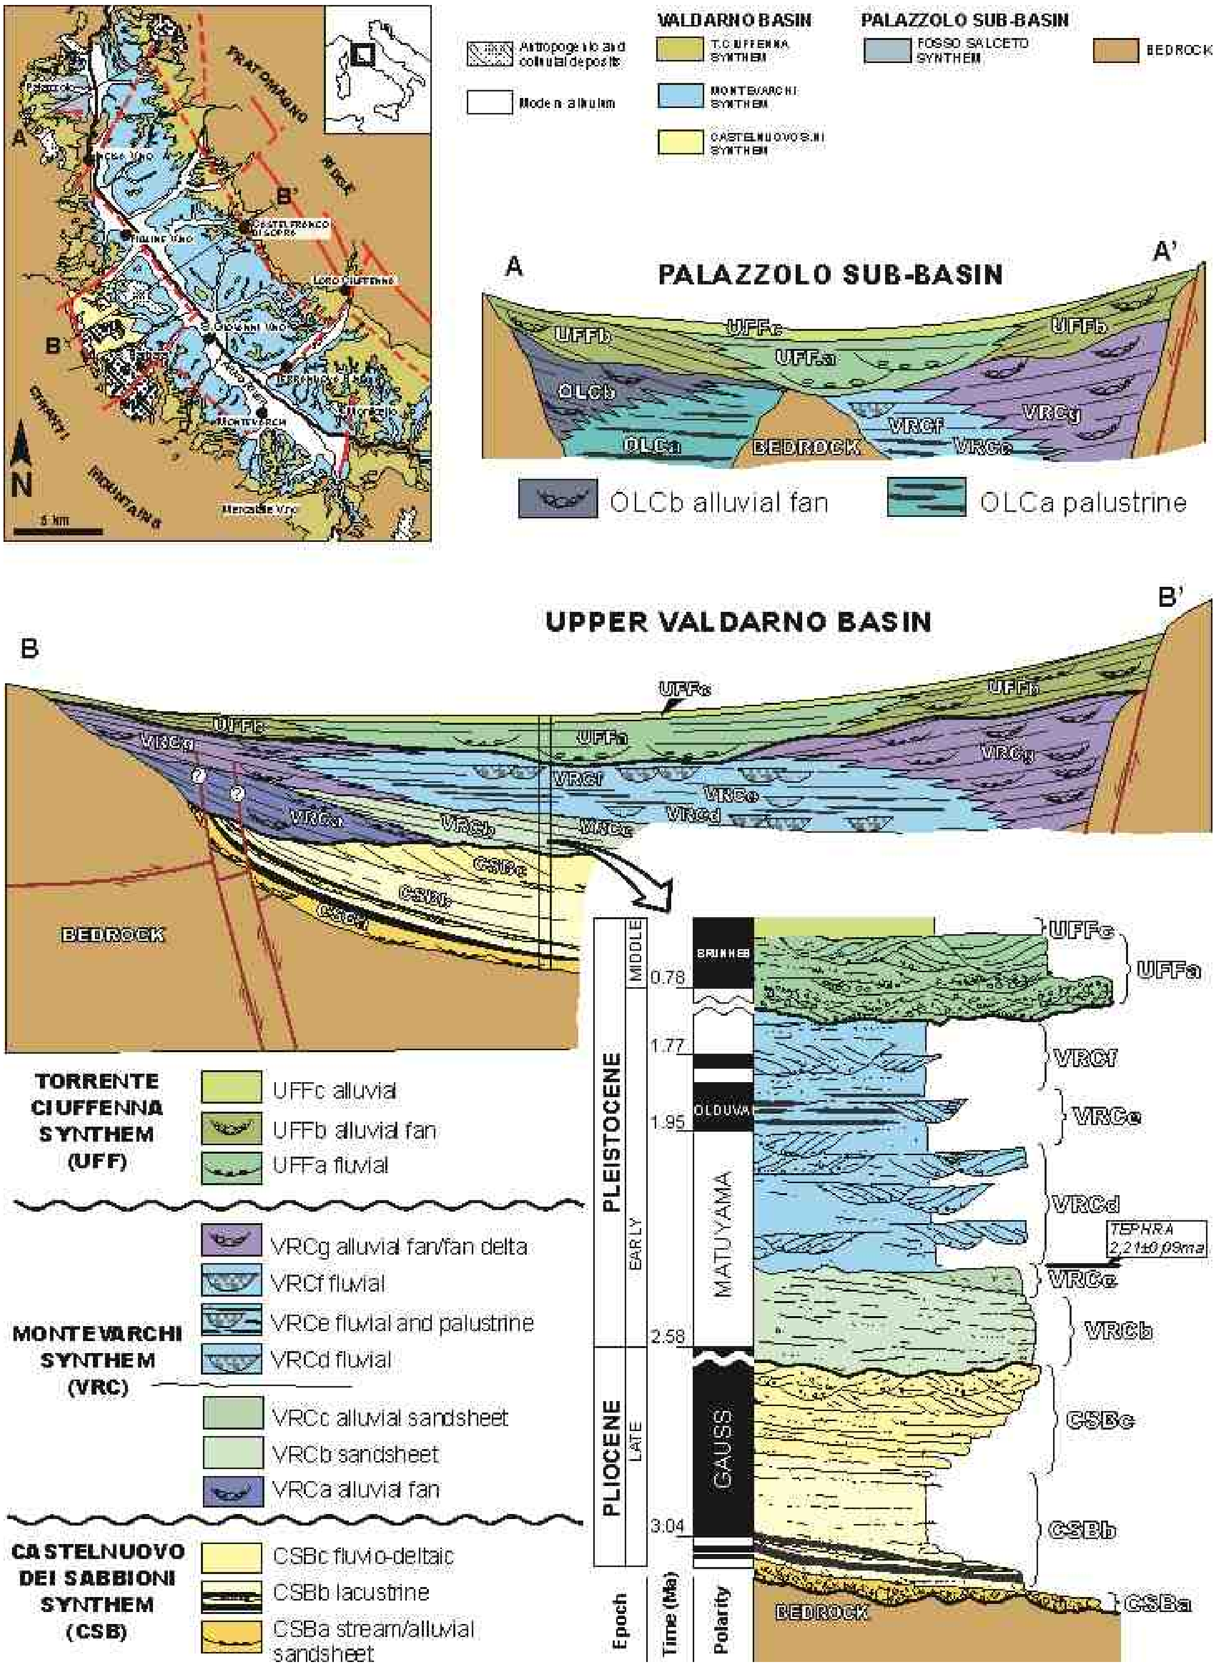

Fig.1 – Stratigraphic scheme of the Upper Valdarno Basin and Palazzolo sub-basin. Paleomagnetic calibration shown in the lower, right side is referred to a composite section measured across the axial part of the basin. Normal faults occurring in the western side of the basin cut the Castelnuovo dei Sabbioni synthem, but their relationship with the Montevarchi and Torrente Ciuffenna synthem deposits is unclear.

and palustrine deposits. The OLC Synthem is exposed in the Palazzolo sub-basin, located in the NW sector of the Valdarno basin (Fig. 1). It consists of palustrine mud (OLCa in Fig. 1) making lateral transition to and passing upward into alluvial fan deposits (OLCb in Fig. 1). These palustrine and alluvial deposits are considered almost coeval with VRCe and VRCg deposits developed in the main Valdarno basin. The UFF Synthem (late Early to Middle Pleistocene) includes fluvial gravel and sand in the central portion of the basin (UFFa in Fig. 1) and alluvial fan gravels and sand developed at the margins (UFFb in Fig. 1). Both UFFa and UFFb deposits are covered by muddy, heavily pedogenized alluvial deposits (UFFc in Fig. 1).

BASIN EVOLUTION

Evolution of the Upper Valdarno Basin can be summarized as follow:

1. The basin was generated during Late Pliocene through a tectonic damming of a north-eastward flowing drainage. The onset of this damming is documented by fluvial, valley-fill gravels at the base of the Castelnuovo dei Sabbioni Synthem, whereas the definitive damming is indicated by development of fully lacustrine conditions at about 3.1 Ma. The lake was progressively filled by deltas fed from the SW margin.

2. A tectonic phase, occurred before 2.58 Ma, caused uplift of the basin margins (Chianti Mountains and Pratomagno ridge) and partial erosion of the Castelnuovo dei Sabbioni Synthem westernmost deposits.

3. Deposition of the lower part of the Montevarchi Synthem testifies a marked basin broadening and re-equilibrium of the morphological profile resulted from the previous tectonic deformation. Such a re-equilibrium allowed accumulation of FU alluvial fan successions, which were capped by aeolian-reworked alluvial sand deposited at about 2.5 Ma.

4. A new deformative phase caused a basin widening, erosion along the SW margin and deposition in distal areas. As a consequence of this tectonic pulse, a topographic low developed in the S. Cipriano area where lacustrine facies accumulated.

5. Deposition of the upper part of the Montevarchi Synthem started at about 2.2 Ma and testifies re-equilibrium of the morphological profile derived from the previous tectonic deformation. Such basin reorganization leaded to the establishment of an axial fluvial drainage and marginal alluvial fans.

6. During the Early Pleistocene (Olduvai Subchron, 1.95-1.78 Ma), a further subsidence pulse triggered a new morphological disequilibrium along the margins and subsidence in the axial portion, where floodplain lakes and swamps developed. The alluvial fans progradation, which stemmed out as response to the morphological disequilibrium, led to development of small isolated fan-delta systems.

7. During late Early Pleistocene, a tectonic pulse and the entrance of the paleo-Arno River into the basin caused development of a marked unconformity, whereas the subsequent re-equilibrium (late Early Pleistocene to Middle Pleistocene) led to formation of a FU depositional trend both in fluvial and alluvial fans successions at about 0.781 Ma (Matuyama-Brunhes boundary). During the Late Pleistocene the paleo-Arno River and its tributaries cut down through the basin fill forming terraced deposits and allowing the basin to reach the modern configuration.

A progressive unconformity-bounded stratigraphic unit within extensional settings, SE Volterra Basin, Italy

ALESSANDRO IELPI (*) & GIANLUCA CORNAMUSINI (*,**)

Key words: *Progressive Unconformity, UBSU, Syn-rift, Volterra, Miocene.*

INTRODUCTION

It is widely accepted that syn-sedimentary tectonism exerts major controls on the stratigraphic arrangement of syn-rift complexes (SHARP *et alii*, 2000), mostly through the growth of normal faults and the associated fault-propagation folding. It is on the other hand poorly understood and documented how depositional systems respond to tectonic paroxysms in terms of sequence arrangement. In these terms, fault displacements and fold growths are in fact potentially capable to trigger both forced regressions and then sub-aerial truncation (GAWTHORPE *et alii*, 2000), both accommodation space and then base level transgressions (ANÁDON *et alii*, 1991). Moreover, these two end-member phenomena are not necessarily mutually exclusive, and mostly coexist, characterizing the uplifting landward footwall and the subsiding basinward hangingwall of a basin system, respectively.

If moving along-dip across an uplifting to subsiding transect, it is then commonly possible to appreciate distinct downdip trends in the deformative motif and stratal packaging of a basin fill. These commonly comprise: (1) a general deformation attenuation, expressed by a progressive widening and broadening of the fault-propagation folds; (2) the decrease and eventual loss of angularity across the truncation surfaces; (3) the evolution from unconformable surfaces of sub-aerial truncation to correlative conformable depositional surfaces; (4) the smoothing and broadening, and eventual disappearance, of incised valley systems; and (5) the concurrent individuation of progressively thicker falling-stage wedges.

In this study, we present a peculiar case of a Tortonian nonmarine to paralic unconformity-bounded stratigraphic unit (UBSU *sensu* SALVADOR, 1987), enclosed into surfaces of progressive unconformity. Fieldwork activities, mainly based on the collection of outcrop stratigraphic and attitude data, were led in the SE Volterra Basin, a key-area in the extensional hinterland of the Northern Apennines. Aims of this research are to firstly propose a preliminary redefinition and improvement of the state-of-the-art regional stratigraphic frame for the pre-evaporitic late Miocene infill, as well as to discuss some paleogeographic implications for the Neogene Volterra Basin. These goals will be achieved through the physical stratigraphic restoration of the studied unit, as well as through the discussion on the nature of the respective bounding surfaces.

GEOLOGICAL BACKGROUND

The inner Northern Apennines are a collapsed fold and thrust belt, firstly structured during an Eocene to earliest Miocene collisional phase related to the Africa-Eurasia convergence, and then subjected since the middle to late Miocene to the Tyrrhenian rifting (CARMIGNANI *et alii*, 1994). Post-orogenic extensional tectonics characterized the Northern Apennines hinterland up till nowadays, driving the evolution of a complex basin and range system. The Volterra Basin, located in the hinterland north-central sector (Fig. 1a), is a NNW-SSE oriented basin, covering ca. 900 km^2 and hosting an up to 2 km thick Miocene to Pleistocene infill. Its SE sector hosts some key Miocene outcrops, and has been selected as study area. The eastern sector of this area is delimited by a NW-SE oriented basin bounding ridge. Such ridge is part of the Middle Tuscan Range, a major morphologic-structural positive element in the inner Northern Apennines. The Middle Tuscan Range uplifting took place, with several paroxysms, between the middle-late Miocene and the Pleistocene, and strongly influenced the hinterland basins development and paleogeographic settings.

STRATIGRAPHIC FRAME

A proposed new stratigraphic frame for the study area has been deducted by field surveys, partially refining the previous scheme by BOSSIO *et alii* (1998). It is hereafter illustrated, prior to discuss the physical stratigraphy of the studied unit, and the nature of its progressive bounding unconformities. Following the literature approach, the post-orogenic succession of the Northern Apennines hinterland was subdivided in “Depositional Units”,

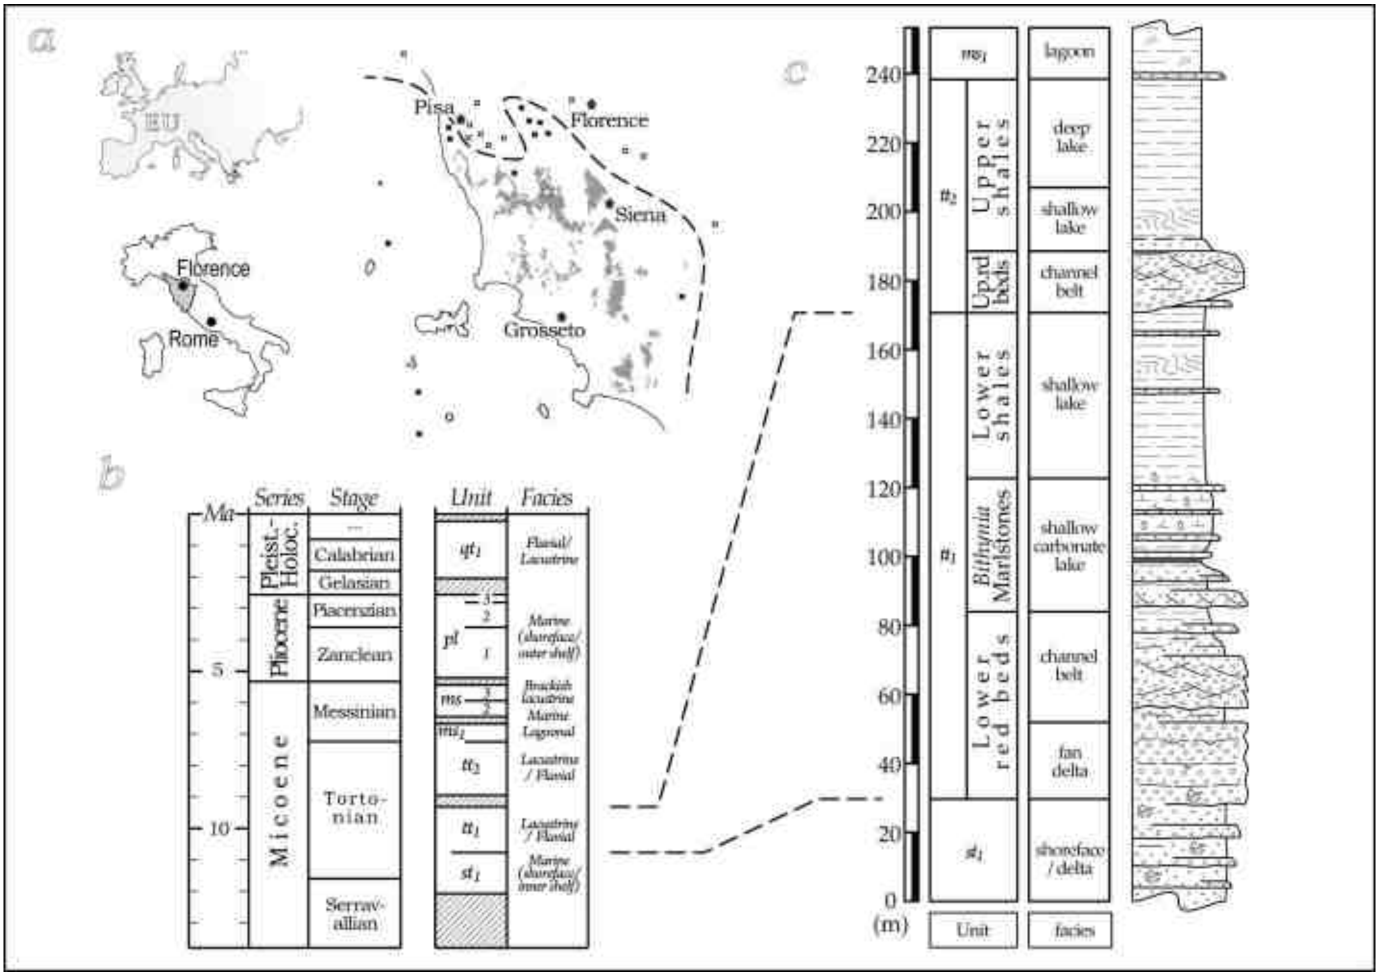

Fig. 1 – Introductory outlines. (a). Geographic and geological sketch of the Tuscan hinterland. Grey areas indicate post-orogenic Miocene outcrops; black and white cross-spots indicate wells that encountered /did not encountered post-orogenic Miocene deposits, respectively; the thick dashed line indicate the western post-orogenic Miocene limit. (b). Proposed stratigraphic frame for the study area. (c). Synthetic stratigraphic log of the units st_1 to ms_1.

indicating different paleogeographic and paleoenvironmental settings, and potentially bounded both by sub-aerial unconformities or depositional surfaces.

The Miocene deposits are buried by Pliocene to Pleistocene deposits (units pl_{1-3} and qt_1), and has been subdivided in six depositional units, comprising (Fig. 1b): late Serravallian to early Tortonian marine facies (st_1); early to middle (?) Tortonian lacustrine-paralic facies (tt_1); middle (?) to late Tortonian lacustrine facies (tt_2); late Tortonian to earliest Messinian lagoon facies (ms_1); early to middle Messinian marine facies (ms_2); and middle to late Messinian brackish lacustrine facies (ms_3). These are grouped in four major UBSUs, comprising respectively units: st_1 (1); tt_1 (2); tt_2-ms_1 (3); and ms_2-ms_3 (4).

A particular focus has been dedicated to the UBSU (2) - unit tt_1, which is enclosed both at the top and at the bottom by surfaces of progressive unconformity. A physical stratigraphic frame has been reconstructed and summarized in Fig. 1c. The bedding relationships with the bounding UBSUs were further investigated across a ca. 7 km long along-dip transect, being roughly oriented ENE-WSW (Fig. 2). Towards the landward ENE, the transect is delimitated by the Middle Tuscan Range; towards the basinward WSW, the transect is instead delimited by an extensive coverage of younger deposits.

Physical Stratigraphy

The unit tt_1, composing the UBSU (2), overlies the unit st_1 shoreface-deltaic marine deposits, and is three-folded in a lower succession of alluvial red beds, capped by middle lacustrine-paralic to fluvial *Bythinia*-rich Marlstones and sandstones, these in turn overlaid by top shallow lacustrine to mudflat shales. The latter are capped unconformably by the unit tt_2. The physical stratigraphic frame has been restored in detail through the implementation of a detailed ca. 70 m thick log, measured bed by bed in the central portion of the transect shown in Fig. 2. Other speditive and lower-resolution logs have been measured across the transect in selected outcrops, and highlight a marked along-dip thickness variability. A general trend shows however a general thickening towards the WSW.

Progressive Unconformities

As prefaced, the major peculiarity of the UBSU (2) consists

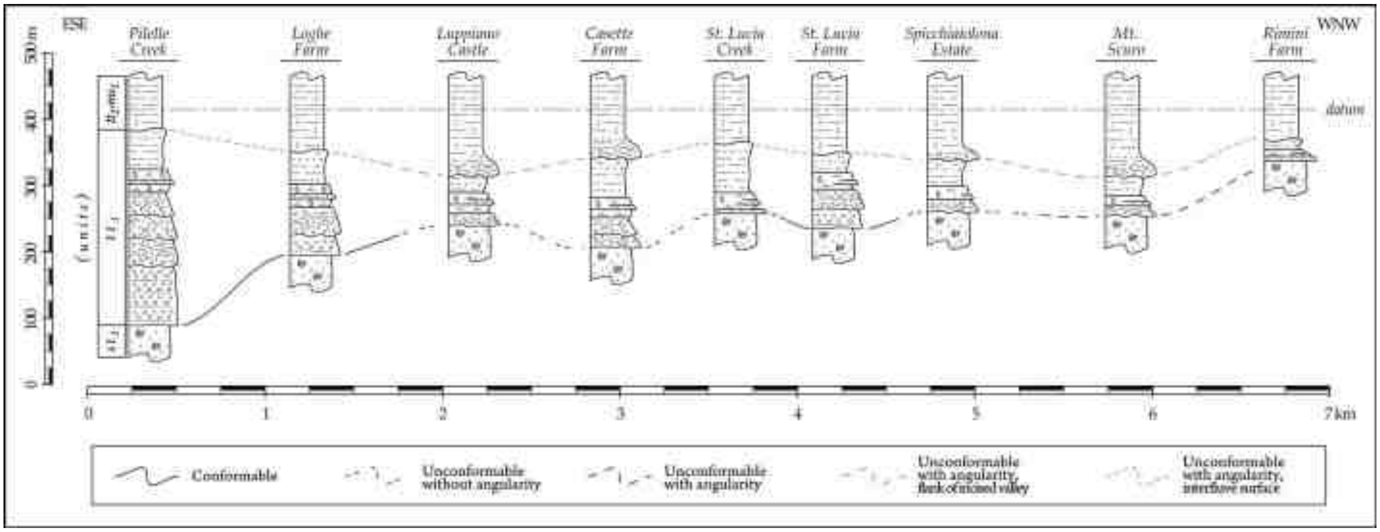

Fig. 2 – Along-strike, ESE-WNW oriented stratigraphic transect, briefly illustrating the architectural features of the unit tt1 in the SE Volterra Basin, and the nature of its progressive unconformable boundaries with the units st_1 and tt_2.

in the progressive nature of its bounding surfaces.

These composite surfaces show a marked along-dip variability in their nature, revealing distinct interplays between tectonics and sedimentation for this basin area. The bottom st_1/tt_1 boundary is a composite of sub-aerial truncations (both with or without angular character in places) and depositional surfaces. Towards the Middle Tuscan Range, it has characters of truncation, with a marked angularity. The angularity decreases progressively proceeding basinward (WSW), and eventually evolves into disconformities and then depositional surfaces. The top tt_1/tt_2 boundary is instead angular for the whole transect, even if a WSW-angularity decreasing trend is appreciable, associated with a general reduction of the unit tt_1 deposits deformation. It is further possible to distinguish in this surface the flanks of two orthogonal incised valley systems cut into the underlying deposits, separated by interfluve paleosoils, and having a NNW-SSE oriented depositional dip.

DISCUSSION AND CONCLUSIONS

Observations on the stratigraphic transect highlight distinctive characters, symptomatic of different interplays between tectonics and sedimentation. The variability in thickness was likely induced both by syn-depositional differential subsidence patterns, both by post-depositional erosional phenomena. The st_1/tt_1 boundary shows a towards-WSW decrease in tectonic deformation, probably associated with an increasing sedimentary supply, eventually outpacing the deformation rate, and forming falling-stage wedges. Similarly, the tt_1/tt_2 boundary is characterized towards WNW by major uplift and deformation rates, progressively decreasing towards the ESE. These trends are straightforwardly associated to an increasing subsidence/uplift ratio towards the basinward ESE sectors, and were probably linked with the early individuation of the Middle Tuscan Range. Besides, the occurrence of unit tt_2 incised valley systems, with an orthogonal depositional strike in respect to the underlying unit tt_1, furthermore suggests marked drainage pattern rearrangements driven by tectonic activity peaks.

Anatomy of falling stage to early transgressive fluvial-deltaic deposits: outcrop and borehole data from the lacustrine late Pliocene of the Upper Valdarno Basin (Italy)

ALESSANDRO IELPI (*), MASSIMILIANO GHINASSI (**) & FRANCESCO FIDOLINI (°)

Key words: *Architecture, Coal, Falling Stage System Tract, Lacustrine, Sequence Stratigraphy, Valdarno.*

INTRODUCTION

During a forced regressions, the base level fall involves the sub-aerial exposures of marginal basin areas, that become affected by prevalent erosion and sediment bypass. The basinward areas, which are below the fallen base level, are instead still capable to host sediments, and accumulate thick wedges, regarded as falling stage system tracts (CATUNEANU, 2006). During the following base level rise, lowstand and transgressive deposits accumulate landward as unconformable onto the truncated highstand deposits, and basinward as conformable onto the falling stage deposits, through a correlative depositional surface.

This basic Depositional Sequence model, elaborated for marine-paralic strata (HUNT & TUCKER, 1992), has been rarely applied to nonmarine beds. This research aims to depict the sequence architecture and geomorphic assessment of a falling stage to early transgressive fluvial to palustrine-lacustrine tract, and to analyze the stratigraphic significance of an interbedded brown coal seam. This study is based on the integration of outcrop and borehole data collected in a 2.0 x 0.5 km wide coalfield, located in the Plio-Pleistocene Upper Valdarno Basin (Italy). The distinctive peculiarity of the succession consists in the complete preservation of its depositional systems, which are in fact composed of an upstream incised valley system linked downdip to a falling stage deltaic to shoreface complex.

GEOLOGICAL OUTLINES

The Upper Valdarno Basin, located between Firenze and Arezzo, belongs to the north-eastern external sector of an articulated basin complex that characterises the Northern Apennines hinterland (Fig. 1a), resulted from the post-orogenic collapse of an over-thickened orogen (MARTINI & SAGRI, 1993). The Upper Valdarno Basin is filled by ca. 550 m of late Pliocene to Pleistocene fluvial to lacustrine deposits, articulated in four major UBSUs (SALVADOR, 1987). The oldest Castelnuovo Synthem crops out in the central-western basin area (Fig. 1b), and has been recently subdivided in two sub-synthems (IELPI, 2012). The Castelnuovo I sub-synthem is composed of bottom alluvial (Spedalino Gravels unit) and top palustrine-lacustrine (Lower Meleto Clays unit) deposits (Fig. 1c). The Castelnuovo II sub-synthem is in turn composed of bottom palustrine-lacustrine (Upper Meleto Clays unit) and deltaic (San Donato Sands unit) deposits (Fig. 1c). The boundary between the two sub-synthems is represented in the northern study area (Fig. 1b) by a surface of sub-aerial truncation flooring an incised valley system, which passes southward to a correlative surface, this latter capping a lacustrine shoreface-deltaic succession. The boundary represents then an episode of major lake level drop, that involved a significant basinward facies shift. The Castelnuovo Synthem is in turn unconformably capped by younger (Pleistocene-Holocene) alluvial deposits, belonging respectively to the Montevarchi, Monticello-Ciuffenna and Arno River synthems.

OUTCROP DATA

Outcrop data are reported from three key-outcrops, representing an upstream fluvial, downstream fluvial and shoreface-deltaic domain, (Fig. 2a), respectively. The measured logs are spaced 1300 and 700 m from each other, and disposed on a NNW-SSE oriented along-dip transect. A 2 m to few dm thick brown coal seam, correlative in the whole coalfield, is a clear key-bed and has been regarded as architectural datum.

The upstream fluvial succession (Log 1, Fig2a) is represented by ca. 6 m of incised valley fill fluvial gravels and sands, passing upward to the 1.5 m thick, coal seam key-bed. The paleovalley is

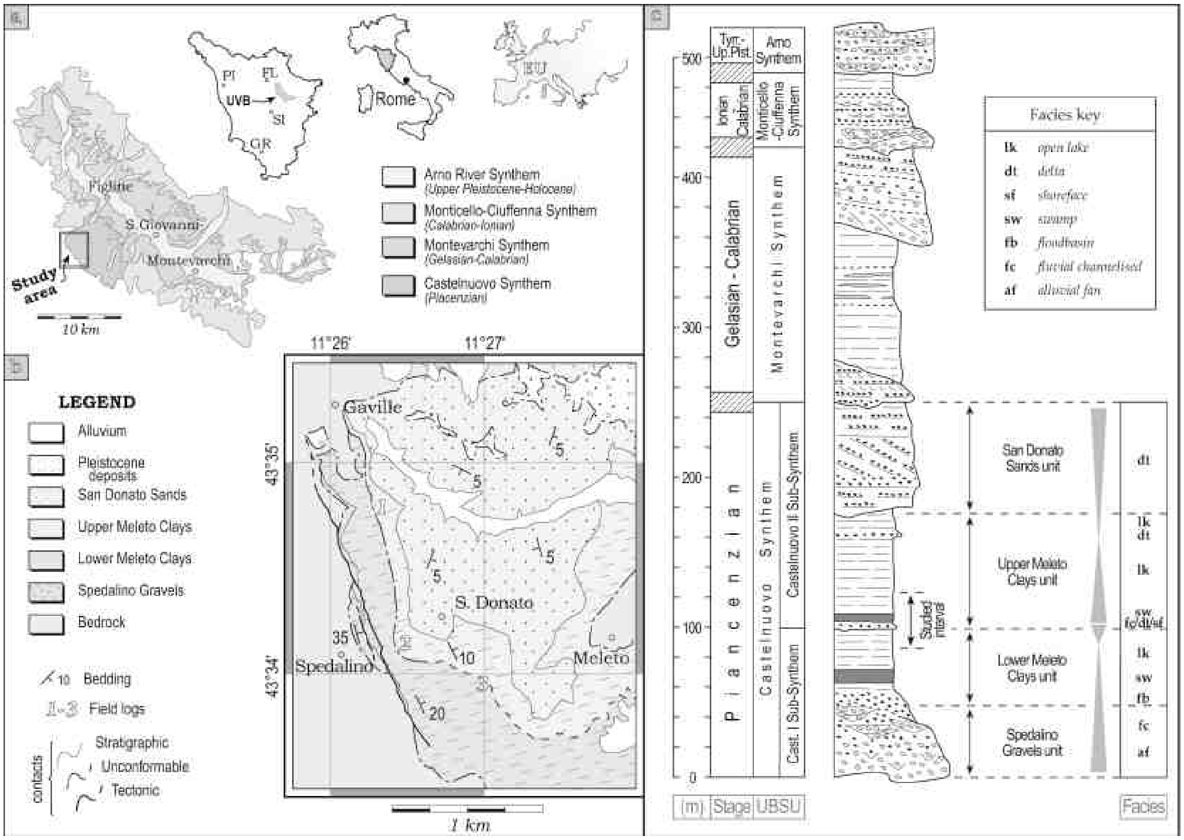

Fig. 1 – General outlines. (a) - Geographical setting and geological sketch of the Upper Valdarno Basin. (b) - Geological setting of the study area, corresponding to the upper seam coalfield of the Castelnuovo II sub-synthem. (c) - Stratigraphic outlines of the Upper Valdarno Basin infill: the lowermost portion, represented by the Castelnuovo Synthem, hosts the succession this study deals with.

incised into the underlying deposits of the Castelnuovo I sub-synthem, consisting of a monotonous stack of organic- and siderite-rich open lacustrine muds.

The downstream fluvial succession (Log 2, Fig. 2a) is composed of a shallowly incised 2 m thick valley, filled with floodbasin to poorly channelised organic sands and iron-encrusted paleosoils. The valley rests unconformably onto 2 m of deltaic mouth bar to distributary channel deltaic facies. Similar to the upstream fluvial domain, the incised valley is overspilled by the coal seam (0.2 m thick), and then sealed by thick open lacustrine deposits.

The shoreface-deltaic succession (Log 3, Fig. 2a) is 40 m thick and articulated in several shallowing- and deepening-upward high-frequency trends. These deposits are located at the valley outlet and conformably overlay the lacustrine mud of Castelnuovo I sub-synthem. The lacustrine domain is prevalently open lacustrine-deltaic in its lower portion, and prevalently shoreface-lacustrine in its upper portion. The upper shorefaces are capped by the coal seam (3 m thick), in turn overlaid by thick open lacustrine deposits.

BOREHOLE DATA

Extensive open pit coal exploitations carried out during the 1950s to 1990s in the Santa Barbara Basin have been assisted by the drilling of some 1200 explorative boreholes. Two main coal seams, the lowermost being economic, were the main drilling target. In this research, a dataset comprising 160 selected borehole stratigraphies has been investigated, aiming at performing a geomorphic assessment of the fluvial valley fill and relative deltaic-shoreface complex underlying the uppermost coal seam. The dataset, reported in Fig. 2b, has been preliminarily subdivided in boreholes encountering: i) valley fill facies; ii) deltaic-shoreface facies; iii) only lacustrine facies. The borehole mapping individuates the paleo-coastline during the late falling - early lowstand.

DISCUSSION AND CONCLUSIONS

Outcrop sedimentary and stratigraphic analyses of the studied succession highlight the along-dip individuation of: (1) an upstream fluvial domain, dominated by strong incision and sediment bypass; (2) a downstream fluvial domain, characterised by accumulation of thin deltaic successions and shallow unconformable scouring by a broad and poorly incised valley system; (3) a shoreface-deltaic domain, represented by a coeval thick deltaic to shoreface succession recording high-frequency base level fluctuations.

In a sequence stratigraphic frame, the study succession is interpreted as developed during falling and early rise of the

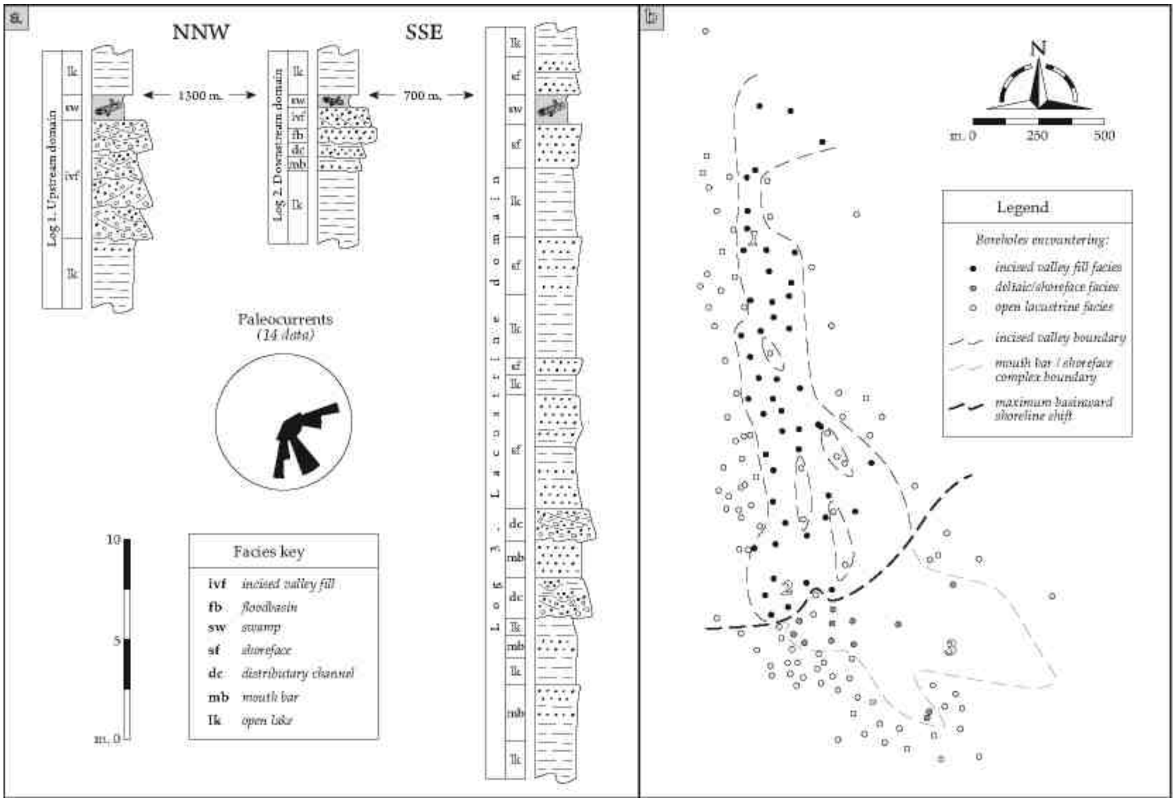

Fig. 2 – Outcrop (a) and borehole (b) data reported in this study. (a) - Measured logs individuate: an upstream fluvial domain, characterised by incised valleys dominated by erosive and bypass processes; a downstream fluvial domain, characterised by the deposition of thin deltaic succession poorly scoured by shallow incised valleys; a shoreface-deltaic domain, represented by a thick and articulated succession of lacustrine, deltaic and shoreface bedsets. (b) - Selected boreholes map the areal distribution of incised valley, deltaic-shoreface and lacustrine facies, allowing to depict the depositional architecture of the system.

lacustrine level.

During the falling stage, valley incision occurred, with consequent accumulation of a shoreface-deltaic lithosome (falling stage wedge) conformably overlying the lacustrine deposits of the underlying sequence.

The subsequent lacustrine rise was outpaced by the rate of sediment supply, leading to a progressive lakeward shift of the deltaic shoreline and parallel aggradation of fluvial deposits in vallive realm (lowstand deposition). When the rate of lacustrine rise outpaced those of sediment supply, the coastline shifted landward. The maximum regressive to early transgressive phase was finally characterized by the coal accumulation. The facies mapping extrapolated by borehole data allows to trace the incised valley and basinward deltaic-shoreface complex boundaries, as well as to outlines the maximum basinward shift of the lacustrine shoreline during the episode of forced regression.

The integration of outcrop and borehole data allows then to extrapolate precise information on the depositional evolution and architecture of the studied succession. The restricted spatial occupation and the complete preservation of the depositional system is a key-character that potentially allows strict comparisons with sub-recent to modern analogues. This latter, aside from being fundamental in any geomorphic assessment, is further critical when relating sequence stratigraphy to modern environments (BOYD *et alii*, 1989).

Carbonate deposition in a fluvial tufa system: processes and products, (Corvino Valley - Southern Italy)

EDOARDO PERRI (*) & ELENA MANZO (*)

Key words: *Biofilm, biomineralization, carbonate deposition, microbial carbonate, Recent fluvial tufa.*

ABSTRACT

In a multi-scale approach to the study of the organic and mineral components in an active barrage-type tufa system of southern Italy, neo-formed deposits, in both natural depositional sites and on inorganic substrates placed in the stream for this study, were observed and compared through one year of monitoring. Dams and lobes representing the basic morpho-facies of the deposits are composed of two depositional facies: vacuolar tufa (a mixture of phytoclastic and framestone tufa) and stromatolitic tufa (phytoherm boundstone tufa). Three petrographic components comprise both facies: micrite and microsparite, often forming peloidal to aphanitc, laminar and dendrolitic fabrics, and sparite, which occurs as isolated to coalescent fan-shaped crystals forming botryoids or continuous crusts. All fabrics occurring in all depositional facies are organized into layers with a more or less well-developed cyclicity, which has its best expression in stromatolitic lamination. The precipitation of all types of calcite (with Mg 1.0 to 3.2 mole % and Sr 0.5 to 0.8 mole %) takes place more or less constantly during all seasons, in spite of the low saturation state of the water (Saturation Index range is 0.75 to 0.89), within the active depositional zone; the latter extends for a few hundred microns through the external surface of the deposit. The active depositional zone has a particular micro-morphology composed of porous micro-columns (50 to 150 μm in size), separated by interstitial channels. Mineral precipitation occurs upon both external surfaces and within internal cavities of the micro-columns, while further point-sites of precipitation occur suspended within the masses of cyanobacterial tufts. Sub-spherical mineral units, 'nano-spheres' (10 to 20 nm in diameter) are the basic biotic neo-precipitate. They commonly form by replacing non-living degrading organic matter and at point-sites along the external surface of living cyanobacterial sheaths. Nano-spheres agglutinate to form first rod-shaped aggregates (100 to 200 nm), which then evolve into triads of fibres or polyhedral structures. Successively, both triads and polyhedral solids coalesce to form larger calcite crystals (mainly tetrahedrons tens of microns in size) that represent the fundamental bricks for the construction of the micro-columns in the active depositional zone. Precipitation is attributed to the presence of a widespread biofilm that occurs in the active depositional zone; this is composed of a heterogeneous community comprising epilithic and endolithic filamentous cyanobacteria, green algae, unicellular prokaryotes, Actinobacteria and fungi, with a variable amount of extracellular polymeric substances. No precipitation takes place where the biofilm is absent, indicating that the biological activities of the biofilm are crucial, with its living organisms and non-living organic matter. Basic aggregates of neo-precipitates do not form in association with any one particular type of organic matter substrate, but appear to be related to the seasonal temperature variation: polyhedral microcrystals mainly precipitate in the colder season, short triads in the intermediate seasons, and long triads in the warmest conditions. These three basic crystal aggregates have a petrographic counterpart, respectively in the spar, microspar and micrite.

LGM glacial retreat in the Astico valley and mismatch with the Adige and Brenta glacial transfluences (NE Italy)

ROSSATO SANDRO (*), MOZZI PAOLO (*), MONEGATO GIOVANNI (°)

Key words: *glacial collapse, glacial transfluence, Last Glacial Maximum, plain evolution, south-eastern Prealps, Venetian Plain.*

INTRODUCTION

Valley glaciers can be fed by transfluence from major glaciers through a gap or a saddle. These glacial systems may be more sensitive to rapid climate changes, in terms of temperature and precipitation rates. Here we present a case study concerning the timing of deglaciation in a Prealpine glacial system connected to transfluences from the Adige glacier. Changes in the position of the end moraines, hosted in the terminal valley reach, are coupled with observation of the glaciofluvial sedimentation in the piedmont area, with special reference to the Astico system, providing new insights on the onset of the glacial decay at the end of LGM.

SETTING

The Adige Valley is located in the Trentino Alto-Adige Region, in the eastern Southern Alps, North of the Garda lake. The major river flowing is the Adige River, which has its source near the Resia Pass, at 1550 m a.s.l. This river flows initially in an E-W valley reach up to the city of Merano and then with a S-E direction as far as the city of Bolzano; there it assumes its final direction, going NNE-SSW up to the Ceraino gorge, where is located the present outlet into the Po Plain.

The Brenta Valley is located few km eastwards of the Adige Valley. The Brenta River originates from the Caldonazzo Lake, at the altitude of 450 m a.s.l. and flows into the valley, initially with a WSW-ENE direction, WNW-ESE down to the town of Borgo Valsugana, and then roughly N-S.

The main tributary is the Cismon River, which drains the south-western sector of the Dolomites. Near the town of Bassano del Grappa, the Brenta River flows into the Venetian alluvial plain, through a narrow canyon, few hundred meters wide.

The Astico valley is located in the Venetian Prealps (eastern Southern Alps), NW of the city of Vicenza (Italy). The Astico River flows within this valley, which has an initial N/S direction and then turns NW-SE. The river has its spring between the Sommo Alto and the Plaut peaks, few km South of the Caldonazzo Lake, and flows on the valley bottom as far as the town of Piovene Rocchette, where it enters a narrow and 50-m deep gorge until reaching the Venetian alluvial plain, about 10 km downstream.

THE LGM GLACIAL SYSTEM

During the LGM the Adige Valley was occupied by the major glacier in the area, a lobe of which flowed along the Lagarina Valley down to Rivoli Veronese (BASSETTI & BORSATO, 2005), where it created well-preserved terminal moraines (VENZO, 1965; CREMASCHI, 1994; FERRARO, 2009). The Brenta and Astico valleys where occupied by transfluences from the Adige glacier, with only minor contributions from local glaciers (TREVISAN, 1939; CUCATO, 2007).

The first LGM glacial deposits in the Adige valley lie on top of a paleosoil which dates back to ca. 18,700 ± 2100 cal a with IRSL method (FERRARO, 2009), while radiocarbon dating in the same palaeosoil dates back at 31,990–33,068 cal a BP (CREMASCHI *et alii*, 1987). These glacial deposits correlate with the 15-km-long outer moraine located near the town of Rivoli Veronese (BASSETTI & BORSATO, 2005). During the LGM some minor fluctuations were registered in the deposits. The last major glacial advance has been recognized and radiometric dated to ca 24 cal ka, which is in good agreement with the indicators founded in other major Venetian Prealpine valleys, like the Tagliamento one (MONEGATO *et alii*, 2007). Deglaciation in the lower Adige Valley was completed before 14 cal ka, as indicated by radiocarbon dating of the base of the lacustrine succession at Terlago Lake (ca. 415 m a.s.l.) and peat accumulation in the Isera bog (219 m a.s.l.) (BASSETTI & BORSATO, 2005).

The transfluence of the Adige glacier into the Brenta valley was through the Civezzano saddle, altitude ca 500 m a.s.l., and the Vigolo Vattaro valley; this tongue, laterally fed by tributary glaciers, joined the Cismon valley glacier near the town of

(*) University of Padua, Department of Geosciences, Padua, 35123, Italy

(°) National Research Council, Institute for Geoscience and Earth Resources, Turin, 10123, Italy

Cismon del Grappa and flowed into the lower Brenta valley. The Brenta glacier front at the LGM maximum expansion is regarded to have been located in the Brenta Valley at Valstagna (TREVISAN, 1939), but no geomorphic evidence of the terminal moraines have been so-far recognized. Significant decay signals start from about 18 cal ka BP, as testified by the smaller sedimentation rates recorded in the alluvial plain sedimentary sequences and subsequent onset of the incision of the megafan

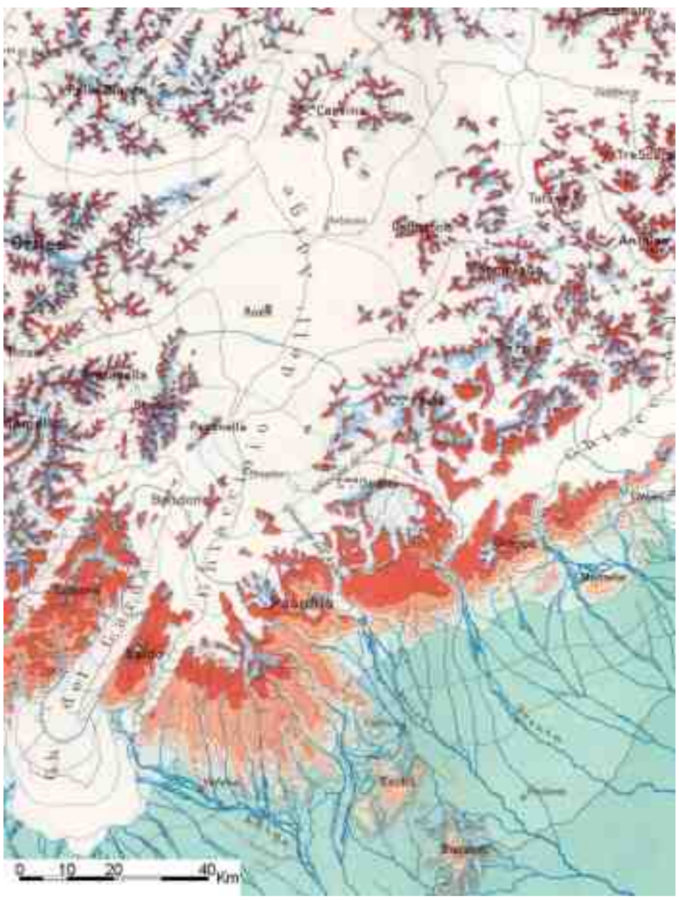

Fig. 1 – The glacial system in the eastern Southern Alps during the last glaciation (CASTIGLIONI, 1940; modified)

(MOZZI, 2005; FONTANA *et alii*, 2008, 2010).

Along the upper Astico Valley and at the margins of surrounding plateaus, several glacial deposits have been recognized and related to the glacial transfluence of the Adige glacier through several saddles; these sediments are ascribed to different glaciations, according to their weathering degree and geomorphological position (CUCATO, 2007). Local glacial units in the Sette Comuni Plateau were also described and mapped (TREVISAN, 1939; CUCATO, 2007). The last glacial event in the Astico valley created the well-preserved terminal moraine system of Cogollo del Cengio that is attributed to the LGM. The outwash apron of the Astico glacier filled the lower part of the Astico Valley and built two fans in the piedmont plain (ROSSATO *et alii*, 2012). Two incised sandur channels are still recognizable in front of the outer terminal moraine (BARTOLOMEI, 1976). During the LGM the local prealpine glaciers remained separated from the Astico one. The LGM moraine system in the Astico valley is composed by three different arcs which are the result of the transfluence of a tongue of the Adige glacier, which flowed through the Carbonare saddle (1075 m a.s.l.) for about 26 km down to the present town of Cogollo del Cengio (ROSSATO *et alii*, 2012). The outer moraine was probably built during the wetter climatic phase recorded in the alpine chain about 27.5 cal ka (PINI *et alii*, 2010), whilst the inner one can be related to the drier phase which led to the first withdrawal of the Alpine glaciers at about 23-24 cal ka. This scenario is in good agreement with the general evolution of glaciers in the Eastern Southern Alps, which tongues oscillated for about 8 kyr at the beginning of the LGM (e.g. MONEGATO *et alii*, 2007; CARTON *et alii*, 2009). These data are in good agreement also with those obtained by FORNO *et alii* (2010) for the Aosta Valley glaciers, in the Western Alps, testifying a comparable climatic situation.

DISCUSSION

Looking in detail to the extension of the various glaciers, the main interesting feature seems to be the vertical extent of the ice mass, since if it is too low the transfluence cannot be sustained and the glacial tongues would collapse. According to BARATTO *et alii* (2003), during the LGM the Equilibrium Line Altitude (ELA) in the Grappa Massif, which is located about 20 km eastwards of the lower Astico, was about 1425 m a.s.l. In the western sector, the Adige glacier reached about 2000 m a.s.l. near the city of Bolzano and ca 1650 m a.s.l. near the city of Trento (BASSETTI & BORSATO, 2005), which is about 15 km NW of the Carbonare saddle.

The chronostratigraphy of two cores drilled near the towns of Vicenza and Villaverla shows that the outwash stream of the Astico glacier changed its outlet to the piedmont plain at the end of LGM, as a response to rapid glacial collapse. This switch led to the deactivation of the north-western sector of the plain (Thiene fan) in favor to the south-eastern one (Sandrigo fan) (ROSSATO *et alii*, 2012). This situation was due to the stop of the ice transfluence trough the Carbonare saddle, which determined a sudden glacial collapse in the Astico valley. This latter system, in fact, was sustained only by this mechanism, due to the lack of local tributary glaciers which could contribute to the ice-feeding of the Astico glacier.

In the Brenta Valley, instead, the lower altitude of the transfluence gap may have allowed for a progressive retreat of the glacier tongue, in accordance to that of the Adige Valley. The onset of glacial downwasting in the terminal Brenta Valley was around 17.5 ka cal BP, as indicated by the timing of fanhead incision of the megafan in the piedmont plain (MOZZI, 2005)

CONCLUSIONS

According to the various data collected, there seems to be a slight mismatch between the glacial decay of the Astico Valley and those of the Brenta and Adige valleys.

The lower and middle Astico Valley proves to be able to register even subtle climatic changes during glaciations, and to allow the preservation of a significant, though fragmentary, geological record concerning past glacial/interglacial cycles.

The definition of the correlation between the glaciofluvial system in the terminal valley sector and the piedmont fans was crucial for the definition of the chronostratigraphy of the LGM glacial complex which took place in this valley, and for highlighting the mismatch of the retreat between the considered glacial tongues.

In a general way, it is possible to affirm that, due to their particular conditions, the small prealpine glaciers are more sensitive to the climatic variations, in particular to shifts of the ELA at the end of a glacial phase and in the intermediate fluctuations. Hence, the retreat of these glacial systems could significantly pre-date those of the larger ones, even if they are connected each other by glacial transfluences.

From volume estimates to carbonate production of Late Paleocene – Early Eocene calcareous nannofossil assemblages: a first step to reconstruct absolute abundances of calcareous nannoplankton

CLAUDIA AGNINI (*°), BIANCA DE BERNARDI (**) & ELISABETTA ERBA (**)

Key words: *Calcareous nannofossils, IODP, Paleocene – Eocene . volume/mass estimations.*

ABSTRACT

Stable carbon and oxygen isotope compilations available from the literature point out that the variations observed in the marine sediments deposited between 60 and 50 Ma are the most prominent of the entire Cenozoic. So far, our knowledge of early Paleogene depicts an articulated and complex evolution, which can be roughly described as a long term global warming trend interrupted by several hyperthermal events. In this paleoclimatic context, we are interested to reconstruct changes occurred in one of the major component of the past (modern) sea surface oceans: the calcareous nannoplancton. Paleoecological interpretations have been proposed based on classical palecological approaches, we instead indicate an alternative/auxiliary methodology which essentially consists of an estimate of carbonate flux of calcareous nannofossil assemblages.

In order to assess the role played in the carbonate budget by calcifying phytoplanktonic organisms, as carbonate producers, it is necessary to provide reliable estimates of the calcite secreted by calcareous nannoplankton, which certainly have had a vital role in the global carbon cycle since the Mesozoic Era by supplying organic carbon and calcium carbonate to the deep ocean.

Here, we present morphometric analyses of selected calcareous nannofossil taxa performed with the aim of providing volume and mass estimations of the most common species present in early Paleogene assemblages. Coccolith volumes (V) were calculated using a volume function, V=Ks*l3 (YOUNG & ZIVERI, 2000), which is direct ratio to a shape constant (Ks) and a characteristic dimension (l). These two parameters were estimated by means of multiple morphometric measurements and geometrical calculations. Study material includes samples from ODP Legs 198 (Shasky Rise), 208 (Walvis Ridge), 207 (Demerara Rise) and 171B (Blake Nose) and DSDP Leg 48 (Bay of Biscay) taken across the Middle-Late Paleocene interval (Fig. 1).

Preliminary results evidence that Ks values measured for every single taxon generally display a wide range of variation but, at the same time, very constant mean values if measured at different sites, eventually suggesting that Ks values given here represent a quite robust datum that can be used with a good degree of certainty in Paleocene-Eocene assemblages.

By contrast, the characteristic dimensions used to calculate volume values (l) show prominent variations both in time and space that is why we suggest caution in assuming a single mean value to each coccolith species and strongly recommend to perform morphometric analysis in every single study section before calculating volumes and masses of different coccoliths. Ks and l values calculated in this study allow us to estimate

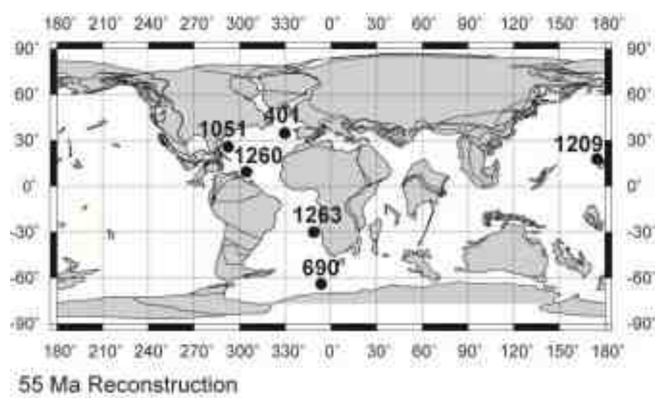

Fig. 1 - The location of sites considered in this study (DSDP 401 and ODP 690, 1051, 1209, 1260, 1263) are positioned on a paleogeographic map (equidistant cylindrical projection) at 55 Ma (http://www.odsn.de/odsn/services/paleomap/paleomap.html).

volumes and masses for several calcareous nannofossil taxa (Fig. 2), which represents the first step if we want to reconstruct the history of carbonate production of calcareous nannoplankton over time and possibly use this parameter as a paleoceanographic proxy of sea surface carbonate productivity during crucial paleoclimatic events, that will be our next step.

High resolution Upper Ladinian/Lower Carnian bio-chronostratigraphic correlations from the western Tethys to North America

MARCO BALINI (*), ALDA NICORA (*), JAMES F. JENKS (°), RICCARDO MARTIN (*), MICHELANGELO BLASI (*), MATTEO BRAMBILLA (*), STEFANO CANTINOTTI (*), ROBERTA MENGHIN (*), GIUSEPPE MOLINO (*) & ANDREA VISCONTI (*)

Key words: *Triassic, Ladinian, Carnian, Biostratigraphy, Chronostratigraphy, Correlations.*

INTRODUCTION

The GSSP (Global Stratotype Section and Point) of the Carnian stage has been defined in 2008 at Prati di Stuores/Stuores Wiesen (Dolomites) after 10 years of intensive research carried out on the most complete sections of the Tethyan Realm and North America. This intense activity was developed within the general framework of the IGPC 467 "Triassic Time and Trans-Panthalassan Correlations" and the Ladinian/Carnian boundary Working Group of the Subcommission on Triassic Stratigraphy.

Starting from 1998, three sections with the most complete record were selected for comparison: Prati di Stuores/Stuores Wiesen (Dolomites), Mud in Spiti Valley (Himalaya, India) and South Canyon (New Pass Range, central Nevada). These sections were sampled in detail, and a quite a lot of new data were published. The final decision of the Working Group of the STS, however, was taken in 2007 after a comprehensive discussion of the possible correlations, but before the publication of an integrated correlation chart of the best sections in the world. Aim of this presentation is to summarize the available data into an integrated correlation chart that includes also magnetostratigraphy and stable isotope variations.

TOOLS AND SECTIONS

The most important tools for bio-chronostratigraphic correlations of Upper Ladinian/Lower Carnian marine sections are the ammonoids, pelagic bivalves (daonellids and halobiids) and conodonts. These tools might be supplemented by palynomorphs and bentic forams. Magnetostratigraphy and stable isotope variations data are available from very few sections.

The best sections selected for correlations are Prati di Stuores/Stuores Wiesen (Dolomites), Mud in Spiti Valley (Himalaya, India) and South Canyon (New Pass Range, central Nevada), that are also compared with Sommeraukogel, Raschberg and Feuerkogel in the Northern Alps.

Prati di Stuores/Stuores Wiesen (Dolomites). This locality was extensively studied by a large team over ten years (BROGLIO LORIGA *et al.*, 1998; MIETTO *et al.* 2007; MIETTO *et al.* 2008). This section show the best record of ammonoids, but a rather poor record of pelagic bivalves.

Mud in Spiti Valley (Himalaya, India). A detailed bio-chronostratigraphy of this section was provided by KRYSTYN *et al.* 2004. This section shows an extremely rich record of daonellids, with the first occurrence of *Halobia*, and a good record of conodonts. The ammonoid content of the succession is unfortunately restricted to few fossil-bearing beds. A revision of the bivalve faunas is provided in the present study.

South Canyon (New Pass Range, central Nevada), is on the contrary characterized by good record of ammonoids and pelagic bivalves (BALINI *et al.* 2007; BALINI & JENKS, 2007; Balini, 2008), while the conodont record (ORCHARD & BALINI, 2007) demonstrates an environmentally controlled faunal change. New ammonoid data now available, allow to precisely recognize the FO of the ammonoid *Trachyceras*, traditionally considered as typical of the Lower Carnian, with respect to the record of *Daxatina*.

Northern Alps. Several localities of the Salzkammergut area are historically important for the definition of the Ladinian-Carnian chronostratigraphic scale of the Tethys. The sedimentary successions of this area are however strongly condensed, even if rich in macro and microfossils (see, KRYSTYN, 1980).

INTERGATED CORRELATIONS

The GSSP of the base of the Carnian is defined in the First

(°)1134 Johnson Ridge Lane, West Jordan, Utah 84084.

Lavoro eseguito bell'ambito del progetto PRIN 2008 "Stratigrafia integrata del Triassico supreiore: GSSP e sezioni ausiliarie in Italia" (coord naz. M. Balini), unità di ricerca di Milano.

Occurrence of the ammonoid *Daxatina canadensis* at level SW4 of Prati di Stuores section (MIETTO *et al.* 2007). This event was originally selected as the best recognizable event, with respect of the other options, that were the FO of the conodont *Paragondolella polygnathiformis* and the FO of the bivalve *Halobia*.

The integration of the data from literature with the revision of the bivalve faunas from Spiti and of the ammonoid fauna from South Canyon, improve the calibration of the most important bioevents and allow to demonstrate:

1. The strongly diachronous position of the FO of *Trachyceras* with respect to the FO of the Carnian marker *Daxatina*.
2. The diachroneity of the FO of *Halobia*, especially as regard the Tethyan record with respect to the north American record.
3. The value of the FO of the conodont *P. polygnathiformis* as the best secondary marker event for the Lower Carnian for its rather common occurrence in the sedimentary successions.

Evolutionary trends in *Nephrolepidina*: neanic acceleration and Golden Selection

ANDREA BENEDETTI (*)

Key words: Nephrolepidina, *Oligocene, Miocene, larger foraminifers, logarithmic spiral, Fibonacci sequence, Golden Section.*

INTRODUCTION

Nephrolepidina is a radial larger foraminifer with a biconvex hyaline test composed of a distinct equatorial layer and lateral chamberlets, and it is a well known genus from the Oligo-Miocene of Thethys, representing the Mediterranean Lepidocyclinidae. Three chronospecies are distinguished by biometrical indexes of Grade of Enclosure of the deuteroconch on the protoconch (A_i), and the number of adauxiliary chambers (C) on the deuteroconch (DE MULDER, 1975).

These routinely employed indexes are often hampered by the oscillation of the mean values along stratigraphic sections (e.g., Schiavinotto & Verrubbi, 1994).

Within lepidocyclinids, evolutionary trends of embryonic and nepionic acceleration with an increase of A_i and C mean values are well known. A third evolutionary trend was hypothesized by SCHIAVINOTTO (1994): the neanic acceleration, consisting in the tendence of the equatorial chamberlets to become more elongated through time.

In lepidocyclinids, chamberlets can be arcuate, rhombic, ogival, subhexagonal or spatulate, changing their morphology ontogenetically and philogenetically (ADAMS, 1987). The shape of chamberlets reflects the distribution of stolons between contiguous chambers and chamberlets, with basal circular stolons, and oblique distal stolons; particularly, in *Nephrolepidina*, each chamberlet commonly develops two distal stolons (EAMES *et alii*, 1962).

The aim of this work is to investigate the pattern of growth of equatorial chamberlets in the Mediterranean lineage of *Nephrolepidina*.

(*) Dipartimento di Scienze della Terra, "Sapienza" University of Rome. Pz.le A. Moro, 5. 00185 Roma.

GIRMM – Gruppo Informale di Ricerche Micropaleontologiche e Malacologiche.

MATERIALS AND METHODS

The equatorial chamberlets arrangement of specimens from five populations, representative of the three known species, have been investigated: two *N. praemarginata* populations, CVM76 from Valle del Maso (Northern Italy; SCHIAVINOTTO, 1978), and PCs0 from Portella Colla (Northern Sicily); *N. morgani*, sample T1 from Monte La Rocca (L'Aquila; MATTEUCCI & SCHIAVINOTTO, 1977); two *N. tournoueri* populations, TLS76 from Monte La Serra (L'Aquila, SCHIAVINOTTO, 1979), and AC5 from Ales (Sardinia; GIOVAGNOLI & SCHIAVINOTTO, 1990).

Inspecting an equatorial section of Nephrolepidina such as those of Fig. 1, the ogival to hexagonal-shaped chamberlets appear to be arranged in families of spirals. Counting the numbers of spirals in each family, we can easily arrive to consecutive numbers of the Fibonacci sequence.

The spirals forming the intersecting curves have been counted for each investigated specimen and vectorialized by the software CANVAS 12; the study of growth function was perfectioned by the software GRAPHER 7.

SPIRALS IN FORAMINIFERS

The spirals in nature, and particularly in foraminifers, have been described since the works of VAN ITERSON (1907) and sir D'ARCY THOMSON (1919) about the forms and the type of growth.

For example, larger foraminifers, such as nummulitids, are arranged in a logarithmic spiral, a marvelous spiral for which the radius grows exponentially with the increase in size, but the shape remains unaltered. The logarithmic spiral is self-similar and it looks the same at every scale.

VAN ITERSON (1907) introduced a model in which the spiral arrangement is densely packed. Each disk obtained defines two families of helixes. Apparently the arcs are related to Fibonacci numbers (1, 1, 2, 3, 5, 8, 13, 21, . . .), in which each number represents the sum of the previous two numbers. Besides, the ratio between two consecutive Fibonacci numbers tends to a very important number, the Golden number (1.618…), better known as Golden Section.

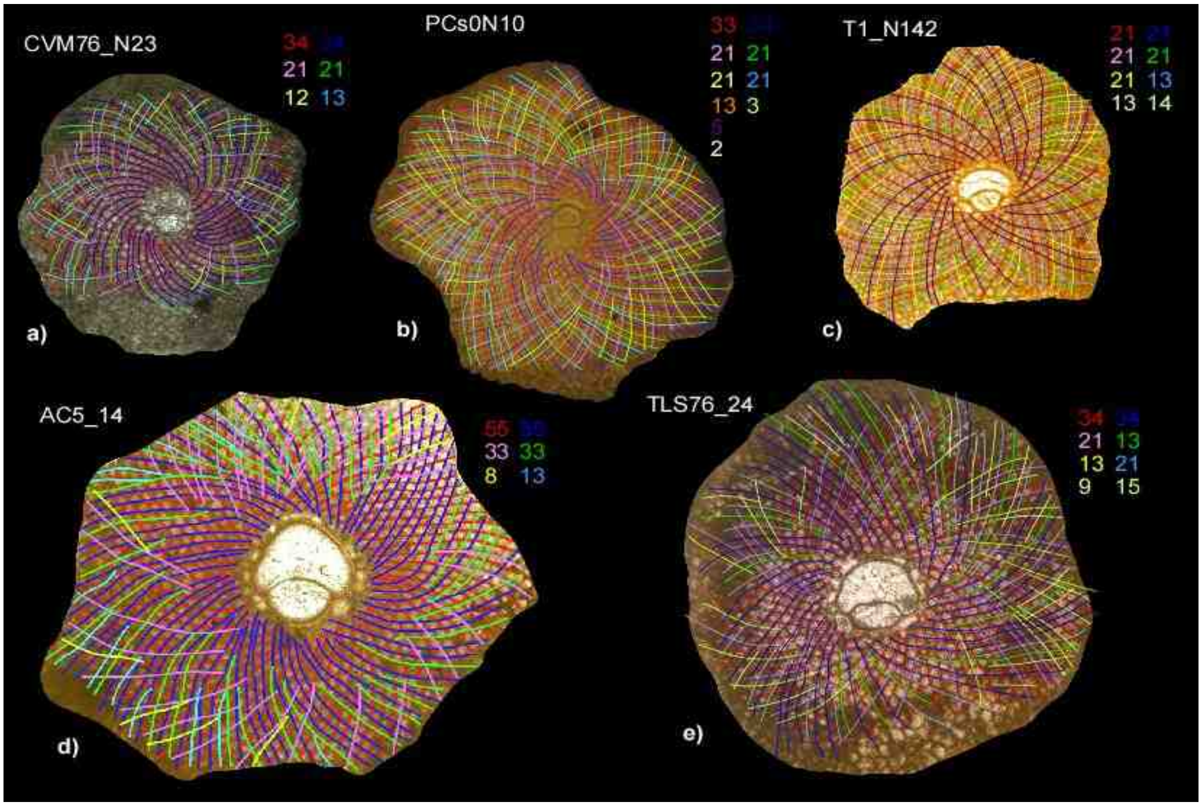

Fig. 1 – Spirals visible in the equatorial sections of *Nephrolepidina*. a-b) *N. praemarginata*; *c) N. morgani*; d-e) *N. tournoueri*.

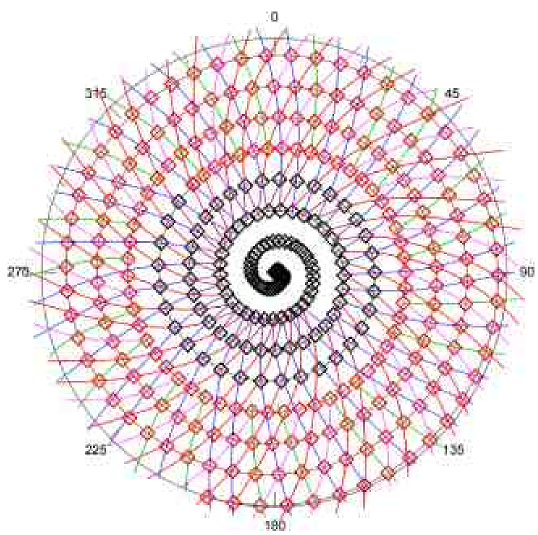

Fig. 2 – The ontogenetic growth of *Nephrolepidina*: a logarithmic spiral parametrized by the golden angle obtained by the software GRAPHER. The number of points increases from the 5th whorl. Joining the rhombs we obtain 34 clockwise spirals, 33 anticlockwise spirals, and 21 right and left secondary spirals.

RESULTS

In *N. praemarginata* about 34 primary clockwise and counterclockwise spirals occur, followed by 21secondary spirals, about 13 or 21 ternary spirals, and 13 in the fourth family of spirals, whereas in *N. tournoueri* we can count up to 55 spirals in the first order. 13, 21, 34, 55 are Fibonacci numbers. So, iIn *Nephrolepidina* up to 6 Fibonacci spirals occur, and they are an optical effect reflecting the growth of the equatorial chamberlets according to a logarithmic spiral (Fig. 2). Besides, the ratio between primary and secondary spirals, tends to phi according to the characteristic of the Fibonacci series.

The distribution of chamberlets, as above mentioned, depends from the direction of the stolons between contiguous chambers and chamberlets. In *Nephrolepidina praemarginata* the oblique stolons make an angle of about 120° respect the direction of the basal stolon (Fig. 3). In *N. tournoueri* the angle formed by the oblique stolons ranges from 133° and 137°, a value close to that of the golden angle 137.507°.

The ratio between the two embryonic diameters (D_{II}/D_{I}) was employed in the past as an alternative index for evaluate the grade of enclosure of protoconch by the deuteroconch in *Nephrolepidina* and seems to be directly correlated with the

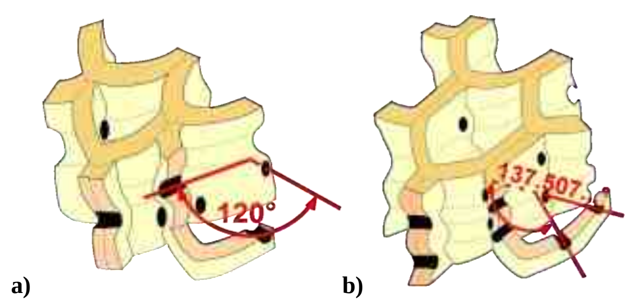

Fig. 3 – Equatorial chambelets in *Nephrolepidina* with emphasis on the direction of stolons between contiguous chambers and chamberlets; a) *N. praemarginata; b) N. tournoueri.*

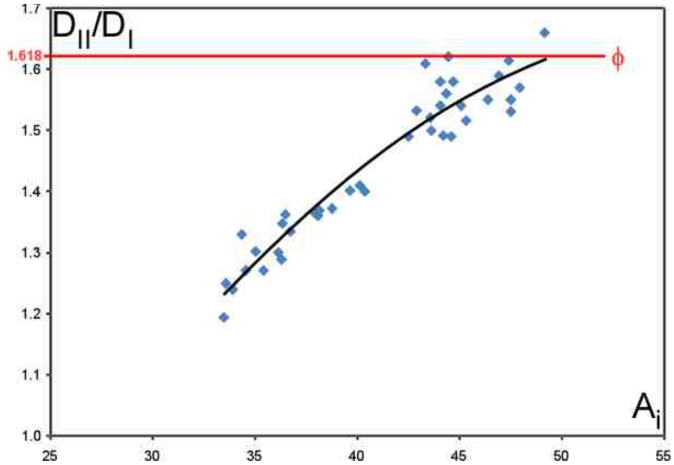

Fig. 4 – A_i vs D_{II}/D_I scatter diagram. Assuming the grade of enclosure A_i as time progressive, the ratio of the diameters of the two embryonic chambers D_{II}/D_I tends to the golden number with R^2=0.917.

grade of enclosure. But investigating the mediterranean lineage of *Nephrolepidina*, the ratio between the diameters of the embryonic chambers tends to phi, 1.618, the golden section (Fig. 4), and then *Nephrolepidina* becomes extinct.

The neanic acceleration proposed by SCHIAVINOTTO (1994) involves the increase in the length of the common wall between contiguous chamberlets, linked to the direction of stolons, but the data here reported allow me to suggest a new selective and evolutionary action: the Golden Selection.

Microfacies and biostratigraphical analysis on Paleogene-Neogene formations cropping out near Antrodoco (Central Apennines, Italy)

ANDREA BENEDETTI (*), MAURIZIO MARINO (°) & RITA MARIA PICHEZZI (°)

Key words: *Antrodoco, microfacies analysis, larger foraminifers, Q-mode HCA, Paleogene, Neogene.*

INTRODUCTION

The Geological Survey of Italy (ISPRA-Istituto Superiore Protezione e Ricerce Ambientale) is carrying on the field mapping of the Sheet 348 "Antrodoco", located between Latium and Abruzzi (Fig. 1).

The related research activities lead to the collection of a great amount of data useful for the reconstruction of the geological evolution of this part of the Central Apennines, characterized by lateral and vertical facies variations of the stratigraphic successions, and occurrence of regional tectonic elements (e.g., the Olevano-Antrodoco line). In the area different successions are exposed, spanning from the Upper Triassic to Upper Miocene interval. These successions document the sedimentation on carbonate platform, platform-basin-transition and basin environments, in different geodynamical frameworks.

This work aims to define some stratigraphic succession of Paleogene-Neogene age cropping out in the area of Sheet 348 "Antrodoco" (scale 1:50000).

MATERIAL

The work involves the micropalaeontological and biostratigraphical analysis of 69 thin sections, obtained from 63 rock samples, belonging to paleogene and neogene sedimentary successions.

The analysis was carried out through an optical microscope for the recognition of the larger foraminiferal assemblages, the benthic fauna, the accompaining taxa and the relative abundances of these bioclasts and textural types.

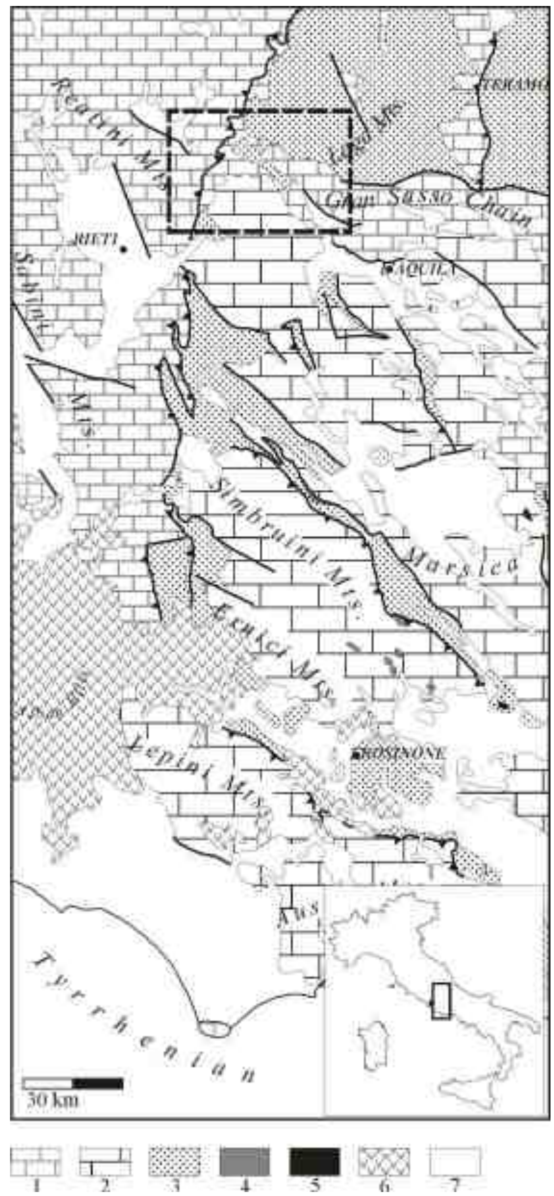

Fig. 1 – Location of the studied area. 1: Meso-Cenozoic transition-to basin deposits. 2: Meso-Cenozoic Latium-Abruzzi Carbonate Platform. 3: Upper Miocene-Lower Pliocene Foredeep siliciclastics. 4: Messinian clastic deposits and evaporites. 5: Messinian-Lower Pliocene thrust-top deposits. 6: Middle-Uppper Pleistocene volcanics. 7: Plio-Pleistocene and Holocene continental deposits (after PAROTTO & PRATURLON, 2004, modified and simplified).

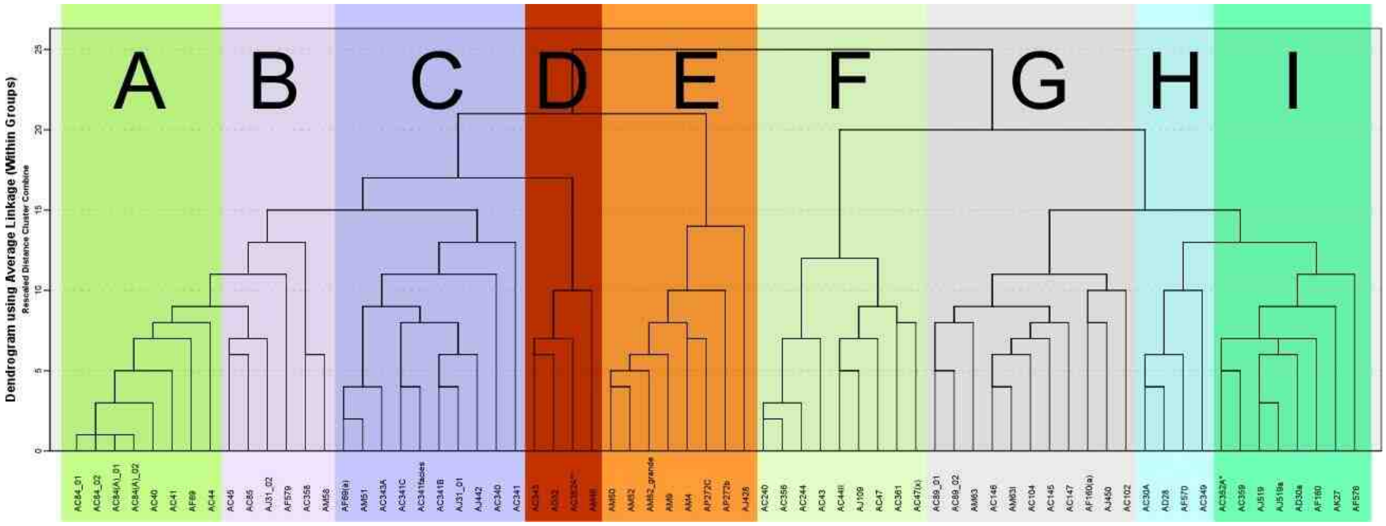

Fig. 2 – Dendrogram resulting from the Q-mode Hyerarchical Cluster Analysis.

We provide a taxonomic analysis of the benthic foraminiferal assemblages and of their accompanying faunas for biostratigraphic dating and paleoenviromental reconstructions. These data are integrated with microfacies observation and, furthermore, a statistical approach is attempted, through a semi-quantitative analysis based on the Q-mode Hierarchical Cluster Analysis (HCA).

The investigated samples are related to the following formations: Scaglia Rossa, scaglia detritica, Scaglia Cinerea, scaglia cinerea detritica, unità spongolitica, marne con Cerrogna.

Particular attention was paid to the study of larger foraminifers often displaced in deep environments by gravity and turbiditic flows. The classification of the investigated taxa at specific rank, when possible, allowed us to assign each sample to the Shallow Benthic Zones (SBZ) of CAHUZAC & POIGNANT (1997), for the Oligo-Miocene, and SERRA-KIEL *et alii* (1998) for the thethyan Paleocene to late Eocene.

RESULTS

The 69 thin sections investigated are grouped into nine main clusters by a Q-mode hierarchical cluster analysis, based on a dataset of 49 semiquantitative parameters, by combining the textural study of microfacies, relative abundance of constituents and taxonomic recognition of the microfaunas.

The cluster analysis allow us to group, as objective as possible, the samples in sets correlated to sedimentary environments and lithostratigraphic units, and it could hopefully helps to compare the Paleogene-Neogene sedimentary successions of the “Antrodoco” area with those of the whole Central Apennines.

The nine clusters resulted after the Q-mode HCA (Fig. 2) are: Cluster A: biodetritic bryozoans packstone-floatstone; B: unsorted packstone-wackestone-floatstone with common planktic foraminifers, bryozoans and red algae; C: planktic foraminiferal wackestone-packstone; D: poorly sorted biodetritic larger foraminiferal packstone; E: poorly sorted biodetritic larger foraminiferal packstone with micritic lithoclasts; F: spongolitic packstone; G: unsorted larger foraminiferal packstone-grainstone; H: larger foraminiferal packstone-wackestone; I: *Nephrolepidina*-bearing packstone-floatstone.

The analysed larger foraminiferal assemblages appear mostly allochtonous and displaced basinward by gravitative flows or turbidity currents, as for the so-called "brecciole a macroforaminiferi". These consist of benthic foraminiferal packstone-wackestone-floatstones, rare to common planktonic foraminifers, fragments of bryozoans, algae and echinids, and are grouped in cluster B (in part), C, D, E, H and I (in part).

The microfacies grouped in cluster A, B (in part), F and G, resemble those described by BARBIERI *et alii* (2004) for the "Guadagnolo Formation", both based on the textural characteristics and on fossil content. The identified microfacies are larger foraminiferal wackestone-floatstones (with frequent *Miogypsina* and *Nephrolepidina*), spongolitic packstones and *Amphistegina* bearing packstone-grainstones, with scarce to frequent peloids and red algae.

As regards the micropaleontological aspects, the occurrence of a new species of *Miscellanea* from Selandian, not referable to any known and recently revised species (HOTTINGER, 2009), is firstly reported. *Ornatorotalia granum*, *O. spinosa* and *Granorotalia sublobata*, easily recognizable in oriented and non oriented thin sections, are confirmed as excellent marker for the Cuisian (BENEDETTI *et alii*, 2011). For the Cuisian two forms, described by VECCHIO (2003) as Rotaliidae n. gen. 1 and Rotaliidae n. gen. 3, are reported.

Depth distribution of *Amphistegina* from Lamu Archipelago (Kenya)

ANDREA BENEDETTI (*) (°), JOHANNES PIGNATTI (*) & RUGGERO MATTEUCCI (*)

Key words: *larger foraminifers, bathymetry, nummulitids, biometry.*

INTRODUCTION

The Amphisteginidae is one of the most studied familes among the symbiont-bearing larger foraminifers. They live on firm substrates, both reefal and phytal (HALLOCK, 1999), and may also occur on sandy substrates (HOHENEGGER, 1994). In the Indo-Pacific region, *Amphistegina* spp. shows a distinct depth zonation, following the depth distribution of the different species according to the test morphology (LARSEN, 1976; LARSEN & DROOGER, 1977; HALLOCK, 1979; HALLOCK & HANSEN, 1979; HALLOCK *et alii*, 1986).

The aim of this work is to analyse the depth distribution and the relative percentage of abundance of the amphistegines from the shallow-water continental platform of an oligotrophic environment with carbonatic sedimentation, and subordinate siliciclastic supply from the continent.

PREVIOUS STUDIES

The depth distribution of *Amphistegina* and the test and wall thickness are influenced by several factors such as temperature (HOLLAUS & HOTTINGER, 1997), salinity of the bottom water and illumination (e.g., HOTTINGER, 1997); for example the shallow-water dwelling species *A. lobifera* requires higher light intensity than other species for reproduction (HALLOCK, 1981).

Moreover, the test and wall thickness reach their maximum in shallower water where biomineralization is favored by light intensity and water motion (HALLOCK *et alii*, 1986), and the thicker walls prevent the photoinibition of symbiont algae (HALLOCK, 1981).

The shallowest-dwelling Indo-Pacific taxon, *A. lobifera*, is the most robust, reaching the highest values of the thickness/diameter ratio (*t/d*>0.6) (HALLOCK, 1999). This species dominate in shallow backreef and reef-margin environments at depths typically < 10 m, and it is un common to rare below 40 m of depth, becoming absent at about 80 m (HANSEN & BUCHARDT, 1977).

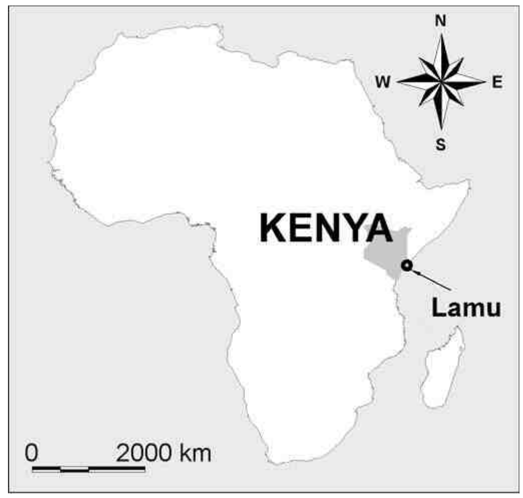

Fig. 1 – Location of the investigated area.

The range of *A. lessonii* (*t/d*=0.35-0.5) usually overlaps with that of *A. lobifera*, with known optimum depths at 10-40 m (HANSEN & BUCHARDT, 1977; HOHENEGGER 1994; HALLOCK 1999), reaching 85 m in the Gulf of Elat (HANSEN & BUCHARDT, 1977; REISS & HOTTINGER, 1984).

Living *A. lessonii* can range from the shallow subtidal depths down to depths of 100 m according to water transparency (HALLOCK, 1999).

Amphistegina radiata (Fichtel & Moll) is common from 20 to 50 m, and occurs down to 100 m depth (HALLOCK, 1999; HOHENEGGER, 1994), but it is absent in the Gulf of Elat; HOTTINGER *et alii* (1993) reported a very small *A. radiata*-like form, living at deeper habitats than those found in the western Pacific.

A. bicirculata Larsen has a thin test (*t/d*=0.2–0.35) (LARSEN, 1976; HALLOCK, 1979); it is commonly absent at depths < 30 m, and can be easily recovered at depths > 100 m.

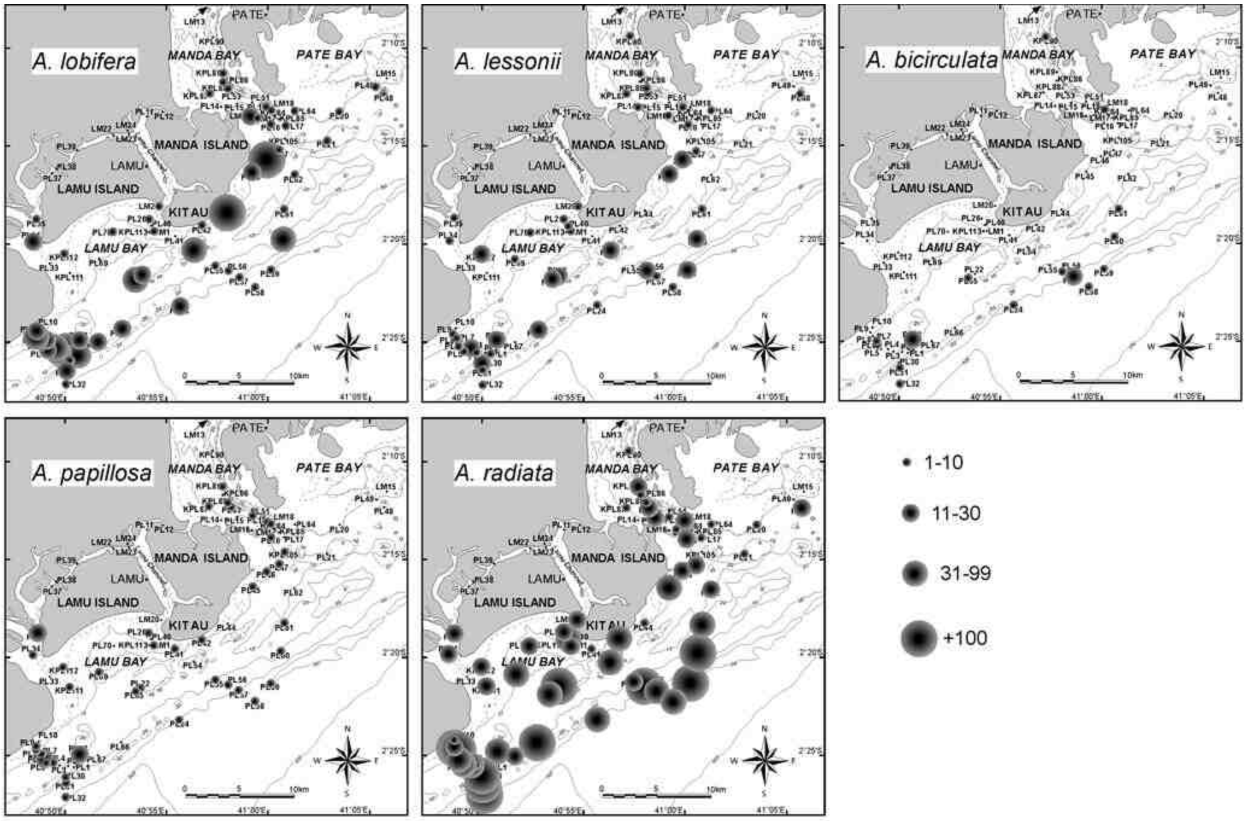

Fig. 2 – Depth distribution of the *Amphistegina* species in Lamu Archipelago.

Amphistegina papillosa Said is the deepest dwelling form of the genus with a test flat with several papillae on test surface, and lives at depths > 100 m where the availability of light is minimal (LARSEN, 1976).

THE INVESTIGATED AREA

The investigated 55 samples were collected in the 1990's from researchers of the Earth Sciences Department of "Sapienza" University of Rome, and of the Centro di Studi per il Quaternario e l'Evoluzione ambientale (C.N.R.) from the Lamu Archipelago, noth-eastern Kenya (Fig. 1), not far from the Somalian border. This area had never been studied previously and a single work exists on the microfaunas of its littoral environments (PIGNATTI *et alii*, 2012).

Lamu, Pate and Manda, the main islands of the archipelago, are characterized by a level land with mangrove-dominated coasts, and are branched by some canals scoured by powerful tidal currents which reach inner areas from the bays. These canals have a coarse and well-washed quartz-dominated floor, and the turbidity of the water is always high because of the organic matter decay, due to the mangroves activity (CARBONE & ACCORDI, 2000).

The continental shelf is covered by bioclastic carbonatic sand with local patch reefs and fringing reefs parallel to the coast-line at about 0.5-2 km.

MATERIALS AND METHODS

Sediments were washed in freshwater, sieved at 125 µm and air dried. Where possible, about 300 foraminifers were picked from each sample, the foraminifers were counted and identified to species level using mainly the illustrated inventory of HOTTINGER *et alii* (1993), and the results are reported in PIGNATTI *et alii* (2012).

From each assemblages we provide to isolate and counte all the *Amphistegina bicirculata*, *A. lessonii*, *A. lobifera*, *A. papillosa* and *A. radiata* specimens in order to note their relative abundance.

RESULTS

The five recovered species co-occur in most of the investigated samples, as summarized in Fig. 2.

In the Lamu embayment, the amount of skeletal carbonate production is low near channel mouth areas and the accumulation rates are linked to water energy conditions; moreover, from the shelf towards the coastline there is a progressive increase of quartz grains within the sediments (PIGNATTI *et alii*, 2012).

In the open shelf, between the coast and the island alignments, a shallow-water carbonate sedimentation prevails, with bottom sediments formed of sand and muddy bioclastic sand.

The relative frequence of the five species reveals a compressed depth distriburion range, as a consequence of water turbidity, sediment transport, nutrient input linked to tidal or water current effects, and especially to terrigenous supply from the continent; these factors affect the interpretation of depth signals in recent and fossils larger foraminiferal asseblages (HOTTINGER, 1997). Mangroves play also a key role of sediment trapping, reducing terrigenous input to the carbonate factory, and all the above mentioned factors involve in the contraction of the trophic resources continuum (HALLOCK, 1987).

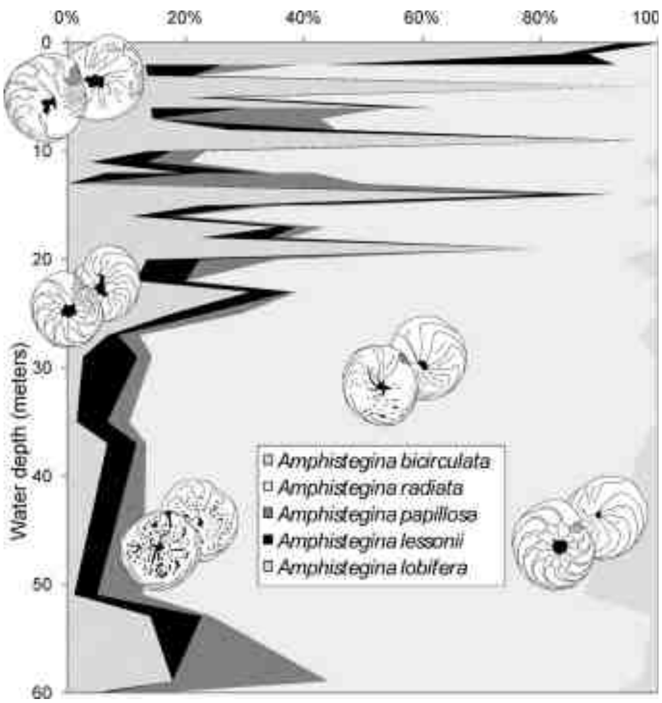

Fig. 3 – Depth distribution of the *Amphistegina* species in Lamu Archipelago; species illustrations from REISS & HOTTINGER (1984).

Amphistegina lobifera is well represented in the shallowest samples, down to 25 m. In particular, the distribution depth of *Amphistegina papillosa* and *A. bicirculata* is much shallower than that recorded from the Gulf of Elat (REISS & HOTTINGER, 1984) (Fig. 3).

The Pleistocene coralgal carbonate bioconstruction of Punta Diamante, southern Italy: a preliminary study

MARIA PIA BERNASCONI (*), MASSIMO CEFALÀ (*) & EDOARDO PERRI (*)

Key words: *biofacies association, coralgal bioconstruction, palaeoenvironment evolution, Pleistocene, Punta Diamante.*

Several Pleistocene small-scale coralgal bioconstructions are reported along the Calabrian Tyrrhenian coast, associated with clastic deposits and belonging to four orders of marine terraces. The present study focuses on Punta Diamante outcrop where a carbonate bank, mainly composed of *Cladocora caespitosa* colonies and coralline algae, has been preliminary sampled. The purpose of the study is to achieve a palaeoecological reconstruction to better define the palaeoclimatic evolution of the area during the Quaternary.

The examined outcrop is located close to the outlet of the Corvino river, on the hydrographic left, and develops from the present mean sea level up to few meters above it. The bank is exposed along a palaeocliff, lying on the metamorphosed limestone of the Ligurian ophiolithic complex; it represents the sedimentary cover, > 300.000 yrs in age, of the IV order terrace (Carobene and Ferrini, 1993).

Three palaeomorphological marine settings have been recognized: a sub-vertical cliff, an abrasion platform and a cave, and three main biofacies associations were distinguished on the basis of the field-work and the thin section analysis. 1) *Cladocora c.* bioherm: sub-hemispherical facelloid colonies of *Cladocora caespitosa*, 40-50 cm high, contiguous and in part coalescent, that form a meter-thick bioherm on the Jurassic bedrock. A variable amount of detritus fills the primary cavities among corallites and colonies; it is composed of micrite-cemented sandy to gravel litho-clasts and skeletal fragments. 2) Algal encrusted deposits: laminar to domal boundstones of crustose coralline algae (mainly *Lithophyllum* sp.), up to 10 cm thick, that represent at least the 50% in volume of a micrite-cemented clastic deposit, coarser than the previous one. These two biofacies associations can be observed on both the cliff and the abrasion platform. 3) A *Spondylus* sp.-rich deposit has been found in the palaeocave environment. This biofacies is characterized by abundant right valves of the scallop species cemented on the calcareous crust that cover the cave walls. Moreover, several encrusting and/or borer organisms such as bryozoan, forams, polychaete, bivalves and gastropods and echinoids remains, have been detected associated with the three biofacies.

The spatial distribution of the biofacies associations suggests an ecologic zonation and an evolution of the bioconstruction, as a whole, in relation to climatic fluctuations during a warm - temperate interval, as well as to others environmental factors such as depth, energy level, light intensity and nutrient supply.

Despite its present nearcoast location, the bioconstruction experienced a continental diagenetic phase suggested by the presence of phreatic meteoric cements that fill most of the cavities.

More information on the evolution of the bioconstruction could be obtained by performing further analyses, such as radiometric datings on autochthonous skeletons, geochemical and stable isotopes measures.

X-ray microtomography as a tool to present and discuss new taxa: the example of *Risananeiza* sp. from the late Chattian of Porto Badisco

ANTONINO BRIGUGLIO (*)(°) & ANDREA BENEDETTI (°) (^)

Key words: *Rotaliidae,* Risananeiza*, microCT, biometry.*

INTRODUCTION

In many earth science studies, especially in palaeontology, examination and/or measurement of internal features of samples are routinely requested.

X-ray computed tomography (CT) is for such tasks very well suited (CARLSON *et alii*, 2003). A variety of different X-ray CT instruments and techniques are now available: they can scan objects of a size range from less than one millimeter, to many decimeters and they can scan at different resolutions: from less than one micron (nanoCT) to one or a few microns (microCT), and up to the millimeters range (CT). The best-known advantage of X-ray CT is its ability to reconstruct quickly and non-destructively the interior of opaque solid objects in three dimensions when the density contrast is high enough to let the X-ray differentiate the internal features (NEUES & EPPLE, 2008; METSCHER, 2009). The computed tomography is thus a powerful tool for biometric study as the obtained scans are scaled according to the reported voxel size and therefore suited for linear and volumetric measurements (SPEIJER *et alii*, 2008; BRIGUGLIO *et alii*, 2011; GÖRÖG *et alii*, 2012; HOHENEGGER & BRIGUGLIO, 2012).

For many fossils, the X-ray CT may be the only practical means of gaining information on internal materials and geometries or other features hidden from external view (e.g., SPEIJER *et alii*, 2008). So far, the X-ray tomography is a well known technique and is extensively used in several earth science disciplines. As computed tomography allows quantification of the scanned material in all 3 spatial dimensions, the metric and biometric analyses represent the main field of application for x-ray methodology.

The description of fossil forms and the quantification of some morphologic relevant parameter are the keys to investigate fossils for taxonomic purposes, and consequently for paleoenvironmental analyses and for biostratigraphic purposes. Measuring morphologic parameters of shells, bones or tests requires often the destruction of part of the body, or oriented cuts through the test. Since the prices for x-ray computed tomography working stations have became available for academia, the use of such technique is spreading in many geological and paleontological research institution.

MATHERIAL AND METHODS

In this study, we used high resolution x-ray tomography to run some measurements on well preserved tests of fossil foraminifers, in particular we have investigated two specimens of a new rotaliid. With dedicated 3D graphic working station at the department of Palaeontology in the University of Vienna, all chambers of the foraminifer have been segmented, rendered and on the extracted three dimensional objects, the reported parameters have been measured.

A new species has been detected and studied by means of x-ray tomography. The specimens have been collected from the type locality of the Porto Badisco Calcarenites, which is the Porto Badisco cove, 8 km south of Otranto, in the Salento Peninsula. PARENTE (1994) defined the stratigraphy of the Upper Cretaceous to Oligocene deposits of Salento Peninsula (Southern Apulia), and assigned the Porto Badisco Calcarenites Formation to the late Chattian (Late Oligocene) according to the fossil content.

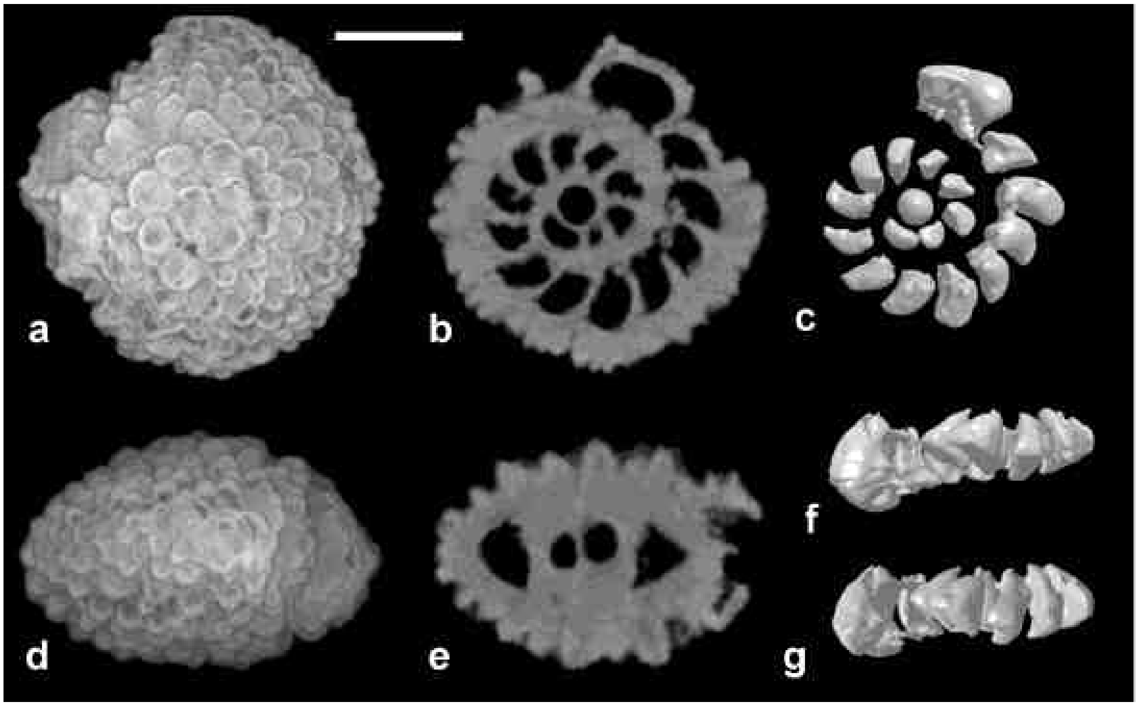

Fig. 1 – Risananeiza sp., possible holotype scanned with microCT (MPURNS161.1). a) External test in equatorial view. b) Equatorial section. c) Chamber lumen in equatorial view. d) Test in axial view. e) Axial section. f-g) Chamber lumen in axial section, note the slowly trochospiral arrangement of the chambers. Scale bar = 0.5 mm.

RESULTS

The new species has been preliminarly named *Risananeiza* sp. as it possesses all morphological features of the relative forms of the genus *Risananeiza* (Boukhary *et alii*, 2008). Detailed biometry on the type material, and the complete description of the new species, are under review by the Bollettino della Societá Paleontologica Italiana.

Since the dataset obtained by x-ray scanning is digital, it can be upload and shared with the scientific community so that the 3D model of the holotype can be seen and studied by everyone (Fig.1). Complete stacks of the holotype sliced on the equatorial (Fig.2) and on the axial planes (not given here), most important for taxonomic purposes, are also reported.

Multidisciplinary study of a new Quaternary mammal-bearing site from Ellera di Corciano (central Umbria, Italy): preliminary data

MARCO CHERIN (*), ROBERTO BIZZARRI (*), NICOLETTA BURATTI (*), TIZIANA CAPONI (**), FRANCESCO GROSSI (°), TASSOS KOTSAKIS (°), LUCA PANDOLFI (°), FAUSTO PAZZAGLIA (*), MASSIMILIANO R. BARCHI (*)

Key words: *calcareous tufa, geotechnics, intermontane basin, fossil mammals, ostracods, palynology, sedimentology*.

A new fossil mammal-bearing site was discovered at Ellera di Corciano (PG) on April, 2011 in a building site where a large mall is under construction. The first bones were recovered by one of the Authors (T.C.), during a survey for archeological purposes. Excavations were funded and directed by the Soprintendenza per i Beni Archeologici dell'Umbria, with the scientific and technical support of the Department of Earth Sciences, University of Perugia.

The presence of fossil mammals in the Ellera area has been already reported by PETRONIO *et alii* (2002) and ARGENTI (2004), who cited a small association recovered from the "ex-Lancia De Poi" site and referable to the upper Villafranchian; this fauna is currently in course of revision because it has been found within the same clay levels that outcrop in the site described in the present work, just few hundred meters SE.

The Ellera area is part of a sedimentary basin whose genesis started in the Early Pleistocene, with a progressive isolation from the easternmost, larger Tiber basin. The evolution of the Ellera basin was controlled by synsedimentary tectonics, in extensional regime.

The stratigraphic section (more than 16 m thick) in the mammal-bearing site is the following:

- 0.00-3.15 m: *calcareous tufa* (phytoherm, phytoclastic, micrite) with cavities filled by red clays;

- 3.15-7.62 m: clay and silty clay with two thin levels (10 cm) of phytoclastic *tufa*. Clays show a strong pedogenesis (root traces, $CaCO_3$ nodules), contain pulmonate molluscs and are rich of organic matter, especially in the upper part;

- 7.62-16.30 m: prevalent phytoclastic and phytoherm *tufa* alternating with clay and silty or sandy clays. Siliciclastic levels present evidences of pedogenesis, while *tufa* levels host cavities filled by red clays.

A sedimentological and geotechnical survey, including grain size analysis and determination of Atterberg's limits, and the evaluation of $CaCO_3$ percentage with the Dietrich-Frühling calcimeter, was carried out along the section, aimed to a comprehensive characterization of the main clay horizons. Measured values highlight the main lithological changes (alternation between clays and *calcareous tufa*); furthermore, minimal variation among fossiliferous clay levels are also recorded, indicating minor transitions between different depositional systems (flood deposits, distal alluvial fan deposits, etc.).

Excavations for paleontological purposes were carried out till August, 2011 and allowed to recover more than 200 vertebrate specimens, mainly referred to large mammals. Recovery methods were partially borrowed from archeological field methods: each specimen was numbered and photographed, and its absolute position and height was registered with a GPS instrument, in order to place them on a digital map. The realization of a 3D model of the area, with the topographic position of each sample together with some anatomical and taphonomic characteristics (type of bone, presence/absence of articulation, fragmentation, etc.), is currently in progress.

Bone samples were discovered within three different clay levels in a span of ~ 3 m (height of the lowest specimen: 246.2 m; height of the highest specimen: 249.4 m above sea level). In the lower mammal-bearing level, called "hippo level", a partial skeleton of *Hippopotamus* cf. *H. antiquus* was found, together with other isolated and fragmented bones. Most of the collection (more than 100 samples) was recovered from the intermediate level; the state of preservation was good on the whole, even if almost all the bones were fragmented, suggesting a certain degree of water transport. In the upper level, a partial skeleton of *Mammuthus* sp. was discovered; it is composed by both the tusks, some vertebrae, and an almost complete posterior leg. Just below the "mammoth level", some very bad preserved bones were collected from a single clay level showing an advanced state of pedogenesis; bones were all fragmented, white-colored, and their surface was cracked with a "mosaic" pattern, suggesting a longer exposition to subaerial conditions.

Beyond the above-mentioned *Hippopotamus* cf. *H. antiquus* and *Mammuthus* sp., the other recognized taxa are: *Panthera* cf. *P. gombaszoegensis*, *Axis eurygonos*,

(*) Dipartimento di Scienze della Terra, Università degli Studi di Perugia

(°) Dipartimento di Scienze Geologiche, Università degli Studi Roma Tre

Fig. 1 – Partial skeleton of *Mammuthus* sp. before its recovery. In the background, the building activities was in progress. Length of the white folding rule: 2 m.

Praemegaceros cf. *P. verticornis*, *Bison degiulii*, and *Equus* sp. Scanty remains of small vertebrates are preliminarly referred to Emydidae, Soricidae and Arvicolidae indet. Some coprolites have also been found.

Praemegaceros cf. *P. verticornis* is represented by three basal portions of antler, belonging to an adult and two juvenile individuals. They show strong affinities with the antlers of *P. verticornis* from Ponte Galeria, that is considered a primitive form of this species, referred to the subspecies *P. verticornis dendrocerus* by AMBROSETTI (1967), and to the forerunner species *P. pliotarandoides* by CROITOR & KOSTOPOULOS (2004). The large deer remains from Ellera noticeably differ both from *P. obscurus* from Pietrafitta and *Eucladoceros* spp. from different Italian sites.

Bovid remains are quite abundant and represented by cranial and post-cranial elements. All the remains lack the typical characters of the Villafranchian genus *Leptobos*, while they show high similarities with *B. degiulii* from Pirro Nord and Capena.

From a biochronological point of view, the occurrence of *Praemegaceros* cf. *P. verticornis* and *B. degiulii* suggests an attribution to the early Galerian, and probably to the Colle Curti Faunal Unit (~ 1.05 Ma), whose type locality is located just few km East from the Umbria-Marche boundary.

Both micropaleontological and palynological analyses are currently in progress in order to depict the paleoenvironmental conditions. Preliminary micropaleontological results show that the lower sample (“hippo level”) yielded few ostracod valves referable to *Cyprideis* sp. instars, and the same very scanty and monospecific assemblage with *Cyprideis* sp. instars has been recognized also in the intermediate sample, testifying for both samples a very shallow oligohaline waterbody. The upper sample (“mammoth level”) yielded an abrupt change in the ostracod assemblage: biodiversity and frequency increased, with *Ilyocypris gibba* and *Candona* sp. juv. as dominant species, accompanied by *Potamocypris* sp., *Pseudocandona* sp. and *Heterocypris* sp. (fragments), testifying a shallow and freshwater permanent waterbody more suitable to host benthic association.

At the state of the art, the integration of sedimentological and micropaleontological data allows to infer two principal depositional environments: a periodically flooded alluvial plain, with ponds and mires (deposition of clays, silty and sandy clays, paleosols) and a lacustrine/palustrine environment (deposition of calcareous tufa).

Evolutionary patterns of genus *Discoaster* in selected time intervals and correlation to paleoenvironmental changes

CIUMMELLI MARINA (*), GARZARELLA ADELE (*) & RAFFI ISABELLA (*)

Key words: *Discoaster evolutionary trends, late Paleocene, middle-late Miocene, paleoecological affinity.*

ABSTRACT

Semi-quantitative analyses of calcareous nannofossil assemblages have been carried out on upper Paleocene (Atlantic Ocean, ODP Site 1262) and middle-upper Miocene (Eastern Equatorial Pacific Ocean - EEP, IODP Site U1338) sediments, with the aim of reconstructing distribution and evolutionary trends of selected taxa of calcareous nannofossils. The availability of complete stratigraphic successions for the considered intervals allowed us to study a complete fossil record that is a prerequisite for depicting in detail evolutionary signals. This study focuses on the genus *Discoaster*, whose stratigraphic range encompasses the middle Paleocene – late Pliocene time interval and is characterized by a dynamic evolutionary history punctuated by extinction and speciation events and episodes of turnovers and renewal within assemblages (BUKRY, 1971, 1973; HAQ, 1971; PERCH-NIELSEN, 1977, 1985; ROMEIN, 1979; THEODORIDIS, 1984; BACKMAN, 1986; RAFFI *et alii*, 1998; AGNINI *et alii*, 2007, 2008). The genus *Discoaster* is considered sensitive to productivity pressure and nutrient availability (BUKRY, 1973; AUBRY, 1992; CHEPSTOW-LUSTY, 1996), resulting in having preferences to oligotrophic and warm water environments (EDWARDS, 1968; BUKRY, 1973; AUBRY, 1998; BRALOWER, 2002).

Morphometric analyses accompanying the delineated abundance patterns provided a clear taxonomy of the considered *Discoaster* species. We tried to relate the observed changes, in terms of abundance and taxonomic composition, within the assemblages to the global and local paleoenvironmental changes in such different time slices. The consistent occurrence of specimens with intermediate morphologies between species, described the structure of the *Discoaster* lineage and validated evolutionary links. Eventually, it has been possible to compare the mode and timing of the evolutionary events in the late Paleocene with those of the middle-late Miocene, and this contributed to understand the evolutionary mechanisms acting on this genus. The relationships between evolution and global climate/environmental changes as the Paleocene Eocene Thermal Maximum - PETM (KENNETH & STOTT, 1991; RAFFI *et alii*, 2005, 2009; RAFFI & DE BERNARDI, 2008) and the different stages of the Miocene climatic transition (i.e., the development of the Eastern Antarctic Ice Sheet, the middle-late Miocene "Carbonate Crash", and the deposition of diatom enriched sediments; VINCENT & BERGER, 1985; KEMP & BALDAUF, 1993; LYLE *et alii*, 1995) have been investigated through comparison with geochemical proxies ($\delta^{18}O$, $\delta\ ^{13}C$, Fe, %$CaCO_3$; ZACHOS *et alii*, 2010; LYLE & BACKMAN, in press).

Moreover, *Discoaster* taxa with unusual paleoecological preference have been identified in the upper Miocene interval of the EEP. This peculiar character of the nannofossil assemblages is related to biosiliceous deposition in the EEP and shows an intriguing correlation with similar upper Miocene Mediterranean sediments (STRADNER, 1973; RAFFI *et alii*, 2003; HILGEN *et alii*, 2010).

Evidence for microbial life in deep time: a geomicrobiological investigation using fluid inclusion studies

ALESSANDRA COSTANZO (*), EMMA MC NULTY (*), MARTIN FEELY (*), TIM LOWENSTEIN (**), ROCCO DOMINICI (***) & JOAN CARLES MELGAREJO (****)

Key words: *evaporite, extremophile, fluid inclusions, halophilic archea, prokaryotes.*

ABSTRACT

Fluid inclusions in evaporite-forming minerals are a suitable environment for extremophile life forms. Halite and gypsum from four different worldwide localities ranging in age from Permian to present time are used to investigate microbial life forms are trapped and preserved within fluid inclusions in these crystals.
Previous investigations on this subject (REISER *et alii*, 1960; NORTON & GRANT, 1988; SCHUBERT *et alii*, 2009) proved the presence of halophilic bacteria inside halite crystals of Permian age by observing the growth of the organisms on external media. The bacteria were deemed to be the same age as the crystals, leading to the possibility that ancient microbes might be present in other evaporite deposits around the world. MCGENITY *et alii*, (2000) proposed the possibility that microorganisms could survive in fluid inclusions as long as nutrients, such as carbon, which they require to survive can be trapped in the inclusions with them. However, it was more difficult to postulate how these nutrients could last for such a long time. They proposed that the halophilic organisms could remain dormant over geological time, until "awoken" upon collection. This finally suggested that studying fluid inclusions could be a way to observe ancient life and its environments.

Evidence presented here demonstrates that living microbes exist in brine-filled fluid inclusions in recent evaporite deposits from Searles Lake, California (Fig. 1), similar to those recorded by LOWENSTEIN *et alii*, (2011) from halite deposits up to 150ka in age from Death Valley and Saline Valley in California. The Searles Lake halite-hosted fluid inclusions contain micro-ecosystems with living microbes whose survival is dependent on the coexistence of nutrients within the enclosed brine (*e.g.*, algal carbon from *Dunaliella sp.*), (Fig. 2). Fluid inclusions from modern (surface deposits collected 1993 and 1994) halite deposits, host live prokaryotes which remained motile for up to 15 months after collection. The older prokaryotes from ancient (10-100 Ka) halite deposits, showed a random zigzag pattern of movement which indicated Brownian motion, meaning the prokaryotes were not alive. SCHUBERT *et alii*, (2010a) cultured halophilic archaea from halite deposits of Death Valley, California. They determined that these archaea could remain viable for 10,000 to 100,000 years inside the halite crystals
Comparisons are made between the microscopic evidence for microbial life trapped in recent fluid inclusions in halite from Searles Lake (Middle Pleistocene) and fluid inclusion evidence from evaporites from the Kingscourt gypsum, Ireland (Upper Permian), the Valencia, Teruel and Almería Province, Spain (Lower Triassic), the massive selenite facies of the Upper Evaporites (Messinian 5.3 to 5.5 Ma) in the Catanzaro Trough, Italy (Cianflone & Dominici, 2011) and halite from the Detritico Salina Formation in the Crotone Basin, Italy (Messinian 5.5 to 5.6 Ma) (LUGLI *et alii*, 2007).

Fig. 1 – Sample of recent halite from Searles Lake, Death Valley California

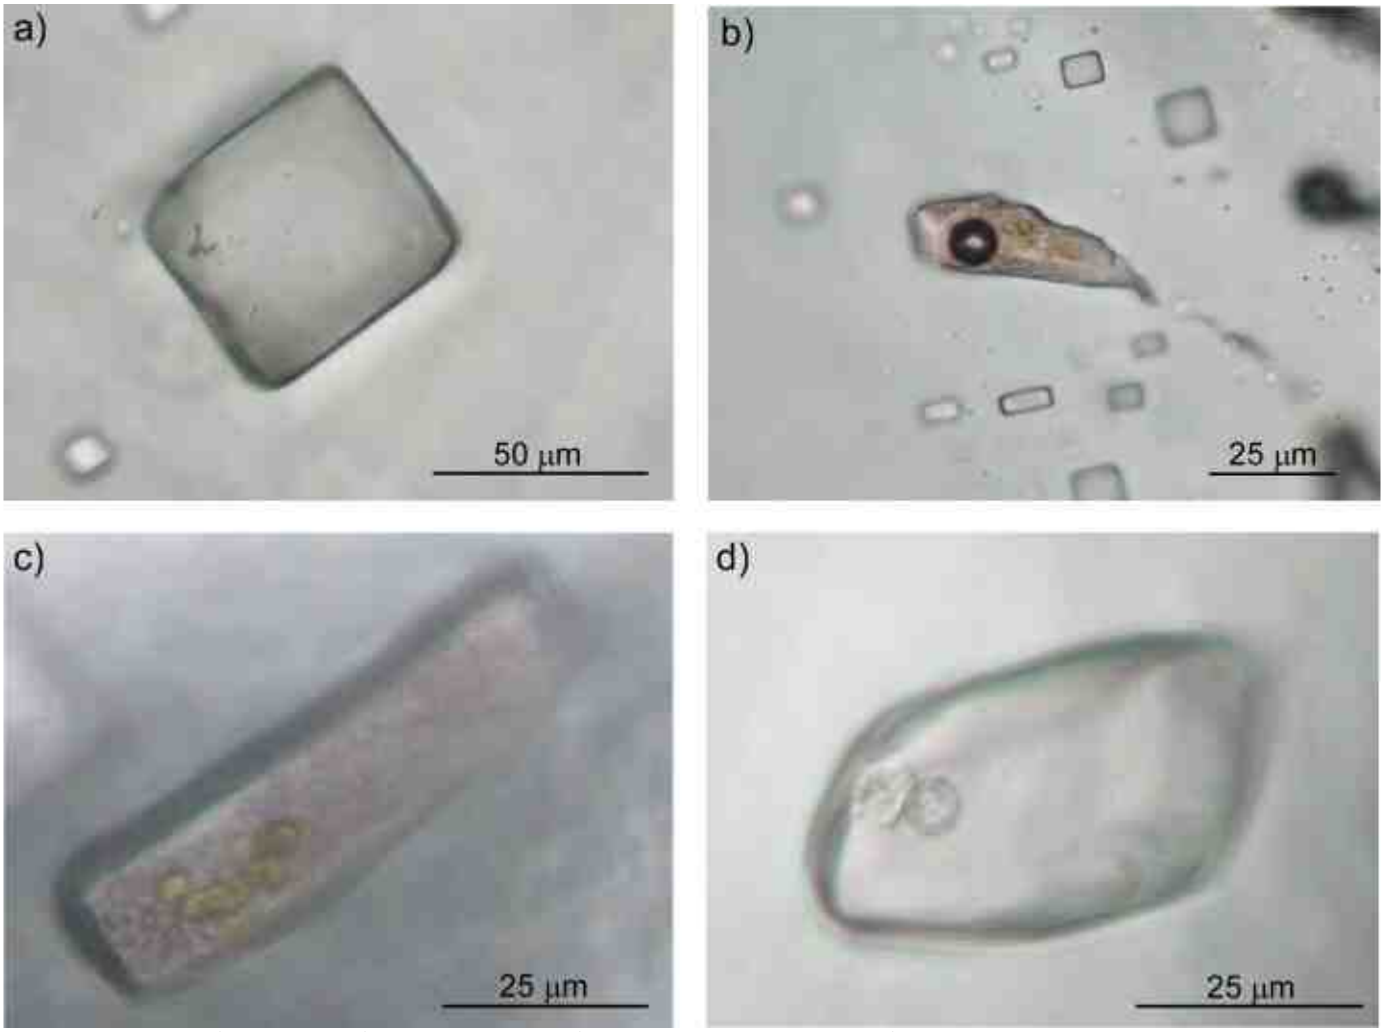

Fig. 2 – Halite hosted fluid inclusions from Searles Lake, California. a) Negative crystal shaped fluid inclusion containing both coccoid and rod-shaped prokaryotes; b) spherical *Dunaliella* cells and pink organic material filling an irregular fluid inclusion; c) rectangular monophase inclusion containing both spherical *Dunaliella* cells and pink organic material; d) large irregular shaped inclusion containing two spherical *Dunaliella* cells.

Fluid inclusion petrography and microthermometry combined with UV microscopy and Raman spectroscopy indicates the presence of similar organic material within halite and gypsum hosted fluid inclusions from these deposits.

The results of this study show that organic material is trapped and preserved in fluid inclusions in halite and gypsum hosts for more than 250 million years. Mars has an Earth-like environment, therefore if evaporite deposits formed on Mars, there is potential for similar fluid inclusion hosted organic material, extinct or even extant life to be found on the Martian surface.

Late Holocene paleoenvironmental evidences from foraminiferal assemblages in the Northern Tyrrhenian Sea (Southern Tuscany, Italy)

V. FREZZA (*), M.G. CARBONI (*) & L. DI BELLA (*)

Key words: *benthic and planktonic foraminifera, climate, environment, Holocene, Mediterranean Sea.*

INTRODUCTION

In the last decades, the Late Quaternary-Holocene marine successions of the Mediterranean have been focused by several studies. Nevertheless detailed studies about the Late Holocene are few (e.g. PIVA *et alii*, 2008; VALLEFUOCO *et alii*, 2012), whereas they can to do a strong contribution to understanding present-day climatic evolution.

The Holocene (11.6-0 kyr BP) appears as a relatively stable climatic period when viewed in a long-term perspective. On the contrary, climate proxy records suggest that the Holocene climate can be subdivided into three main phases: the first is a temperate interval (11.6-9 kyr BP), characterised by a climatic amelioration, during which the large ice caps melt; the second phase (9-6 kyr BP) is a warm and arid period named "Climate Optimum"; the last phase (6-0 kyr BP) is characterised by a general cooling trend contemporary with an aridification progression. Three warm-cold events have been recognised during the last 5500 years and two within the last 2000 years: the Medieval Warm Period (MWP: AD 800-1300), warmer than present, and the Little Ice Age (LIA: AD 1300-1870), the coldest event occurred in the Late Holocene.

In the Mediterranean basin, Holocene climate reconstruction is still controversial because of the different timing and amplitudes of the events in different areas of the basin (SBAFFI *et alii*, 2004). The importance of a semi-enclosed basin as the Mediterranean Sea is linked to its capacity to register and amplify each smaller climatic and environmental change occurring at the mid-latitude regions. Moreover, these variations can be considered linked to more extensive events observed in the Atlantic Ocean.

The Tuscany continental platform situated between Piombino-Isola d'Elba to the north, and the Monte Argentario-Isola del Giglio to the south is characterised by the presence of the small Ombrone River delta (with terrigenous contributes and organic matter enrichment).

The specific aim of this research is to document the paleoenvironmental changes in the Ombrone River delta area during the Late Holocene, as response to climatic oscillations, using benthic and planktonic foraminiferal assemblages.

MATERIALS AND METHODS

The core BOK X, collected at 99.4 mwd (latitude 42°35'15"N, longitude 10°56'22"E) and 296 cm length, was considered in this study. It was collected during the cruise "Maremma '96" carried out by R/V Urania (November 15-29, 1996).

For the foraminiferal analyses 26 samples were collected, when possible, every 10 cm. Each sample consists of a 1 cm thick mud slice. In the laboratory, the sediment was wet-sieved through >63 and >125 μm, but in this study data from >125 μm size fraction were employed. In all samples at least 300 benthic foraminifera with well-preserved tests were separated and identified. Moreover, for each sample at least 300 planktonic foraminifera were counted and identified to investigate the planktonic assemblage variations.

The Q-mode Hierarchical Cluster Analysis (HCA) was performed on benthic foraminiferal assemblages, using SPSS (version 12) statistical software. Only the 14 benthic species more abundant than 5% in at least one sample were considered to create a matrix of data for the statistical treatment. The following parameters were also calculated for each sample: the diversity indices (α-Fisher index and the Shannon index) and the percentage of dominance.

RESULTS AND DISCUSSION

The core BOK X shows a homogeneous lithology, and is composed of the clayey silt. The silty fraction is always major than 50% (50.6-62.3%), whereas the clay ranges between 37.5 and 49.4%. The sandy fraction is really negligible (0-0.9%).

(*) Dipartimento di Scienze della Terra – "Sapienza" Università di Roma, Piazzale A. Moro, 5 – 00185 Roma; e-mail: virgilio.frezza@uniroma1.it

Benthic foraminifera

A total of 142 species belonging to 63 genera were identified. The α-Fisher index show values variables between 13.75 and 20.85, whereas the Shannon index varies from 3.01 to 3.51. The percentage of dominance ranges between 8.0 and 21.0%. Fourteen species show a relative abundance ≥ 5% in at least one sample, but only 4 species (*Bulimina marginata*, *Cassidulina carinata*, *Melonis pompilioides*, and *Valvulineria bradyana*) have a frequency > 10% in at least one sample.

The Q-mode HCA (Ward method, Squared Euclidean distance) grouped the analysed samples into clusters, characterised by distinct foraminiferal assemblages reflecting different ecological conditions. The cluster A, subdivided into 3 subclusters (A1-A3), is characterised by the dominance of *B. marginata*, *C. carinata*, and *M. pompilioides*; the cluster B includes samples showing a dominance of *V. bradyana*.

The subcluster A1 comprises 7 samples, in 6 of which *B. marginata* prevails, whereas the 7th sample is dominated by *C. carinata*. In this group *B. marginata* ranges between 7.3 and 14.3%, and *C. carinata* from 5.0 to 11.7%. *Valvulineria bradyana* (8.3-11.3%), *M. pompilioides* (3.3-10.0%), and *Hyalinea balthica* (2.3-8.0%) are the other species showing significant values. *Bulimina marginata*, *C. carinata*, and *V. bradyana* are characteristic of muddy bottoms with high organic matter (SGARRELLA & MONCHARMONT ZEI, 1993; FREZZA & CARBONI, 2009). *Hyalinea balthica* is abundant in circalittoral and bathyal muds (SGARRELLA & MONCHARMONT ZEI, 1993), whereas *M. pompilioides* has its maximum abundance in circalittoral assemblages (BERGAMIN *et alii*, 1997). The diversity indices show the highest values, whereas the percentage of dominance is low. Along the core, this assemblage is present from 177 to 170 cm, from 160 to 140 cm, from 80 to 70 cm, from 60 to 50 cm, and finally between 30 and 10 cm. On the whole, the more abundant taxa are typical from the circalittoral zone, but can tolerate organic matter amounts. This assemblage is comparable to *B. marginata* assemblage actually present in the lower circalittoral zone of this area (FREZZA & CARBONI, 2009).

Melonis pompilioides (7.3-13.3%) and *B. marginata* (7.0-12.3%) dominate the subcluster A2, with *C. carinata* (5.3-11.0%), *V. bradyana* (3.7-7.7%), *Textularia bocki* (3.3-7.7%), *H. balthica* (3.3-7.7%), and *Bulimina etnea* (1.3-7.7%) as subordinate taxa. *Melonis pompilioides* has its maximum abundance in circalittoral assemblages (BERGAMIN *et alii*, 1997; FREZZA *et alii*, 2005) and is well adapted to nutrient-rich environments but does not seem tolerate a strong ecological stress. *Textularia bocki*, and *B. etnea* are reported from infralittoral and circalittoral zones (DI BELLA, 1996; FREZZA *et alii*, 2005). Diversity indices are relatively high, whereas the percentage of dominance is generally low. This assemblage affects the lower part of the core, from the bottom to 220 cm, between 190 and 180 cm, from 170 to 160 cm, but also toward the top, between 50 and 40 cm. The species of this assemblage are characteristic of circalittoral zone, and were largely found in the modern assemblage present in this area. Nevertheless, the presence of *M. pompilioides* (no tolerating a high stress degree) relatively high diversity indices and low values of dominance can be related to less stressed ecological conditions.

The small subcluster A3 includes 4 samples in which *C. carinata* (11.7-19.7%) and *B. marginata* (12.3-15.0%) prevails. *Valvulineria bradyana* (5.3-11.0%), and *H. balthica* (3.0-9.7%) are the only species showing significant values. The α-Fisher index ranges from 17.64 to 20.85, whereas the Shannon index is comprised between 3.21 and 3.33. The percentage of dominance shows values ranging from 14.0 to 19.7%. This cluster was found from 220 and 190 cm, and at the top-core. Also this typical circalittoral assemblage can be related to recent *B. marginata*, *C. carinata* and *V. bradyana* assemblage (FREZZA AND CARBONI, 2009), but whit a major stress degree than the assemblage of subcluster A2.

The cluster B consists of 6 samples in which *V. bradyana* is the dominant species (14.3-21.0%). *Bulimina marginata* (6.0-14.0%), *C. carinata* (5.7-10.3%), *H. balthica* (4.7-8.7%), *T. bocki* (4.0-7.3%), and *M. pompilioides* (3.0-7.0%) are subordinate species. *Valvulineria bradyana* is an opportunistic foraminifer, in organic matter enriched sediments (FREZZA & CARBONI, 2009 and references therein). The species founded in this assemblage are the identical species of clusters A, but the dominance of *V. bradyana* is related to a major influx of Ombrone River contributions. This assemblage is characterised by relatively low values of diversity indices, and by the highest values of the dominance. It is present in the upper portion of the core, between 140 and 80 cm, from 70 to 60 cm, and from 40 to 30 cm. Today, this assemblage characterises the infralittoral-upper circalittoral zones front the Ombrone River mouth, but it is recorded in other areas characterised by the presence of river mouths.

Planktonic foraminifera

Twenty-three species and height genera of planktonic foraminifera were classified. Eleven species show an abundance ≥5% in at least one sample, whereas only six taxa are more abundant than 10% (*Globigerina bulloides*, *Globigerinoides elongatus*, *Globigerinoides quadrilobatus*, *Globigerinoides ruber*, *Globigerinoides sacculifer*, and *Turborotalita quinqueloba*).

The planktonic foraminifera species abundances indicate three main different intervals. At the bottom of the core the assemblage shows high percentages of the cold-water species as *G. bulloides* (22.4%) and *T. quinqueloba* (20.8%). Among the warm-water species only *G. ruber* is abundant (25.1%). This species is linked to warm and oligotrophic conditions, whereas *G. bulloides* and *T. quinqueloba* are eutrophic species, abundant in upwelling areas (SBAFFI *et alii*, 2004).

From 285.5 to 95.5 cm, the assemblages are characterised by a strong increase of warm-water taxa (45.2-82.6%), as *G. ruber*, *G. elongatus*, and *Orbulina universa*. All these taxa reflect surface water stratification and oligotrophic conditions (SBAFFI *et alii*, 2004).

Globigerinoides quadrilobatus and *G. sacculifer* show significant percentages only at 255.5 and 245.5 cm: 24.4-25.7% and 4.9-19.7%, respectively. These species prevail in tropical-subtropical water and are indicative of oligotrophic waters. Successively, these two species show always low or very low frequencies: in particular, along the upper part of the core *G. sacculifer* is very rare (0-1.3%), and disappears at 145.5 cm. PIVA *et alii* (2008) indicate a Last Occurrence of this species in the Adriatic Sea around 550 yr BP and suggest that this bioevent may approximate the base of the LIA. Between 85.5 cm and the top, the cold-water species are dominant (56.2-72.9%), with *T. quinqueloba* and *G. bulloides*. Nevertheless, two warm-water taxa as *G. ruber* (18.3-24.9%) and *G. elongatus* show relatively high percentages.

CONCLUSIONS

The benthic assemblages of cluster A comprise the majority of the sediments, all of them referable to a typical circalittoral environment. In the lower part of the core, from the bottom to 140 cm, only cluster A is present. From the 140 cm to the top, cluster B (referable to an organic matter enrichment) alternates with subclusters A1-A3. From the bottom to 220 cm, the *M. pompilioides* and *B. marginata* assemblage (subcluster A2) indicates a circalittoral environment characterised by an elevated organic flux but with a good oxygenation degree, as attested by the dominance of *M. pompilioides*. Between 220 and 190 cm, the *C. carinata* and *B. marginata* assemblage (subclusters A3) marks an environmental stress increase, because these species are typical of areas whit high organic flux. From 190 to 140 cm, there is an alternation between subclusters A2 and A1. The dominance of *B. marginata* in the subcluster A1 indicates a correlation with organic matter enrichment, with seasonal low oxygen content. This hypothesis is testified also by the increase of an opportunistic species as *V. bradyana*. From 140 to 80 cm, the presence of *V. bradyana* assemblage (cluster B) indicates a strong influence of Ombrone River run-off, with an interplay of increasing food availability and low oxygen concentration. Between 80 and 10 cm, cluster B alternates with subclusters A1 and A2, indicating two strong pulsations of river contributions. At 5.5 cm, the *C. carinata* and *B. marginata* assemblage is present, suggesting that the top of core BOK X is representative of the Recent conditions.

As regard the planktonic foraminifera, at the bottom of the core, cold-water taxa (*G. bulloides*, *T. quinqueloba*) dominate, but *G. ruber* is the more abundant species. The coexistence between these taxa at this level may be imputed to the end of the cold phase, with a return to more warm and oligotrophic conditions. From 285.5 to 95.5 cm, warm-waters species (*Globigerinoides* spp., *O. universa*) dominate the foraminiferal assemblages. The upper part of the core (85.5 cm-top) is dominated by cold-water species *T. quinqueloba* and *G. bulloides*, but with significant frequencies of two warm-water taxa as *G. ruber* and *G. elongatus*. This cold phases can be related to the LIA, with the dominance of cold-water and eutrophic species, that are well adapted to an increase of fluvial run-off linked to cold-wet climate.

An integration of these micropaleontological data with radiocarbon datings and stable isotopes analyses will provide a necessary support to carry out an accurate paleoclimatic and paleoenvironmental reconstruction.

Late Quaternary palaeoenvironmental evolution of the central Adriatic coast in the Trigno mouth area (Molise Region)

VIRGILIO FREZZA (*) (°), CARMINE D'AMICO (**) (°), GIUSEPPE AIELLO (***), DIANA BARRA (***), VITO BRACONE (**), LETIZIA DI BELLA (*), DANIELA ESU (*) & CARMEN MARIA ROSSKOPF (**)

Key words: *Central Adriatic, Foraminifers, Late Quaternary, Molluscs, Ostracods, Palaeoenvironments, Stratigraphy.*

INTRODUCTION

Three cores (MBS1, MBS2 and MBS3), 15-12 m thick, were drilled offshore near the Trigno river mouth (Central Adriatic coast, Molise Region), 150-300 m from the present coastline. Palaeoecological analyses by means of benthic foraminifers, molluscs and ostracods, supported by stratigraphic and chronological data, have been performed to reconstruct the Late Quaternary palaeoenvironmental evolution of the northern sector of the Molise Adriatic coast.

STRATIGRAPHY

Five main lithofacies (G, C*g*, Cs*g*, Cs*b*, S) were recognized in the studied cores (fig. 1).

Lithofacies G: this lithofacies is present at the bottom of the cores MBS1 and MBS3 and is made up of matrix supported gravels mostly represented by poorly sorted sub-spherical calcareous clasts of variable dimensions (cm to dm). Matrix consists in light brown, silty sands. Moreover, in MBS1 this lithofacies is also characterized by clast-supported gravel.

Lithofacies C*g*: lithofacies C*g* is present in MBS2 and MBS3 where it overlays lithofacies G. It is made up of homogeneous grey clays with locally scattered calcareous concretions (“calcinelli”).

Lithofacies Cs*g*: this lithofacies, recognized in MBS1, overlays lithofacies G. It is made up of homogeneous grey silty clays with locally scattered plant remains (seeds, leaves).

Lithofacies Cs*b*: lithofacies Cs*b*, recognized in MBS2 and MBS3, overlays lithofacies C*g*. It consists in light brown, consolidated silty clays occasionally interrupted by grey layers. The top of this lithofacies is always characterized by brown silty sands.

Lithofacies S: this lithofacies is characterized by fine to medium and light brown to brown sands. In MBS1, lithofacies S is characterized by a 2 m thick intercalation of medium to coarse sands. In MBS3, at 5.20 m core depth, a 20 cm thick intercalation of gravel is observed. Intercalations of amalgamated sands with silt are also present. At the top of the cores MBS1 and MBS3 silty sand intervals with dark grey organic matter locally occur.

FORAMINIFERS

A total of 101 samples from the three cores have been processed. The foraminiferal content is generally scarce; 10 samples are barren of benthic foraminifers. A total of 91 benthic species were identified. Moreover, 16 planktonic species were recognized. Conservation status of foraminiferal tests is generally good. The 91 samples with foraminiferal tests can be grouped into three main groups (fig. 1).

The first group (FA) comprises 52 samples where the benthic foraminifers are very scarce and characterized by a mixing between infralittoral and circalittoral species. This group was found in all the three cores, in particular in the lower part of the cores.

The second group (FB, 28 samples) dominated by typical infralittoral species as *Ammonia beccarii, A. inflata, A. papillosa, A. parkinsoniana, Buccella granulata* and *Elphidium granosum*, was found in the central part of the three cores and at the top of MBS2 and MBS3.

The third group (FC), present only in cores MBS2 and MBS3, shows a dominance of circalittoral species such as *Bolivina spathulata, Bulimina marginata, Cassidulina carinata, Valvulineria bradyana*, with subordinate percentages of infralittoral species (*Ammonia* spp., *E. crispum* and *E. granosum*).

MOLLUSCS

A total of 197 samples from the three cores have been analyzed. 128 mollusc species were recognized. All theidentified species were previously reported for modern non-marine and

marine settings of the Mediterranean area. Faunal changes through the sequences of the three cores allowed to recognize eight local mollusc zones (fig. 1).

- Zone MA: barren samples from lithofacies G.

- Zone MB: poor oligotypic terrestrial assemblages with *Carychium minimum*, *Punctum pygmaeum*, *Succinea* sp., *Vallonia pulchella*, *Vitrea subrimata* and *Vitrinobrachium breve*. This zone is present in all the three cores.

- Zone MC: poor marine infralittoral assemblages. Molluscs are scanty and represented by juveniles of *Donax semistriatus, Glycymeris insubrica* and *Lucinella divaricata*. This zone is present in cores MBS2 and MBS3.

- Zone MD: marine infralittoral assemblages characterized by the co-occurrence of species of different benthic infralittoral biocoenoses (PÉRÈS & PICARD, 1964). Molluscs consist mainly of juveniles forms. Species richness and abundances of species are higher than that of the zone MC. Species mainly represented are *Abra alba, Chamelea gallina, D. semistriatus, G. insubrica, Spisula subtruncata* and *Antalis dentalis*. This zone is present in all the three cores.

- Zone ME: rich polytypic marine infralittoral assemblages characterized by high species richness, high abundances of marine species and co-occurrence of taxa belonging to different infralittoral biocoenoses. Juveniles specimens are dominant; however adults of *A. alba* and *D. semistriatus* were locally found (MBS3). Marine species such as *C. gallina, Corbula gibba, Dosinia lupinus, G. insubrica, L. divaricata, Mytilaster lineatus, S. subtruncata, Tellina* spp., *Bittium reticulatum* and *A. dentalis* were also recorded. This zone is present in cores MBS2 and MBS3.

- Zone MF: poor marine infralittoral assemblages. Samples record low values of both species richness and specimen abundances. Both shell fragments and specimens are generally reworked. This zone is present in all the three cores.

- Zone MG: rich marine infralittoral assemblages. High species richness, high abundances of marine species with both juveniles and adults, and the dominance of species of the upper clean-sand biocoenosis (*C. gallina*, *D. semistriatus* and *Lentidium mediterraneum*) characterize this zone. This zone is present in all the three cores.

- Zone MH: poor mixed marine infralittoral and non-marine assemblages characterized by the co-occurrence of marine infralittoral and terrestrial mollusc assemblages, both with low species richness and low specimen abundances. Marine record consists mainly of juveniles and fragments often reworked of *C. gallina, D. semistriatus, L. mediterraneum, M. lineatus*. Non-marine assemblages consist of relatively better preserved specimens and shell fragments of *Discus rotundatus*, Hygromiidae indet., *P. pygmaeum*, *Succinea* sp. and *T. cylindrica*. This zone is present in all the three cores.

OSTRACODS

100 samples of the three cores have been studied. 8 samples resulted devoid of ostracods; the remaining 92 yielded 84 ostracod species. Analysis of fossil assemblages indicates the presence of three different ostracod groups (fig. 1).

The first group (OA) comprises shallow marine water species mostly living in the Mediterranean. In the main part of the samples they are well preserved and with both adults and juvenile specimens. The most abundant forms are *Pontocythere turbida, Cytheretta subradiosa, Semicytherura incongruens, Loxoconcha ovulata, L. rubritincta* and various species of the genera *Callistocythere, Leptocythere, Semicytherura, Xestoleberis*.

The second group (OB) is formed by ostracod taxa presently occurring in continental waters pertaining to the families Candonidae, Cyprididae, Ilyocyprididae and Limnocytheridae. These species have been recognized alternatively as autochthonous, thus indicating non-marine palaeoenvironment, or displaced on sea bottom sediments.

The third group (“allochthonous species”) is formed by specimens preserved in the Plio-Pleistocene marine clays of the Montesecco Clays outcropping near the study area (BRACONE *et alii*, 2012), which were eroded by the Trigno River. Species characteristic of outer circalittoral - bathyal palaeoenvironment (e.g. *Henryhowella*, *Krithe*) are represented. All of these forms indicate influence of fluvial sediment supply.

DISCUSSION AND CONCLUSIONS

At the bottom of the cores MBS1 and MBS3 (fig. 1), fluviatile barren gravels (lithofacies G) are present. In the core MBS2 the succession starts with grey clays (lithofacies C*g*) containing marine infralittoral foraminifers, hygrophilous terrestrial molluscs and freshwater ostracods. Sediments of lithofacies C*g* were also recognized above lithofacies G in the core MBS3; here the fossil record consists of marine infralittoral foraminifers, freshwater and hygrophilous terrestrial molluscs, freshwater and marine infralittoral ostracods. Two AMS C dates constrain the deposition of lithofacies C*g* (MBS3) between 19945 ± 345 and 19165 ± 195 yr BP (fig. 1). In the cores MBS2 and MBS3, lithofacies C*g* is overlaid by light brown silty clays (lithofacies Cs*b*) containing marine infralittoral foraminifers and molluscs, and marine and freshwater ostracods. In the core MBS1, both lithofacies C*g* and Cs*b* lack, and lithofacies G is overlaid by grey silty clays (lithofacies Cs*g*) containing hygrophilous terrestrial molluscs and mainly freshwater ostracods. The three cores are closed up by brown, fine to medium sands (lithofacies S) recording the dominance of marine infralittoral fauna. One AMS C date carried out on benthic foraminifers (*Ammonia* sp.) collected from the lower portion of lithofacies S (core MBS3) gave an age of 8120.5 ± 108.5 yr BP (fig. 1).

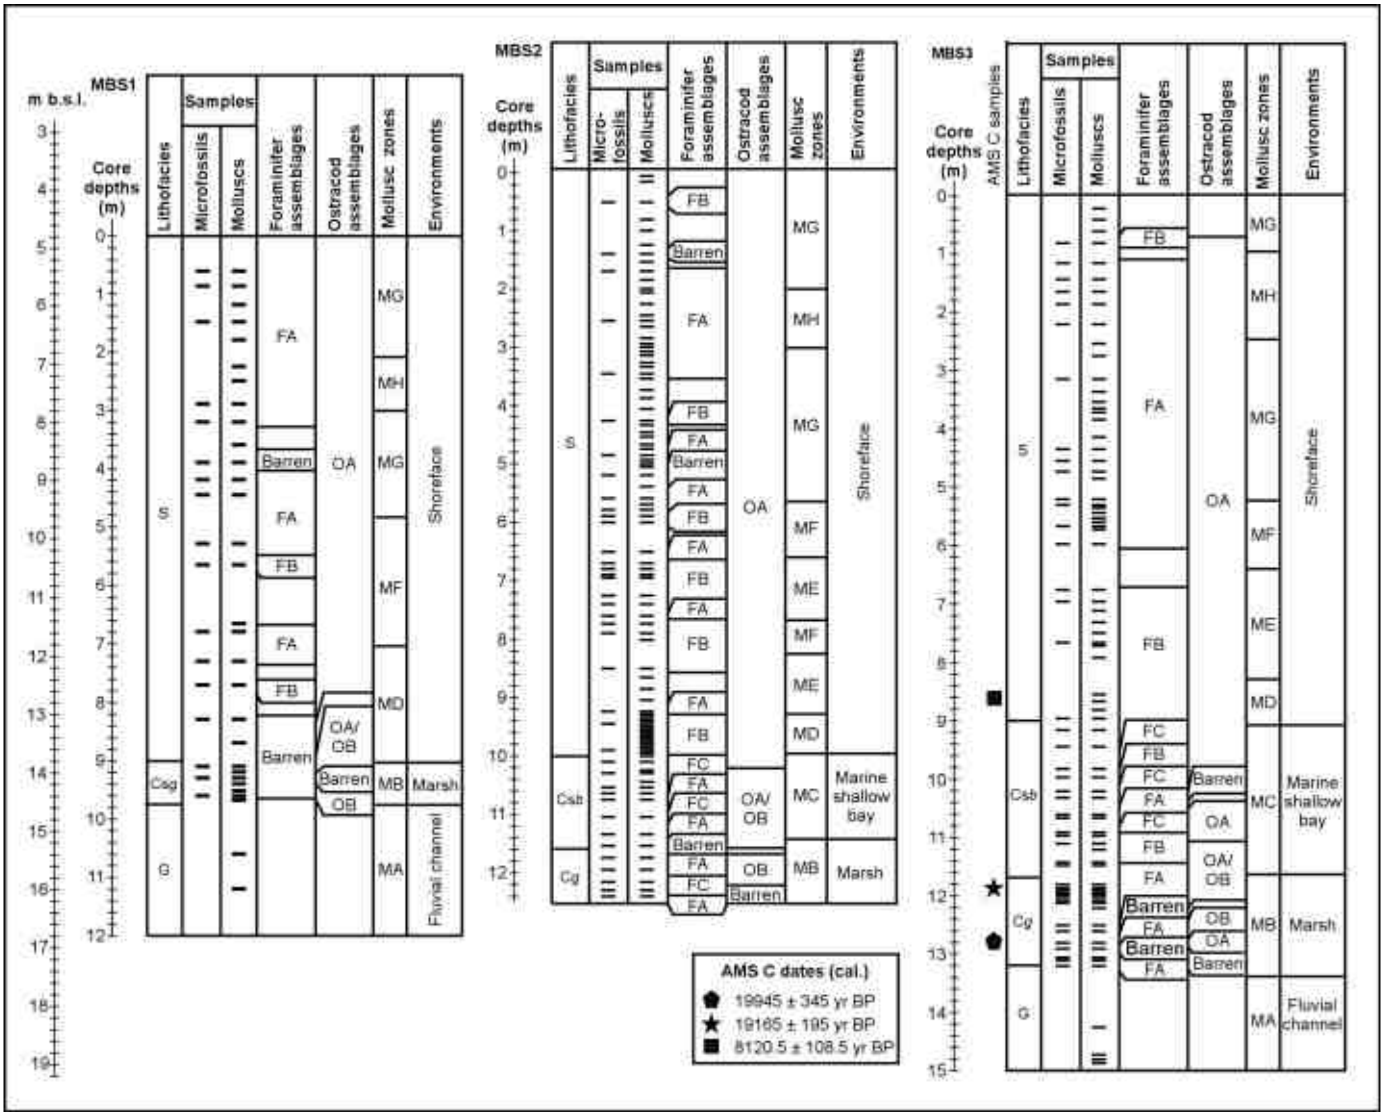

Fig. 1 – General scheme showing the results of stratigraphic and paleontological analyses carried out on the three studied cores.

The results of this study point out that, in the Trigno river mouth area, during the Last Glacial, as the eustatic sea-level dropped and the coastline was located several km seaward with respect to its present position (VAI & CANTELLI, 2004), fluvial gravels (lithofacies G) deposited and successively were incised. Incisions were filled by clays (lithofacies C*g*) of marshes developed on the alluvial plain. At the end of the Last Glacial, as the eustatic sea-level rised, a shallow marine bay developed and sediments of lithofacies Cs*b* deposited. Lithofacies Cs*g*, overlaying lithofacies G in the core MBS1, is very likely heteropic with lithofacies Cs*b* of the cores MBS2 and MBS3; therefore marshes on fluvial deposits located at major heights developed contemporaneously to the shallow marine bay. Finally, both the lithology and the faunal content of lithofacies S suggest the development in the study area of a shoreface under marine infralittoral conditions.

Palaeoenvironmental evolution of the post-evaporitic Messinian sequence of Eraclea Minoa (Sicily) by means of ostracods: preliminary results

FRANCESCO GROSSI (*) & ELSA GLIOZZI (*)

Key words: *Ostracods, palaeoenvironmental reconstruction, Sicily, lago-mare facies*

The Eraclea Minoa section, located on the south-western coast of Sicily, 33 km SE of the city of Sciacca, is a well known geological site as it is the type locality for the Messinian/Zanclean GSSP (VAN COUVERING *et alii*, 2000), and also one of the most famous section for the study of the Messinian Salinity Crisis (MSC). Although numerous authors have studied the Eraclea Minoa section with a great detail from a sedimentological and stratigraphical point of view (see ROVERI *et alii*, 2006 for updated references), the paleontology of the post-evaporitic Messinian portion counts very few studies (DECIMA, 1964; BONADUCE & SGARRELLA, 1999).

Recently, the 258 m-thick sedimentary succession cropping out at Eraclea Minoa (Fig. 1) has been sampled again with a great detail with the aim of a multidisciplinary approach, paleontological (benthic foraminifers, molluscs, ostracods, pollen, dinocysts) and geochemical (Sr, O, C stable isotopes and trace elements), in order to depict the palaeoenvironmental changes that occurred during the lago-mare phase of the MSC. In this communication are presented the preliminary results of the ostracod analyses.

The Messinian portion of the Eraclea Minoa succession is made up ten sedimentary cycles, each of which (except for cycles 6' and 6") starts with clays and marls interbedded with sands and thin layers of fine-grained carbonates and, in the upper part, is made of alternating layers of finely-laminated gypsum and gypsarenites. About 170 paleontological samples were collected from each fine-grained portion of all the cycles.

The lowest three cycles crop out very badly. The few samples collected from Cycles 1 and 2 were sterile, while Cycle 3, completely barren at the base, yielded few ostracod valves in its upper silty portion, referable to *Cyprideis agrigentina* and *Loxoconcha mülleri*, the first Paratethyan species that appears in the succession.

This very scanty assemblage, to which few instars of Candoninae indet. are added, has been recognized also at the beginning Cycle 4, but more diversified assemblages, although with low frequencies, have been recovered going upwards in the remaining portion of Cyle 4, and in Cycles 5 and 6. Together with *Cyprideis agrigentina* and *Loxoconcha mülleri* a progressively richer contingent of Paratethyan ostracod species appears along the succession: *Loxocorniculina djafarovi*, *Loxoconcha eichwaldi*, *Loxocauda limata*, *Zalanyiella venusta*, *Loxoconcha kochi*, and *Amnicythere* spp. Cycles 6', 6" and 7 marks an abrupt change of the assemblage: infact, for about 75m of thickness it become monospecific, made only by abundant to very abundant *Cyprideis agrigentina*. In the upper portion of Cycle 7 and in the whole Cycle 8 (that in part includes the Arenazzolo Fm), the ostracod assemblages become diversified again, with the same species that occurred in the lower cycles, to which some other Paratethyan species are added: *Tyrrhenocythere pontica*, *Cytherura pyrama* and *Euxinocythere (Maeotocythere) praebaquana*.

A first palaeoenvironmental interpretation based on the ostracod assemblages would suggest, at the base of the post-evaporitic Messinian succession, the existence of a subaqueous environment characterised by physico-chemical parameters not suitable to host life. Going upwards, the first ostracods colonized the environment, *Cyprideis agrigentina* (which can withstand very huge salinity variations and low oxygen

Fig. 1 – An outcrop of the Eraclea Minoa composite section

(*) Dipartimento di Scienze Geologiche, Università degli Studi Roma Tre, fgrossi@uniroma3.it

contents) and *Loxoconcha mülleri*, the first Paratethyan ostracod that it is supposed to inhabit brackish waterbodies up to mesohaline waterbody. The environmental amelioration continued upsection, and the assemblages became more diversified, pointing to a brackish environment with salinities comprised in the mesohaline range. Abruptly, after the deposition of the selenitic gypsum that marks the end of Cycle 6, it is possible to suppose a remarkable salinity increasing towards and hyperhaline environment that was again diluted to oligo-mesohaline conditions only at the end of Cycle 7 and during Cycle 8. The results of the percentage analyses of the sieve-pores on *Cyprideis agrigentina* valves carried out by Bonaduce & Sgarrella (1999) on two scattered samples along the Eraclea Minoa section gave salinity estimates around 50-70‰, supporting this palaeoenvironmental interpretation. Anyway, preliminary results obtained in this work by the same analysis carried on well-preserved valves of *Cyprideis agrigentina* collected in samples with monospecific assemblages from the base of Cycle 6' does not show any hyperhaline condition, but gave salinity values around 8-11‰, in the mesohaline range, showing that the palaeoenvironmental history of the lago-mare facies at Eraclea Minoa is more complicated than it was supposed.

The Cretaceous gastropod *Trochactaeon matensis* (Fittipaldi, 1901): first occurrence in the central Apennines (Rocca di Cave, Prenestini Mts.)

FRANCESCO GROSSI (*)

Key words: *Upper Cretaceous, Acteonidae, neritic shelf facies, Prenestini Mts.*

The "Ardito Desio" Civic Geopaleontological Museum of Rocca di Cave (Rome) is located at the southern Prenestini Mountains, and its geopaleontological collections are strongly connected to the territory. The Rocca di Cave area has a huge paleogeographic and paleoenvironmental significance since it stands out as the westernmost end of Upper Cretaceous neritic "laziale-abruzzese" shelf facies. Furthermore, it is the almost unique witness for the presence of a Cenomanian-Santonian edge in the western part of the shelf, whose fossil reefs were characterized by typical associations with dominant bivalves (rudists and others), gastropods, corals, sponges and rare sea urchins. Nearby the inhabited of Rocca di Cave, in Cretaceous deposits referred to the Turonian (CARBONE *et alii*, 1980), it was found an outcrop very rich in *Trochactaeon matensis* (FITTIPALDI), a gastropod species never reported before in the literature for the central Apennine, whose some specimens are now preserved and exposed in the "Ardito Desio" Museum (Fig. 1).

T. matensis is an extinct gastropod pertaining to the family Actaeonidae, established at the beginning of the XX century by the doctor and naturalist Emilio Fittipaldi in the cretacic levels of the Matese Mts. It is characterized by a strong, sub-elliptical or oval-shape shell, seldom bulbous-shaped, with the columellar lip marked by 3 folds, a common feature to many species pertaining to this family. Specimens of *T. matensis* show a marked dimensional variability: its height is included between 3 and 10 cm, generally with rather pronounced spire but sometimes short and slightly protruding: in these cases, the last whorl occupies almost the whole shell height.

T. matensis, as all the acteonids, was a common back-reef and lagoon dweller, sectors characterized by a lower wave motion's energy than the reef margin. Moreover, as all the species referable to the genus *Trochactaeon*, *T. matensis* had an epibiont life mode too, in contrast to the *Actaeonella* genus, which assumes, after the post-larval development, an infaunal life mode (SOHL & KOLLMANN, 1985). From this also derives the greater morphological and dimensional variability in *Trochactaeon*, which was more exposed to the environmental changes than *Actaeonella*.

Regarding its paleogeographical and chronostratigraphical distribution, *T. matensis* had been so far reported in the Cenomanian and Turonian levels of the Matese Mts. (Molise), the italian and slovenian Carso, in Romania, Greece and Caucasus. Thus, this new finding in the Turonian deposits of Rocca di Cave allows to extend its distribution to the central (latial) Apennine.

Investigation on the vertebrate remains from Monte delle Piche (Rome, Central Italy)

FRANCESCO GROSSI (*) & LUCA PANDOLFI (*)

Key words: *Monte delle Piche, rhinoceroses, ostracods, Pleistocene.*

INTRODUCTION

Due to the intense urbanisation of Rome between the 19th century and the beginning of the 20th century, a large number of vertebrate fossil remains were collected from the deposits outcropping in the are of Rome city (MELI, 1896; PONZI, 1878; PORTIS, 1893; *inter alios*). At the beginning of the second half of 19th century, large mammal remains were recovered in deposits at the base of Monte delle Piche (PONZI, 1858). These remains are preserved in the Museum of Paleontology at the Sapienza University of Rome (MPUR).

The aim of the present paper is to define the stratigraphic origin and chronological position of the above-mentioned remains.

THE MAMMAL REMAINS FROM MONTE DELLE PICHE

The mammal remains from Monte delle Piche include three fragmentary mandibles of rhinoceroses and a femur of a large-sized hippopotamus. The latter (MPUR999) was filled and covered with fluvial conglomerates and can be referred to *Hippopotamus* sp.. The rhino mandible MPUR1515 consists only of a partial horizontal ramus with the two last molars. The remain is covered by thick and hard crust of sediment. The specimen is assigned to Rhinocerotidae indet.. The rhino mandible MPUR1516 consists of two horizontal rami with teeth. The specimen is covered by a black, hard and relatively thick silt. The two rami are relatively slender, get thinner below the premolars and have a convex lower border. Teeth are brachyodont and the cingula seem to be lacking. Basing on morphological and morphometrical characteristics, the specimen can be ascribed to *S.* cf. *S. etruscus*.

The rhino mandible MPUR138 (Fig. 1) was discussed by PORTIS (1899) and GUÉRIN (1980) (which refers it to *Chilotherium*). The symphysis of the mandible seems to be robust and narrow and begins curving upwards below P/2. The symphysis includes the right tusk (I/2) and the partial alveolus of the left one (they are very slight divergent). There is no indication of any alveolus for I/1 and these teeth were certainly absent. The alveoli of the tusks are very close to each other and the right tusk curves strongly upwards. The horizontal ramus of the mandible is deep and displays a uniform height. The premolars are large and the lingual valleys have a broad V-shaped morphology. These valleys do not reach the base of the lingual side. The general shape and morphology of the mandible are very close to those of *Acerorhinus zernowi* from Sebastopol (Crimea) (BORISSIAK, 1914). The mandible MPUR138 differs from *Chilotherium* which has a broader symphysis, the axes of the tusks oblique, the lower border of the mandible slightly convex, the height of the mandible below the premolar shorter and a generally smaller dimensions of the premolars and molars.

Fig. 1 – Mandible MPUR138, lingual view. Scale bar = 10cm.

OSTRACODS

Sediments covering these mammals remaining were analysed from a micropalaeontological perspective in order to add some palaeoenvironmental informations or to corroborate existing data. The MPUR999 covering deposits yelded few valves of *Cyprideis* instars, in agree with very shallow (optimum of *Cyprideis* <10 m, Neale, 1988) and oligohaline waterbody. The hard blackish crusts of sediment on the MPUR1515 and MPUR1516 mandibles provided few valves of *Loxoconcha* sp. (MPUR1515) and instars of *Krithe* sp. and *Bairdoppilata* sp. (MPUR1516), testifying a marine environment from infralittoral to circalittoral. The MPUR138 mandible provided an ostracod association constituted

(*) Dipartimento di Scienze Geologiche, Università degli Studi Roma Tre, fgrossi@uniroma3.it, lpandolfi@uniroma3.it

by *Parakrithe* sp., *Cytherella* sp. and *Eopajenborchiella* sp., suggesting a marine circalittoral environment. The association was recovered from clayey sediment filling the rooth of incisive in MPUR138.

CONCLUSION

Basing on stratigraphic data (see PONZI, 1858; MARRA, 1993, CARBONIO & IORIO, 1997; *inter alios*) and paleontological analysis, at the Monte delle Piche two vertebrate-fossiliferous levels can be recognized. The younger level is represented by fluvial conglomerates and sandstones referable to the Ponte Galeria Formation (>0,800 Ma) which contain the femur of *Hippopotamus*. The older level is represented by siltly deposits, with marine ostracods and foraminifera, referred to the Early Pleistocene (Monte delle Piche Formation) (MARRA, 1993; CARBONI & IORIO, 1997). The age of these deposits is confirmed by the presence of the mandible of *S.* cf. *S. etruscus* (MPUR1516); the species is reported in Italy approximately from 2,5 to 1,0 Ma (PANDOLFI & PETRONIO, 2011). The mandible MPUR138 can not be referred to the Monte delle Piche succession (as notice by KOTSAKIS, 1984). Indeed, *Acerorhinus zernowi* is typical of late Miocene localities; it is recorded in Turkey, at Pentalophos-1, Crimea and Tung-gur (BORISSIAK, 1914; CERDEÑO, 1996; HEISSIG, 1999; KYA & HEISSIG, 2001). Recently, the genus *Acerorhinus* has been also reported in the latest Miocene of Bulgaria (GEERADS & SPASSOV, 2009).

In Italy, several Miocene mammal remains have been recovered in marine deposits (see KOTSAKIS, 1984) and we can not excluded an Italian origin of the mandible. Probably, additional analysis on the sediment will be useful to investigate on the origin of the specimen.

Stratinomy and taphonomy of trace fossils from Eocene to Miocene turbidites in Northern Apennines (central Italy)

PAOLO MONACO (*)

Key words: *Ichnology, ichnotaxa, stratinomy, turbidite deposits, Miocene, Apennines.*

INTRODUCTION

In turbidite and hemipelagite deposits of Northern Apennines (Italy) deep-sea ichnotaxa have been approached in order to define ichnocoenoses using taphonomy and stratinomic value (MONACO & CHECCONI, 2008). Studied deposits range from Early Eocene to Late Miocene and are represented by shales and limestones with carbonate turbidites (Scisti Varicolori Beds and Scaglia Toscana Group), siliciclastic turbidites or mixed deposits (Macigno, Vicchio and Verghereto Marls, Cervarola and Marnoso Arenacea of Apennine foredeep and ridges). Stratinomic analysis allows to recognize five ichnia classes: A-type = hypichnia; B1-2-types = sandy or muddy endichnia; C-type = crossichnia of many beds and D-type = epichnia.

A-type category is characterized by pre-depositional traces preserved as hypichnia and comprises several networks, more or less regular, of ichnogenus *Paleodictyon* (and their preservational variants: *Squamodictyon, Glenodictyon, Ramodictyon*) preserved as horizontal meshes or vertical shafts. Many forms have been found, from small and regular (e.g. *P. minimum, P. strozzii, P. italicum*) to very large and robust forms (e.g. *P. hexagonum*) (MONACO, 2008). This category also includes meandering-shaped graphoglyptid ichnogenera (e.g. *Belorhaphe*, *Cosmorhaphe, Desmograpton, Helicolithus, Helminthorhaphe, Megagrapton, Paleomeandron, Protopaleodictyon, Urohelminthoida* and others with many ichnospecies and variants). Spiral-shaped graphoglyptids or structured non-graphoglyptids (e.g. *Rotundusichnium*, *Rutichnus*, *Spirorhaphe*, *Spirophycus* with many ichnospecies and variants) are also common in Macigno of Trasimeno area. Radiate forms (*Lorenzinia* and *Glockerichnus*, plug-shaped *Parahaentzschelinia* and *Bergaueria*, and some bilobate forms of *Scolicia* group are preserved as hypichnia. But, analysis indicates that not all hypichnial preservation is equal to a pre-deposition event; in many case some doubts and revisions are needed in order to review all these groups in their pre-depositional origin. Preliminary taphonomic analyses on the graphoglyptid *Desmograpton* indicates without doubts that this form was a post-depositional, and this can be extended also to many other graphoglyptids as occurs clearly for many other non-graphoglyptids (e.g. *Rutichnus* and *Spirophycus*).

B1-type category includes post-depositional trace fossils preserved as endichnia within sandy beds to exploit grains and nutrients transported directly by turbidity or gravelly flows. They consist of branched tubes, straight or sinuous and more or less structured (e.g. *Halopoa imbricata, Ophiomorpha annulata?, O. rudis, Palaeophycus, Rutichnus rutis, Sabularia (Granularia) simplex, Spongeliomorpha, Thalassinoides*), bilobate-trilobate forms (*Scolicia strozzii* and their variants) and simple short traces plunging in sand (*Arthrophycus*). Many other forms as *Gordia, Helminthopsis, Strobilorhaphe, Subphyllochorda-Cardioichnus* and other ichnogenera are doubtfully included in B-type category and requires more analyses.

B2-type is a sub-category of endichnia, because occurs in mud turbidites or in biocalstic fine-grained turbidites. It consists of structured or tree-like forms, mainly produced close the top of beds (see Fig. 1), usually as branched agrichnia/domichnia or chemichnia (e.g. *Alcyonidiopsis, Avetoichnus luisae*, *Chondrites*, *Cladichnus* and *Trichichnus*). These forms developed vertically downward or upwards in calcilutites and in cm-thick muddy turbidites (e.g. in Eocene Scaglia Toscana or Varicolori Fm. and locally also in Miocene deposits). Some pustulose *Nereites*-like forms occur but require more analyses.

C-type involves traces crossing more beds (crossichnia). Vertical burrows are commonly branched and structured (e.g. *Ophiomorpha rudis* and other subquadrate form in transversal section). Other crossichnia are helicoidal or lobate structures, up 1 m wide (*Zoophycos, Spirophyton* groups), common also in thick hemipelagic deposits of Eocene-Oligocene Scaglia Group and Early Miocene Bisciaro–Schlier Formations.

D-type category is represented by epichnia which develop at the top of turbidites and correspond to a preservational variant of *Nereites* (multiserialis, biserialis and uniserialis); very common are meandering forms (e.g. *Scolicia prisca, S. vertebralis*) or similar trails which exhibit backfill meniscate structures and are crossed by many other types (e.g. *Taenidium*, simple sinuous traces as *Planolites, Phycosiphon* and radiate *Glockerichnus*-like forms). In the ichnofossil-*lagerstatte* of Verghereto (MONACO & CHECCONI, 2010) cm-thick calcarenites of overbank deposits show a very abundant and diversified epichnial ichnoassemblage (overbank ichnocenosis) with many foraging trails and horizontal backfilled structures. Abundant are also *Zoophycos*-like structures, *Scolicia prisca* and *Phycosiphon* or *Chondrites*.

These five peculiar A-D ichnia categories are very sensitive to facies distribution, bottom morphology (e.g. ridge or deep

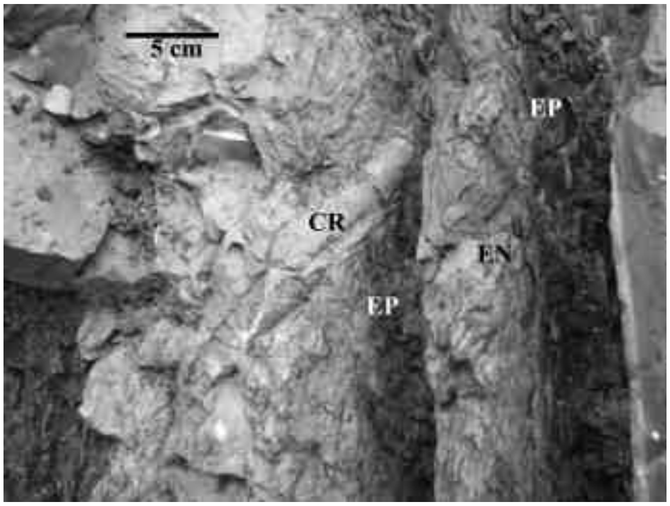

Fig. 1 – Torbiditi fangose (Scisti Varicolori *Auct*. Del Trasimeno, sez. M. Solare) assai bioturbate con ichnotaxa: CR = crossichnia (e.g. *Ophiomorpha rudis*), EN = endichnia, EP = epichnia

trench) and specific parameters of the substrate in the sea-floor (MONACO *et alii*, 2009). Facies distribution in slope, fans, deep-sea plains, overbank and levee deposits are determinant features to preserve ichnocenoses as far as the sedimentation rate in hemipelagic or turbiditic conditions; heterogeneous and diversified ichnocoenoses reflect variations in environmental parameters primarely sedimentation rate, organic matter, oxygen content, consistency, temperature, and bottom traction-currents. This study also provided to identify many taphonomic features that are supposed to be the most important factors influencing mainly hypichnia preservation. They are induced by biogenic (bulldozing and burrowing) and physical agents (e.g. currents and creep). In studied thin-bedded and fine-grained turbidites both agents produced, for example, several three-dimensional oriented pre-turbiditic deformations in the A-type burrows.

Palaecologic signatures of fossil assemblages in a candidate GSSP section of the Middle Pleistocene Stage at San Mauro Marchesato (Crotone, Southern Italy)

D. SCARPONI (*), S. RAFFI (*), L. CAPRARO (°) & M. GHINASSI (°)

Key words: p*aleoecology, sequence stratigraphy, Ionian, mollusc, Italy.*

ABSTRACT

Pleistocene successions recording transgressive-regressive (T–R) cycles were used to asses spatio-temporal variations in preserved macro-invertebrate biotas (i.e., mainly mollusc assemblages) by means of multivariate ordination analyses. This approach permits gauging the informative strength of marine macrofaunal associations as a tool for basin analysis and correlations (MILLER *et alii*, 2001; SCARPONI & KOWALEWSKI, 2004; HOLLAND, 2005).

Detailed macrobenthic investigations were performed on the basal-middle portion (lower 40 meters) of the candidate GSSP section for the Middle Pleistocene Stage (CITA *et alii*, 2006), namely the Valle di Manche section (Crotone Basin, Calabria; fig. 1). The densely sampled interval (20 samples, >3000 specimens) dominated by extant species with known environmental distributions, was analyzed using Detrended Correspondence Analysis (DCA; HILL & GAUCH, 1980), which is one of the most widely used ordination techniques in paleoecologic studies (BUSH & BRAME, 2010 and references therein).

The basal-middle part of Val di Manche section records two complete T–R cycles mainly driven by glacioeustasy (RIO *et alii*, 1996). Biochronology and oxygen isotope stratigraphy indicate that the sedimentary succession spans from Marine Isotope Stage (MIS) 22 to MIS 18.3 (*i.e*. ~900 to ~700 ka), thus spanning the Matuyama–Brunhes boundary that, in agreement with open ocean records, occurs in the midst of MIS 19 (CAPRARO *et alii*, 2005 and references therein).

Macrobenthic marine associations when "ordinated" by means of DCA indicate two sets of a deepening-upward trend followed by a shallowing-upward trend, delineating the expected T-R pattern. Indeed, faunal curves constructed on the basis of stratigraphic changes in sample scores for DCA axis 1 track closely the oxygen isotope curve for this section obtained from the benthic foraminifer species *Uvigerina peregrina* (CAPRARO *et alii*, 2005).

These finding indicate that:

1) T-R cycles are delineated by succession of depth and turbidity adapted benthic faunal assemblages recording faunal tracking as these migrated up and down slope/shelf in response to relative sea-level changes.2) Depth related faunal curves constructed on stratigraphic changes in sample scores of DCA could be employed - if framed in a highly refined chronostratigraphic framework - as a tool of correlation at basin or regional scales.

Vincoli biostratigrafici sull'età del vulcanismo alcalino paleozoico dei Monti Peloritani (Sicilia nord-orientale)

ROBERTA SOMMA (*), PILAR NAVAS-PAREJO (**), AGUSTÍN MARTÍN-ALGARRA (**), CARLOS MARTÍNEZ-PÉREZ (°), VINCENZO PERRONE (°°) & ROSARIO RODRÍGUEZ-CAÑERO (**)

Parole chiave: *conodonti, Devoniano, Siluriano, vulcanismo alcalino.*

ABSTRACT

The Palaeozoic successions of the Longi-Taormina Unit (Peloritani Mountains, north-eastern Sicily) are formed mainly by slightly metamorphosed siliciclastic sequences, containing Upper Ordovician acidic rocks and undated alkaline volcanic layers at different stratigraphic heights. These Palaeozoic successions are locally capped by fossiliferous calcareous beds. A detailed biostratigraphic study on conodonts yielded by these carbonates has revealed an Upper Silurian-Lower Devonian age for this interval. These new biostratigraphic data are very useful as they indicate that some of the undated alkaline volcanic layers, being overlain by Upper Silurian-Lower Devonian conodont-bearing metalimestones, are surely related to volcanism not younger than the Late Silurian-Early Devonian and presumably Silurian in age.

INTRODUZIONE

Le rocce paleozoiche del basamento dell'Unità di Longi-Taormina (Monti Peloritani, Sicilia nord-orientale) sono principalmente costituite da successioni silicoclastiche interessate da un debole metamorfismo viseano (datazioni K/Ar: 347-323 Ma, GUERRERA *et alii*, 1999). Tali successioni contengono a diverse altezze stratigrafiche livelli vulcanici sia acidi (porfiroidi) sia basici (metabasalti) e terminano superiormente con strati carbonatici fossiliferi a conodonti e tentaculites. L'età dei livelli più antichi è considerata ordoviciana inferiore (Tremadociano) sulla base del ritrovamento di acritarchi nei livelli silicoclastici (MAJESTE-MENJOULAS *et alii*, 1986). Le vulcaniti acide si collocano al passaggio Ordoviciano medio-Ordoviciano superiore (datazioni U/Pb: 456–452 Ma, TROMBETTA *et alii*, 2004), mentre per le vulcaniti basiche, unanimemente considerate come prodotti di vulcanismo intraplacca, sono state proposte età contrastanti, dall'Ordoviciano al Devoniano (FERLA, 1978; BOUILLIN *et alii*, 1987; ACQUAFREDDA *et alii*, 1991), non essendo mai state datate per via isotopica. Per quel che concerne l'età dei termini più giovani, sia i calcari a conodonti sia quelli a tentaculites sono risultati devoniani (LARDEUX & TRUILLET, 1971; MAJESTE-MENJOULAS *et alii*, 1986). Infine, per alcuni livelli metasedimentari sono state proposte età siluriane e carbonifere, basate, però, solo su somiglianze e correlazioni litostratigrafiche (MAJESTE-MENJOULAS *et alii*, 1986; BOUILLIN *et alii*, 1987; e bibliografia citata).

Lo scopo principale della presente ricerca è quello di datare i livelli carbonatici tramite lo studio dei conodonti. Tale datazione è importante perché consente di stabilire con maggiore precisione l'età delle successioni e anche di porre vincoli all'età di quelle vulcaniti basiche che, nella successione stratigrafica, sono presenti non molti metri al di sotto dei calcari.

ASSETTO GEOLOGICO-STRUTTURALE

La catena dei Monti Peloritani è formata da una serie di falde di crosta continentale, alcune delle quali caratterizzate da coperture sedimentarie meso-cenozoiche, messesi in posto durante il Miocene inferiore (DE CAPOA *et alii*, 1997). Le falde in posizione geometricamente più elevata (Unità dell'Aspromonte e del Mela) sono formate da metamorfiti di medio-alto grado che hanno subito una complessa evoluzione tettono-metamorfica pre-varisica, varisica, e localmente anche alpina (età Rb/Sr da 314 a 26-22 Ma; BONARDI *et alii*, 2008). Le falde sottostanti (dall'alto verso il basso: Unità di Piraino-Mandanici, di Alì-Montagnareale, di Fondachelli e di Longi-Taormina) sono invece costituite da rocce metamorfiche di grado da medio a molto basso, e presentano coperture sedimentarie meso-cenozoiche più o meno estese (LENTINI & VEZZANI, 1975; BONARDI *et alii*, 1976; e bibliografia citata).

L'Unità di Longi-Taormina (ULT), in particolare, affiora lungo una fascia ad andamento ONO-ESE, che corre lungo la cosiddetta Linea di Taormina, un allineamento strutturale che si estende da Taormina, sulla costa ionica, a Sant'Agata di Militello, sulla costa tirrenica.

L'ULT è suddivisa in tre principali subunità, denominate in base alla loro posizione geometrica. La subunità superiore affiora estesamente nei settori occidentale e centrale della Linea di Taormina (da Sant'Agata di Militello a Roccella Valdemone); la subunità inferiore è esposta solo nell'area orientale (area di Gallodoro-Letojanni, nei pressi di Taormina), mentre la subunità intermedia affiora estesamente lungo l'intera Linea di Taormina.

Fig. 1 - Synthetic stratigraphic column of the Longi-Taormina Unit basement.

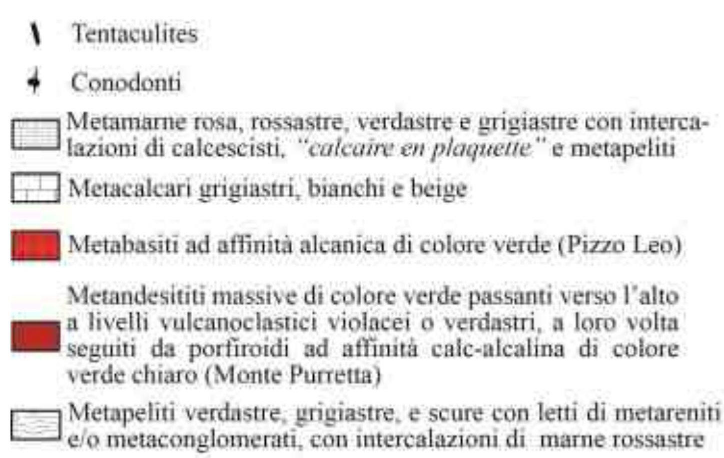
LITOSTRATIGRAFIA E BIOSTRATIGRAFIA

Le successioni stratigrafiche più significative analizzate nella presente ricerca sono state ricostruite nelle subunità superiore ed intermedia dell'ULT (Fig. 1). Campionature dei livelli carbonatici sono state eseguite comunque anche nella subunità inferiore, sebbene essa sia esposta solo in affioramenti di estensione estremamente limitata.

Le sezioni litostratigrafiche e biostratigrafiche nella subunità superiore sono state ricostruite principalmente nell'area di Pizzo Leo e di Rocca Licopeti (circa 30 km a NO di Taormina). Le successioni paleozoiche sono costituite da una formazione silicoclastica basale (potente circa 100 m), debolmente metamorfica, che presenta nella porzione stratigraficamente più alta diverse lenti di metabasalti verdastri con struttura vacuolare e strutture a cuscino. A queste rocce vulcaniche è sovrapposta una successione carbonatica (potente 100-150 m), formata da metacalcari e metamarne con intervalli metapelitici. In questa successione, grazie allo studio dei conodonti, sono state riconosciute diverse biozone appartenenti al Siluriano superiore-Devoniano inferiore.

Le successioni litostratigrafiche della subunità intermedia sono principalmente costituite da una formazione silicoclastica basale (potente diverse centinaia di metri) debolmente metamorfica. In tali successioni sono presenti il potente livello vulcanico acido dell'Ordoviciano medio-superiore, datato 456–452 Ma da TROMBETTA *et alii* (2004), e diverse lenti, a volte molto potenti, di metabasalti, ad oggi mai datati con metodi isotopici. Tuttavia, il ritrovamento di Acritarchi in alcuni livelli ritenuti essere alla base delle suddette vulcanite testimonierebbe un'età tremadociana per questo evento vulcanico basico (MAJESTE-MENJOULAS *et alii*, 1986).

I nostri dati geologici e stratigrafici non si accordano con tale interpretazione dal momento che le vulcanite basiche si trovano in una posizione stratigrafica più alta rispetto a quella delle vulcanite acide ordoviciane.



Infine, l'analisi biostratigrafica dei campioni prelevati nei metacalcari, potenti alcune decine di metri, presenti nella successione silicoclastica della subunità inferiore è risultata infruttuosa.

DISCUSSIONE E CONCLUSIONI

La colonna stratigrafica illustrata nella Figura 1 rappresenta la stratigrafia sintetica del basamento paleozoico dell'ULT, ricostruita sulla base di diverse sezioni stratigrafiche realizzate nelle subunità superiore ed intermedia.

I livelli più antichi (Fig. 1) appartengono principalmente alla subunità intermedia e sono rappresentati da una successione basale silicoclastica contenente i livelli vulcanici acidi ordoviciani (età U/Pb: 456–452 Ma; TROMBETTA *et alii*, 2004). In questa subunità, discussa è invece la posizione stratigrafica dei metabasalti alcalini poiché non sono mai stati datati per via isotopica. Secondo i nostri attuali dati geologici e stratigrafici, la loro posizione non sarebbe sottostante ma soprastante a quella dei livelli acidi, e pertanto l'età sarebbe successiva a 456–452 Ma. Questo dato sarebbe confermato anche dagli studi stratigrafici realizzati nella subunità superiore, affiorante nella zona di Pizzo Leo e Rocca Licopeti, dove diverse lenti di metabasalti alcalini, presenti nella successione silicoclastica, sono ricoperte dai livelli carbonatici fossiliferi, che risultano essere di età Siluriano superiore-Devoniano inferiore sulla base dei conodonti in essi rinvenuti.

In conclusione, poiché alcuni livelli vulcanici basici del basamento dell'ULT risultano sicuramente di poco anteriori alla deposizione dei calcari di età Siluriano superiore-Devoniano inferiore, tale vulcanismo non sembra essere più giovane del Siluriano superiore-Devoniano inferiore, e quindi presumibilmente potrebbe essere siluriano come osservato in altre zone della catena varisica (SCHÖNLAUB & HEINISCH, 1994).

INTRODUCTION

Over a variety of mountain belts, it has been shown that spatially averaged millennial-scale erosion rates are comparable with exhumation rates over millions of years (e.g., KIRCHNER *et alii*, 2001; MATMON *et alii*, 2003; VANCE *et alii*, 2003; STOCK *et alii*, 2009). These findings support the idea that, under conditions of steady uplift and over time scales of 10^3 to 10^6 years, mountain belts tend to achieve dynamic equilibrium between uplift and denudation. The same has recently been proposed also for the central and northern Apennines by CYR & GRANGER (2008), for which the Authors suggest that dynamic equilibrium was achieved within few million years (*c.* 3) after emersion of the mountain belt.

We investigate the relationships between uplift and denudation over Quaternary times in a younger portion of the Apennine orogen, *i.e.* the southern Apennines mountain belt. This is carried out by the integration of geomorphologic and morphometric data with constraints on the uplift and erosion rates, the latter being provided by independent datasets.

TECTONIC FRAME

The southern Apennine chain is a NE-directed fold and thrust belt, with the Apulian promontory representing the orogenic foreland. The thrust belt consists of carbonate platform (Apennine Platform) and pelagic basin (Lagonegro) successions, locally covered by Miocene foredeep and/or wedge-top basin sediments, and overthrusted by the 'internal' tectonic units (e.g. CIARCIA *et alii*, 2012). The thrust belt is superposed onto the western portion of the Apulian Platform succession, which was involved in the younger shortening phases (e.g., MOSTARDINI & MERLINI, 1986; MAZZOLI *et alii*, 2001, 2008; SHINER *et alii*, 2004).

During the Messinian, a generalized emersion affected the chain, chain, followed by the formation of shallow-water to continental wedge-top basins on top of the Apennine allochthonous units since the late part of the Early Pliocene. Basin subsidence followed a progressive SE-ward shift from *c.* 4 to *c.* 2.8 Ma (ASCIONE *et alii*, 2012).

Since Late Miocene times, thrusting was accompanied by back-arc extension in the southern Tyrrhenian Sea, which, during the Quaternary, affected the southern Apennines with the formation of large peri-Tyrrhenian grabens (e.g., SARTORI, 1990).

Crustal shortening in the southern Apennines ceased in the early part of the Middle Pleistocene, at about 0.7 Ma, and was followed by regional uplift involving the thrust belt and the neighbouring Bradanic foredeep (e.g. CINQUE *et alii*, 1993; AMATO, 2000; PATACCA & SCANDONE, 2001). A new tectonic regime, characterized by a NE-SW oriented maximum extension, was established in the chain and adjacent foothills (e.g., CELLO *et alii*, 1982; HIPPOLYTE *et alii*, 1994). The structures related to this new regime, include dominantly extensional faults that postdate and dissect the thrust belt (e.g., BUTLER *et alii*, 2004). Striking evidence of such extensional faulting are widespread, and include large fault-bounded intramontane basins filled with lacustrine and/or alluvial deposits.

LARGE SCALE GEOMORPHIC FEATURES AND CONSTRAINTS TO UPLIFT AND DENUDATION

The southern Apennines are characterized by an asymmetric topography, with maximum elevations shifted towards the steeper southwestern flank of the chain. Also asymmetric is the position of the main divide, which follows neither the chain axis nor the crest line, and develops for most of its length to the E of the latter.

Analysis of the topographic features of the mountain belt shows that the distribution of the maximum elevation is shifted with respect to that of the highest medium elevation. The latter, in fact, is located relatively to the east with respect to the highest maximum elevations, which are essentially controlled by the

° Dipartimento di Geoscienze, Università di Padova.

occurrence of the less erodible carbonate successions. Similarly, the minimum elevations reach higher values in the northeastern flank than in the southeastern flank.

Constraints to the amount and timing of the southern Apennines mountain belt-foredeep system uplift are provided by elevation of marine terraces and shorelines from both the Tyrrhenian (e.g., ASCIONE & ROMANO, 1999; FILOCAMO *et alii*, 2009) and the Ionian coastal belts (e.g., AMATO, 2000; CAPUTO *et alii*, 2010). In addition, littoral deposits from Pliocene-Pleistocene wedge-top basin provide information on the uplift of the axial belt of the chain.

Available constraints point out that uplift coeval with shortening was both spatially and temporally uneven, and was slower than that recorded in the latest stages, following ceasing of shortening. In fact, the post-0.7 Ma time span is characterized by a distinct increase in the uplift rate to values around 0.8 mm/yr, and involves both the foredeep and the eastern belt of the chain, including the axial belt. On the other hand, coeval uplift in the Tyrrhenian belt was much slower, and basically comparable with earlier (Early Pleistocene) uplift.

Constraints to the denudation history of the mountain belt are provided by independent datasets, *i.e.* (i) cosmogenic nuclides and long-term sedimentary yield, which constrain erosion rates, and (ii) low-T thermochronometric data, which provide information on the unroofing of originally deeply buried tectonic units (Lagonegro basin succession, and Apulian Platform in the M. Alpi area; CORRADO *et alii*, 2002, 2005).

Paleoerosion rates from cosmogenic ^{26}Al and ^{10}Be were estimated form alluvial sediments from the Bradanic foredeep area, and from the Sant'Arcangelo wedge-top basin. Based on the different ages of the sampled deposits, the estimated paleoerosion rates provide information on denudation active over different time windows, which collectively span from the upper part of the Early Pleistocene to the upper part of the Middle Pleistocene. In addition, such values average denudation active both over the entire eastern flank of the mountain belt, and over the axial zone of the mountain belt.

Cosmogenic nuclide-based paleoerosion rate values range from *c.* 0.2 and 0.4 mm/yr. Such values are consistent with that – around 0.3 mm/yr – estimated, for the chain axial belt, based on long-term sediment yield from continental wedge-top basin deposits of late Lower Pleistocene-early Middle Pleistocene age (Sant'Arcangelo basin). The obtained values are also consistent with previous estimates – of 0.2–0.3 mm/yr – of erosion rates from the axial and eastern parts of the chain, based on the evaluation of volumes eroded from reconstructed paleo-topographies, and averaged over the Middle Pleistocene to the Present, and the Early Pleistocene to the Present, respectively (AMATO *et alii*, 2003; CAPOLONGO *et alii*, 2008; SCHIATTARELLA *et alii*, 2004).

Apatite (U-Th)/He cooling ages provide information on exhumation processes in the axial belt of the Apennines. Estimated exhumation rates, averaged over time spans ranging from about 6 to 2 Ma, are of the same order of estimated erosion rates, essentially varying between 0.6 and 0.3 mm/yr.

Collectively, available independent estimates are representative of denudation active over a large part of the mountain belt, which includes bedrocks with largely variable resistance to erosion, the more erodible ones being dominant with respect to the more resistant (e.g. carbonates) ones. In addition, such estimates, providing information on different time windows, collectively cover both the warmer, "pre-glacial" climates, and the late Quaternary glacial-interglacial fluctuations. This indicates that, as observed also in other scenarios (e.g. STOCK *et alii*, 2009), denudation rates averaged over long time spans are insensitive to climatic fluctuations.

In addition, the overall data set on uplift, erosion/paleoerosion rates and exhumation rates, indicates that the changing style and rate of uplift has not affected the development of denudation in the southern Apennines mountain belt. Such imbalance between uplift and denudation may be interpreted as a result of the long response time of hillslope and fluvial systems with respect to the relatively young age (*c.* 0.7 Ma) of uplift acceleration. This implies that the northeastern belt of the chain has been subject to surface uplift over the Middle Pleistocene, as it is also inferred from both the small and large-scale topographic features of the mountain belt, *i.e.* from the occurrence of wide and flat divide areas (e.g. the so-called paleosurfaces, or the wide marine terraces in the Bradanic area), and from the asymmetrical position of the medium elevation peak with respect to the chain axis, which apparently is less dependent on bedrock erodibility than on large-scale vertical motions.

Palaeo-landscape reconstruction and assessment of long-term erosion rates through DEM analysis: preliminary results from the Molise Apennine (Central-Southern Italy)

PIETRO P.C. AUCELLI (*), VINCENZO AMATO (°), VITTORIA SCORPIO (°), VITO BRACONE (°) & CARMEN M. ROSSKOPF (°)

Key words: *Palaeosurfaces, DEM analysis, erosion rates, Palaeo-landscape, Molise Apennine, Italy*

INTRODUCTION

Since some decades, long term and regional landscape reconstructions are of increasing importance for the study of the relationship between tectonics and exogenous dynamics in a long-term perspective (AUCELLI *et alii*, 2011 and references therein). The geomorphic markers traditionally used for the estimation of uplift and denudation rates in orogenic areas are marine terraces, palaeosurfaces (*sensu* WIDDOWSON, 1997) and associated remnants of slope and fluvial landforms which equally refer to ancient base levels of erosion. Although more difficult to date than marine terraces, palaeosurfaces are frequently used because of their great extent which allows geomorphic long-distances correlations and facilitates the recognition of differential tectonic movements.

The estimation of uplift and denudation rates represents an active research field in studying the interaction between climate, tectonics and landscape evolution. In tectonically active areas a precise definition of such rates can offer an important information about landscape evolution and the interplay between uplift and denudation (GIOIA *et alii*, 2011 and references therein).

Furthermore, palaeo-topographic reconstructions of former base level morphology and the comparison with the present day topography can be used to estimate the eroded volume.

In the central-southern Apennine, various studies using morpho-stratigraphic approaches allowed to constrain the ages of many palaeosurfaces that are cut both on chain and foredeep terrains (AMATO *et alii*, 2011; AUCELLI *et alii*, 2011 and references therein).

Starting with an analysis of the identified palaeosurfaces and the related palaeo-topography, aim of this study is to reconstruct the palaeo-landscape and to estimate the erosion rates of a portion of the Molise Apennines.

GEOLOGICAL-GEOMORPHOLOGICAL SETTING

The Molise Apennine is located in the junction zone between the southern and the central-northern arcs that form the Apennine chain (PATACCA *et alii*, 1992). Only a minor portion of the Molise Apennine is characterized by a Tyrrhenian orientated drainage (Volturno river network), while great part of it is drained by rivers flowing to the Adriatic Sea. Major rivers, Trigno, Biferno and Fortore, cut transversally the eastern flank of the Molise Apennine (hereinafter MA) dissecting the compressive structures of the chain, represented by complex fault-thrust structures prevalently oriented in a NNW-SSE and north-east verging direction, then affected by strike-slip and extensional tectonics during the Quaternary.

The western, inner sector of the eastern flank of the Molise Apennine is built prevailingly on limestones and marly limestones and dominated by a mountainous landscape, while its eastern sector, cut instead on more erodible prevailing pelitic rocks, shows a hilly to locally terraced morphology and is characterized by moderate to low relief and low-gradient denudational slopes. Within the inner sector, the main outcropping tectono-stratigraphic unit is represented by the Sannio unit (PATACCA & SCANDONE, 2007), which tectonically overlies the Molise and Flysch units. The Sannio unit reaches a total thickness of about 1500 m and is made up, from bottom to top, by carbonate terrains, varicoloured clays, and prevailing siliciclastic top-thrust deposits referring to the Numidian and S. Bartolomeo Flysch (PATACCA & SCANDONE, 2007; CESARANO *et alii*, 2011; ISPRA, in press).

The MA is deeply dissected by the drainage network developed in time by major trunks and is characterized by a landscape that clearly evidences the strong and long-term interaction between fluvial and hillslope processes.

An important feature of the MA landscape are the palaeosurfaces, mostly of erosional origin, which represent the remnants of gently-rolling ancient landscapes, now hanging at different altitudes above the local base-levels of erosion. Their genesis can be related to prolonged periods of relative tectonic stability alternating with periods of uplift, or to the interplay between steady tectonic uplift and climatic fluctuations. In the MA, the palaeosurfaces are represented by relics of ancient planation surfaces (hereinafter Tops) and by hanging valley side glacis (hereinafter Glacis). The first ones coincides with narrow water divides of variable altimetry and sinuous plan shape. The Glacis are present along the valley flanks of the main trunks and major tributaries and are represented by gentle convex-concave hillslopes terminating downslope with remnants of almost planar surfaces dipping very gently toward the valley axes, and separated from the thalweg by steep high fluvial scarps. Their genesis is referred to periods of prevailing valley widening and nil to low downcutting rates.

The present study is performed along a transect located in the inner sector of the MA, between the northern front of the Matese massif and the foreland basin of the Apennine fold-thrust belt (Fig. 1) including in particular the medium-upper sector of the Biferno valley system.

METHODS

To assess the erosion rate in the last 600ky we used a multi-methodological approach based on geomorphological analysis followed by GIS elaborations in ArcGis.

The palaeo-surfaces were mapped in GIS environment (Fig. 1) as polygons on the basis of topographic map and orthophoto interpretation.

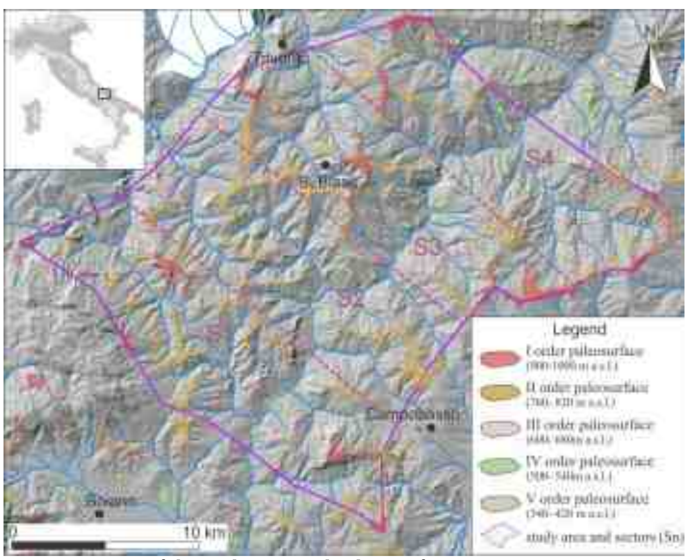

Fig 1 - Location of the study area, and palaeosurfaces map.

Overlaying the shape of palaeosurfaces with the DEM of Molise region (resolution of 40x40 m per pixel and certified by the Molise regional cartographic authority – herein after MDEM) it was possible to obtain the clouds of elevation points inside the polygons. These points have an elevation derived from the MDEM and were selected by means of a clip operation. The DEM representing the palaeo-landscape (hereinafter PDEM) was obtained interpolating the clouds of elevation points. As interpolation procedure we used the "*topo to raster*" method (HUTCHINSON, 1993) implemented in Arcgis. The obtained PDTM presents a resolution of 250m per pixel.

Below, we present the results relative to the computation of the eroded rock volumes and rate of erosion derived as the difference between the 600Ky palaeo-landscape (PDEM) and the present-day landscape (MDEM).

RESULTS

Detailed geologic-geomorphological analysis of the palaeosurfaces (Tops and Glacis) allowed to put in evidence their distribution along the main trunk, the Biferno river, and the major tributary valleys both in terms of order and elevation.

In this work we considered the remnants of palaeosurfaces present between ca. 1000 m a.s.l. and a few meters above the thalweg.

In this way, five orders of palaeosurfaces (Fig. 1) were recognized: I (900-1.000 m a.s.l), II (760—820 m a.s.l.), III (600—680 m a.s.l.), IV (540-500 m a.s.l.) and V (420-340 m a.s.l.) whose correlation with the palaeosurfaces identified in the adjacent Matese and Montagnola di Frosolone massifs and the Sessano basin (see AUCELLI *et alii*, 2011) is also discussed.

The first (I) order is cut into the bedrock. While it corresponds to remnants of Glacis in the adjacent Matese and Montagnola di Frosolone massifs, in the study area (Fig. 1) it is represented by Tops.

The II order, along the northern flank of the Matese massif, at S. Massimo is cut into Quaternary deposits, forming Glacis, while in the sector between the Trigno and Biferno rivers it is located mainly at the top of the relief. Their maximum age is clearly constrained by the age of 0.6 Ma BP obtained by Ar/Ar datings (DI BUCCI *et alii*, 2005) for the S. Massimo fluvio-lacustrine deposits on which the II order is cut locally.

The III order, cut both into Quaternary deposits and pre-Quaternary bedrock, along the borders of Boiano and Sepino basins is represented by Glacis, within the study area, mainly instead,

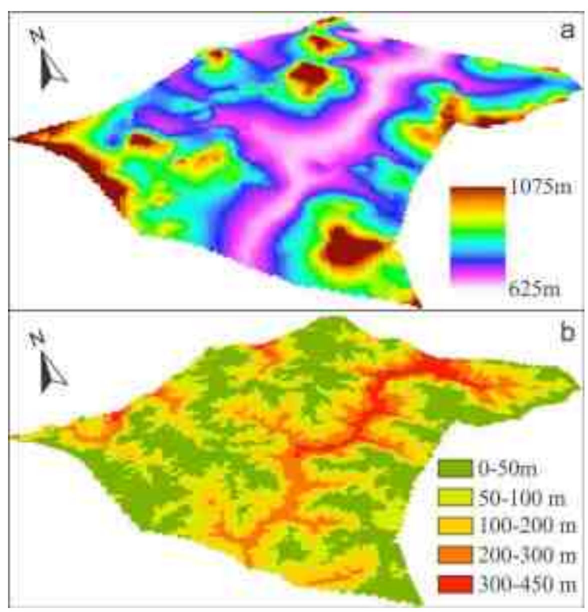

Fig 2 - a) DEM representing the palaeo-landscape (PDTM). b) Differential erosion evaluated as the differences between the two DEMs: PDEM and MDEM.

by Tops and, secondly by Glacis. This order can be tentatively correlated with the SBP palaeosurface of the very close Sessano basin (AUCELLI *et alii*, 2011; AMATO *et alii*, 2011), which was dated at ca. 0.3 Ma BP. The IV order is present along the borders of the Boiano basin forming mainly Glacis and along the Biferno and Trigno valleys, while the V order is located only along the Trigno and Biferno Valley.

In order to assess the erosion occurred during the last 600Ky, the differences between the two DEMs, PDEM and MDEM (Fig. 2), were calculated taking in reference I and II order palaeosurfaces.

The derived average erosion rate is about 0.20 mm/y. It is more elevated within the more incised valley sections (from 200 to 400m of incision) and decrease towards the higher portions of the slopes (Fig. 2). The study area was then divided in 4 equal areas (see Fig. 1) arranged perpendicularly to the valley direction. The erosion rates calculated for each sector (Tab. 1) show an increasing value for outer part of the chain (Sectors 2-4, Tab. 1)

Sectors	***Av. Elevation (m)***	***Av. Erosion Rate (mm/y)***	***Max. Erosion Rate (mm/y)***
1	692	0.13	0.46
2	578	0.18	0.63
3	642	0.16	0.62
4	570	0.23	0.71

Tab 1 - Erosion rate for each sectors. (Av. Elevation= Average elevation in the sector; Av. Erosion Rate= average erosion rate; Max. Erosion Rate= maximum erosion rate).

Finally, the relation between erosion rates and substrate lithology was analyzed. The most widespread rock types in the area are Varycoloured clays, marls and clay, followed by sandstones and limestones.

Varycoloured clays have the major erosion rate (average value 0.3 mm/y, maximum value 0.7 mm/y), followed by marls and clay (average value 0.16 mm/y, maximum value 0.7mm/y), and finally by sandstones and limestones (average value 0.11 mm/y, maximum value 0.51 mm/y).

CONCLUSION

The present paper provides first preliminary results about erosion rates in the Molise chain, during the last 600 k/y.

The differences in rates of uplift between the most inner sector (1) of the study area and the more outer ones surely may be related to the differences in erodibility of the outcropping rocks (major in the external sectors than in the inner one), but could also indicate differences in the uplift regime that has however to be better investigated. The erosion rates in this Apenninic sector are consistent with the estimated value of GIOIA *et alii* (2011) in Southern Apennine.

The effects of the interaction between ground deformation and the erosion on the visibility of Permanent Scatterers Features on SAR interferograms: an example from Mount Etna (Eastern Sicily)

STEFANO CATALANO (*), ALESSANDRO BONFORTE (**), FRANCESCO GUGLIELMINO (**), GINO ROMAGNOLI (*), CATIA TARSIA & GIUSEPPE TORTORICI (*)

Key words: *Etna, ground deformation, SAR, weathering.*

INTRODUCTION

Mount Etna is one of the most studied volcanoes by Interferometry SAR (InSAR) spatial techniques (MASSONNET & FEIGL, *1998;* FROGER *et alii, 2001).* In these study particular attention has been dedicated to the recognition and definition of the "Permanent Scatterers Features" (PSFs) (BONFORTE *et alii, 2011)* that represents permanent discontinuities in the ground deformation, corresponding to active fault segments recognised on the field. Our study consisted of the interpretation of 1549 DInSAR interferograms that have been generated by comparison of couples of ENVISAT images, covering the period from the 2003 to the 2010. The analysed interferograms thus refer to variable time-intervals that correspond to the lapse of time between the acquisition of the earlier (master) and the latter (slave) combined images. For each interferogram, the visibility of the PSFs has been assessed by a visibility index, whose trend vs. the increase of the temporal interval covered by the interferograms has been estimated. This mostly innovative approach aims to emphasize the short-term behaviour of the Permanent Scatterers Features (PSFs) of Mt. Etna (Fig. 1), by the reconstruction of the periodicity of their visibility, to be correlated to the dynamic processes active in the region.

PERMANENT SCATTERERS FEATURES (PSFs) ON MOUNT ETNA

On an interferogram, the scatterers are all the pixels that are affected by very low decorrelation and that are coherent throughout the analysed time span of a series of interferometric acquisitions. In the Permanent Scatterers (PS) technique perspective, the entire radar image can be, thus, considered as a very dense network of natural geodetic benchmarks, providing time series of displacements from which a detailed map of the ground velocities can derive. Our study evidenced that the main active tectonics on Mt. Etna, representative of the entire active tectonic picture of the region (Fig. 1) (MONACO et *alii*, 2005), are imaged on interferograms as PSFs, separating blocks with different velocities. The analysed period is characterised by the absence of a significant seismicity producing co-seismic ground deformation. As a consequence, the motions appreciated by the interferograms have to be related to the interseismic, almost continuous creeping, usually characterising most of the active fault lines of Mt. Etna.

RESULTS AND CONCLUSIONS

The analysis of the complete set of the interferograms has evidenced two distinct families of PSFs that are characterised by different behaviours. A first group includes all the features that are visible during the entire examined time-span, with a visibility index increasing with the time-interval covered by the interferograms, to suggest their attitude to cumulate amounts of ground deformation. This group is composed of structures that are characterised by variable displacement-rate with a prevalent strike-slip component of motion (e.g. PSF1= Pernicana Fault; Fig. 1). A second family groups the PSFs that show an opposite behaviour, as they are characterised by sporadic periods of appearance, with a visibility index, which is decreasing as the time-span between the acquisition of the master and that of the slave enlarges. This second group is composed of faults that are usually characterised by a prominent dip-slip component of motion. The possible origin of this distinctive behaviour has been tested by the detailed analysis of the PSF 6 (Trecastagni Fault; Fig. 1) that, in the considered time-interval, has been characterised by an almost continuous aseismic creep, well evidenced by the displacements of several artefacts, crossing the fault line. Despite of the mode of deformation of the fault, the analysis of the interferograms revealed discrete periods of the visibility of the PSF6, which are summarised on the diagram of Fig. 2. These results refer to interferograms that have been obtained by combination of distinct 35 images, acquired over the entire studied time-interval. The diagram clearly indicates that, for each selected master image, the feature appears on interferograms only when it is combined with slave acquired, at least, one year after. On the contrary, the images acquired in

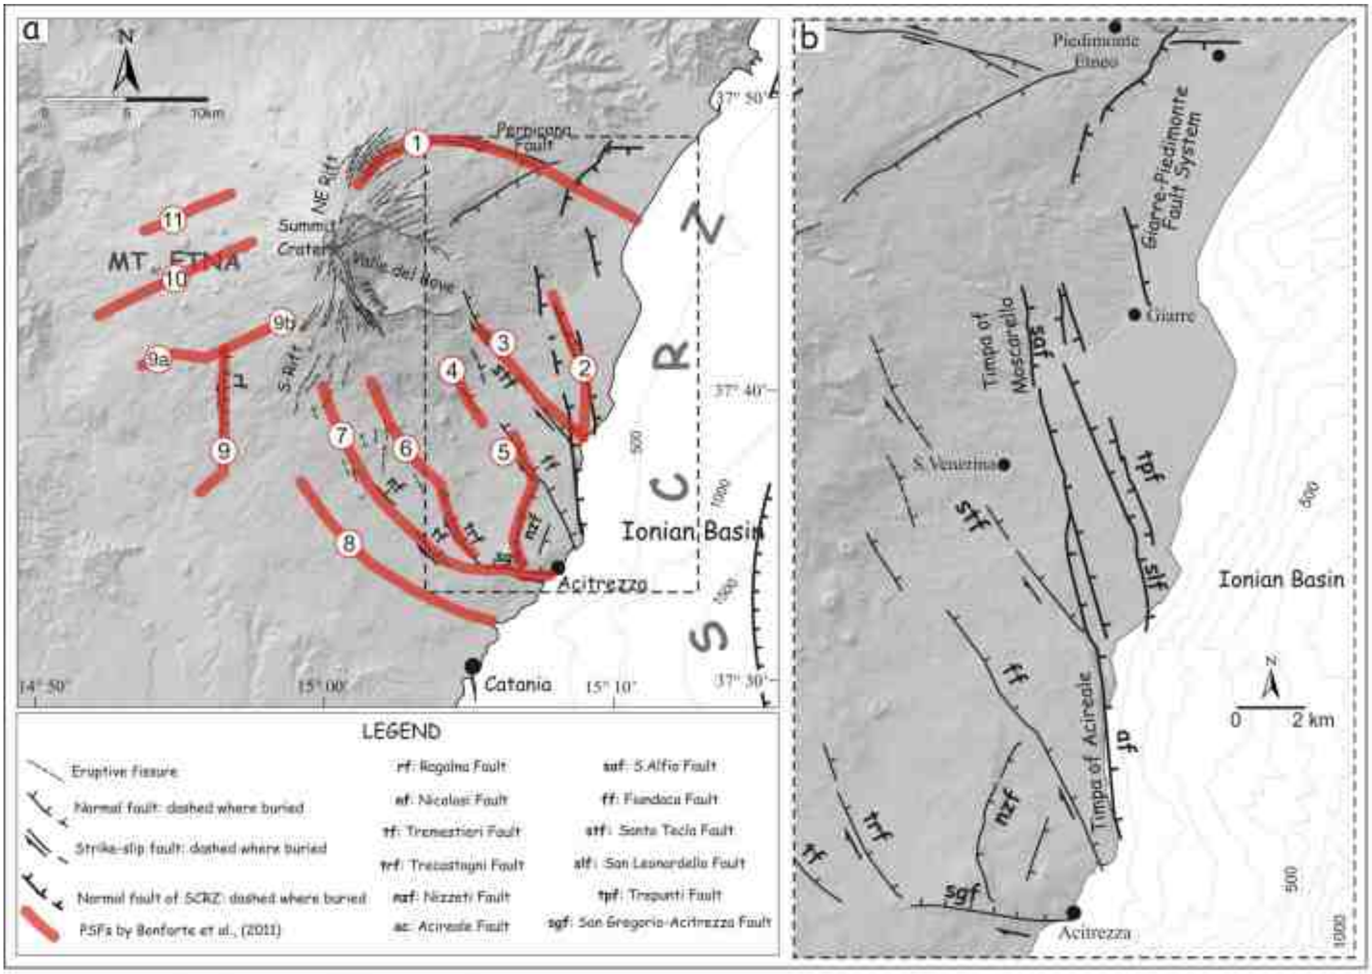

Fig. 1 – PSFs and active tectonics of Mount Etna.

sequence for shorter periods, if combined each to the other, generate interferograms where the feature is totally absent. This behaviour would suggest the occurrence of apparent episodic remobilisations of the fault that contrasts with both the field evidence and the tendency of the feature to progressively disappear on interferograms as the elapsed time from the master and slaves increases. For each considered master image, in fact, some years after the moment of the early appearance, the visibility of the PSF6 progressively decreases to zero. This would imply that the repeated appearances of the fault on interferograms does not result in the accumulation of ground deformation, as in the case of the features of the first group. The history of the visibility of the structure can be better explained considering the interaction between the almost uniform tectonic deformation with the variable effectiveness of weathering and runoff across the fault, balancing the amounts of tectonic displacement. This relation is strongly suggested by the clear correlation between the appearances of the structure with the time distribution of the rainfalls in the area of the fault. The feature is, in fact, almost absent on interferograms referred to images from the same seasonal wet period, during which the runoff and mass transport from the upthrown to the downthrown block almost balance the ground tectonic deformation. On the contrary, the feature generally appears at the end of prolonged dry periods, during which the structure can cumulate discrete displacements, without any significant episode of sculpturing across the fault line. It is to remark that in the studied time-span an impressive heavy rain (267 mm) episode occurred on 12.27.2006. This event produced a transient visibility of the feature, probably due to huge mass transfer across the fault, causing a significant topographic changes along the Line Of Sight (LOS) of the radar sensor.

Geomorphic numerical analysis based on wavelet transform

ANGELO DOGLIONI (*) & VINCENZO SIMEONE (*)

Key words: *Data-driven modeling, wavelet transform, geomorphic analysis, geomorphic anomalies delineation.*

INTRODUCTION

The analysis and delineation based on quantitative evidences of large geomorphological anomalies is of particular importance for the study of large landslides. Numerical geomorphic analyses constitute valid approaches to this kind of studies, allowing for a detailed and relatively accurate identification of topographic anomalies sometimes not clearly evident that may be related to hidden geological structure or large landslides.

Here a geomorphic numerical analyses of the Digital Terrain Model (DTM) is presented. The introduced approach is based on 2D discrete wavelet transform (ANTOINE *et alii*, 2003; BRUUN & NILSEN, 2003, BOOTH *et alii*, 2009).

Here the introduced approach is applied to an interesting cases study of south Italy, in particular for the identification of a large anomaly associated to a huge landslide, located at the transition between Apennine chain domain and the foredeep domain, in low Biferno valley. The 2D discrete wavelet transforms are performed on multiple levels, thus trying to address the problem of which is the level extent for an accurate analysis fit to a specific problem.

DESCRIPTION OF THE METHODOLOGY

Wavelet transform is a methodology for analyzing localized variations of power within a series of data. Given a set of spatial data, e.g. an elevation profile, it is decomposed into space–frequency space. This allows for determining both the dominant modes of variability and how those modes vary in space. In fact, as in DAUBECHIES (1992), wavelet transform allows for decomposing data into different frequency components, which can be studied and analyzed with the proper resolutions matching to their scales. Wavelet transform is particularly used for the analysis of time-evolving signals, which depends on two variables: frequency, and time. Then wavelets provide accurate time-frequency localization. This approach can be easily adapted to other distributed data, in particular topographic data coming from a grid-based description of earth surface.

Discrete Wavelet Transform (DWT) is an orthogonal function applied to a finite set of data. Similarly to Discrete Fourier Transform (DFT), DWT is orthogonal: a signal passed twice through the transformation is unchanged, and it is assumed the input signal as a set of discrete-time samples. While DFT is based on a sinusoid, DWT is based on a set of functions defined by a recursive difference equation

$$f(x) = \sum_{k=0}^{M-1} c_k f(2x - k) \qquad (1)$$

where M is the specified number of nonzero coefficients, which is arbitrary, and referred to as the order of the wavelet. The values of the coefficients are not arbitrary, but determined by constraints of orthogonality and normalization. Moreover, the area under the wavelet is required to be one. This class of wavelet functions is bounded to be zero outside of a small interval. This is what makes the wavelet transform able to operate on a finite set of data, i.e. compact support. The functions commonly used for performing transforms consist of a few sets of well-chosen coefficients resulting in a function, which has a discernible shape. There exist several mother wavelets, the specific choice of a mother wavelet depends on the features of data to be analyzed. The choice of the mother wavelet for DEM analysis is also dependent of the resolution of the elevation models, which affects the description of terrain detail. For the analysis of large landslides influenced by tectonical displacements, medium-low resolution DEMs can be used. Therefore, the biorthogonal 1.1 mother wavelet (DAUBECHIES, 1992) is here chosen. Biorthogonal Wavelets are families of compactly supported symmetric wavelets. Biorthogonal wavelets use two scaling functions, which may generate different multiresolution analysis and then two wavelets, one for decomposition and the other for reconstruction instead of the same single one, are used, thus implying interesting properties.

DWT (DAUBECHIES, 1992) is performed columnwise and linewise, which basically represent horizontal and vertical directions, thus retuning a 2D map of coefficients for each direction. In particular, the outcomes of this analysis are low-

(*) Dipartimento di Scienze dell'Ingegneria Civile e dell'Architettura, Politecnico di Bari, via E. Orabona 4, 70125, Bari, Italy. a.doglioni@poliba.it ; v.simeone@poliba.it

frequency approximation coefficients and high-frequency detail coefficients. Detail coefficients are analyzed, since their variations are associated to discontinuities of the DTM. Fig. 1 The maps of detail coefficients are then analyzed to quantify potential anomalies of the land surface (DOGLIONI & SIMEONE, 2011). Moreover, 2D DWT can be pushed to further levels, assuming a higher scale number of the transform. This may potentially return further interesting results, in terms of identification of the anomalies of land surface. In this kind of approach, the choice of a proper mother wavelet function is a tricky point, since it conditions the analysis and then their outcomes. Therefore multiple levels as well as multiple wavelet analyses are guessed.

CASE STUDY

A case study where the use of 2D DWT is here introduced, in order to show the potentialities and the effectiveness of this approach, which can be of particular use for geomorphic analysis. The study area is the low valley of river Biferno downstream of Ponte Liscione Dam in South Italy. It is located at the transition zone between Apennine chain and Adriatic foredeep domains (Fig. 1), where allochthonous nappes are partially buried under Pleistocenic foredeep deposits (C.N.R, 1992). In particular, towards the coast, on both sides of the valley Plio-Pleistocenic foredeep deposits outcrop, with a general gradual gentling of the shapes. This shows the typical configuration of the foredeep deposits: conglomerate regressive terraces rest on the sub-Apennine grey-blue clays. The left side of the river is higher and steeper than the right one and it is strongly affected by large retrogressive landslides up to Guglionesi town (Fig. 1). On the right side between Biferno and Cigno valleys, there is Larino Plateau (Fig. 1).

It appears as a large regressive terrace (Pleistocene). Larino Plateau gently slopes (about 1°) NE toward the confluence of Cigno stream with Biferno river. On the south side of this plateau, there is the valley of Cigno stream and an high scarp up to a crest where the towns of Ururi, San Martino in Pensilis and Portocannone are located. On this crest regressive sandy-gravelly soils deposits, similar to those of Larino Plateau crop out. The particular geomorphological characteristics of the study area are here meant as consequence of a huge deep-seated landslide on the right side of Biferno valley (GUERRICCHIO *at alii*, 2010; DOGLIONI & SIMEONE, 2011). Larino Plateau is the landslide body, while Cigno valley is a large trench downstream the main scarp of the landslide, which arrives up to Ururi and San Martino in Pensilis crest. The morphological characters of low Biferno valley as well as the paths of rivers Biferno and Cigno are analyzed through a wavelet analysis of a medium resolution (30 m square cells, ASTER GDEM) DEM to give the evidence of this large deep-seated landslide, also affecting the landslide hazard on the left bank of low Biferno valley.

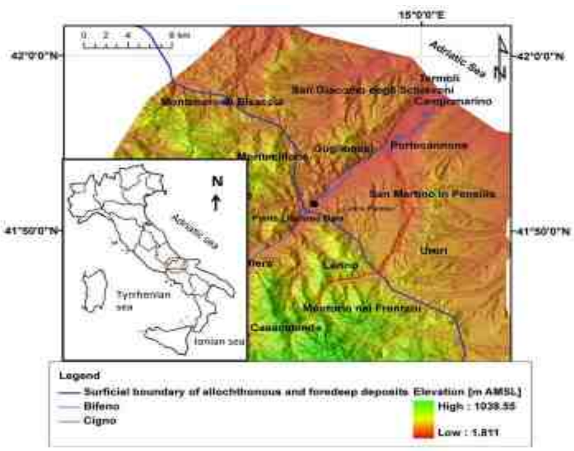

Fig. 1 – Investigated area and DEM.

RESULTS AND DISCUSSION

2D DWT is performed on the investigated area, covering a surface of about 1340 km^2, from the coastline towards Apennines. The decomposition was performed on 4 levels, each of them associated to horizontal and vertical wavelet transforms. Detail coefficients are expected to be of high magnitude where the topography is disturbed, i.e. abrupt change of slopes exists, while they are expected to be of low magnitude where the topography is flat and undisturbed. Therefore, Apennine domain is expected to be denoted by high values of detail coefficients, while after the transition from the chain into the foredeep domain occurs, low values of detail coefficients must prevail. However, the map of detail coefficient does not present the aforementioned expected scenario. Indeed, detail coefficients show values which emphasize some anomalies, which were not easily identifiable just looking at the DEM and which delineate a peculiar scenario.

The following Figure 2 show level 3 absolute values of detail coefficients of Biferno valley along the horizontal direction, which corresponds to W-E direction. The color map of the figure represents the magnitude of detail coefficients of the DWT.

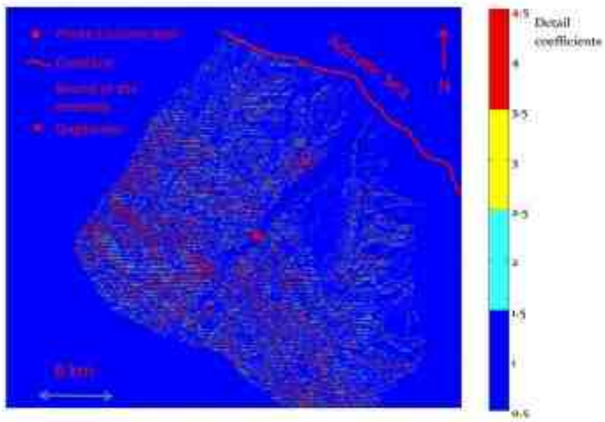

Fig. 2 – Level 3 2D-DWT along W-E direction.

In particular the meaning of these coefficients is: the higher is their value the sharper is the discontinuity of the section. On the other hand, the lower is the detail coefficient, more regular is the surface of the terrain. It is clear that the south-west area of the figures is characterized by high values of detail coefficients, and this is consistent with the topographic anomalies due to the presence of the Apennine. These two figures clearly show a sort of flat area without any anomalies, which corresponds to Larino plateau, whereas it is somehow bounded by Cigno stream on its east side. This large anomaly is asymmetrical with respect to Biferno valley, being on the right side of the river. This sort of anomalous hole can be associated with the main body of the giant landslide identified on the base of an observational geologically-based approach by GUERRICCHIO *et alii* (2010). On the left side of Biferno valley, in front of the landslide, Fig. 2 shows the presence of the peak of Guglionesi, which is quite well outlined by high magnitude detail coefficients. This area is characterized by a number of shallow landslides, which are likely due to the effect of the erosion of river Biferno, forced to flow on the left side of the valley by the giant landslide. It is noteworthy that the landslides under Guglionesi town were reported by RIGHINI *et alii* (2012), according to an approach based on Persistent Scatter Interferometry.

CONCLUSIONS

This work introduces the 2D DWT applied to the DEM as a powerful and reliable tool for geomorphic numerical analysis. The methodology aims at delineating characteristic morphological structures, emphasizing how terrain shapes can be interpreted on the base of local tectonics and geomorphology, identifying large geological structures, e.g. large deep-seated gravitational phenomena. 2D DWT allows for identifying the anomalies and/or singularities of DEM in terms of detail coefficients of the transform. The methodology is applied to the case study of low Biferno valley. The developed analysis showed the presence of a large singularity at low right Biferno valley, consistent with the presence of a large deep-seated landslide involving the area between rivers Cigno and Biferno, as reported by GUERRICCHIO *et alii* (2010). The analysis of DEM by 2D DWT is therefore potentially a very powerful and promising approach, which may reveal details and help in the reconstructions of not clearly evident of hidden geological structures, deep seated slope gravitational deformations or large landslide and of ongoing tectonic phenomena.

Dynamic topography: processes, uncertainties and possible application in the Mediterranean

CLAUDIO FACCENNA (*), THORSTEN W. BECKER (**), FRANCESCA FUNICIELLO (*), LAURENT HUSSON (°) & ANTOINE ROZEL (*)

Key words:, *mantle convection, Mediterranean, Topography*

Thermally driven mantle convection generates stresses at the base of the lithosphere creating a "dynamic" topography. Unlike isostatically compensated topography, dynamic topography gives a transient signal, responding to time-dependent mantle flow. Dynamic topography can be computed from global models of mantle convection, resulting on moderate amplitude (10^2-10^3 m) long wavelength undulations (10^5-10^6 m). While the causes of the (iso-)static topography are rather well constrained, the dynamic topography signals are often hidden or ambiguous, the time scale of this process is disputed, and the correlation between expected dynamic and residual topography is poor. For example, the rate of change in surface elevation predicted by dynamic topography models is one-two orders of magnitude smaller than surface observations. Failure of model predictions can be related to at least three different causes. Here we will discuss about dynamic topography and about its possible application to the Central and Eastern Mediterranean.

Numerical modeling of drainage network development on active mountain belts

EMANUELE GIACHETTA (*), DOMENICO CAPOLONGO (**) & ALBERTO REFICE (°)

Key words: *drainage network, landscape evolution model, mountain belt, SIGNUM.*

Drainage network organization on active mountain belts results from the complex interactions and the continuous feedbacks among tectonics, erosion and climate.

Regularities in drainage networks, e.g. the linear spacing of outlets on active mountain fronts, have been shown by previous studies. Recent works using landscape evolution models have shown that some geomorphic features of real landscapes can be numerically predicted.

In this work, we illustrate numerical experiments of long-term landscape evolution of an active mountain belt, using SIGNUM, our Matlab, TIN-based landscape evolution model. SIGNUM is capable of simulating the main geomorphic processes acting on the Earth surface, such as hillslope diffusion and river incision, coupled with tectonic uplift and climate change. We performed several numerical experiments in SIGNUM changing the model parameters and we analyzed the effects of these changes on drainage network and watersheds distribution on an evolving mountain range.

Investigating the Plio-Quaternary landscape evolution of the Iberian Chain: a numerical approach

EMANUELE GIACHETTA (*), VALENTINA NICOLE SCOTTI (*), CLAUDIO FACCENNA (*) & PAOLA MOLIN (*)

Key words: *Iberian Chain, landscape evolution, numerical modeling*.

The Iberian Chain is an intraplate range located in the central-eastern Iberian Peninsula, showing a dome-shaped topography characterized by low relief landscape located at a mean elevation of 1200 m a.s.l.

The mountain range results from the tectonic inversion of a Permian-Mesozoic basin related to the Alpine compression (Late Cretaceous to Middle Miocene). During the Upper Neogene, compressive structures experienced planation processes presently recorded by wide erosion surfaces. Since about 2.5 Myr (?), a regional tectonic uplift occurred guiding the organization of the present fluvial network.

We performed numerical experiments to simulate the evolution of a landscape characterized by the same tectonic and erosion inputs of the Iberian Chain area. We tested the models using a range of physical parameters calibrated on field, radiometric, and morphometric data. For our purposes, we used SIGNUM (Simple Integrated Geomorphological Numerical Model), a Matlab TIN-based landscape evolution model able to simulate tectonic uplift, hillslope diffusion and river incision.

The comparison between real and simulated landscapes provide us a quantitative view on the origin of present topographic features of the Iberian Chain.

Assessment of soils and substrates using Remote Sensing, Terrain Analysis and Stochastic Modeling in southern Basilicata

MICHAEL MAERKER (*)

Key words: *boosted regression trees, mineral mapping, soil characteristics, terrain analysis, GIS.*

INTRODUCTION

Changing spatial and temporal climate pattern acts locally to influence weather conditions in the Mediterranean with significant impact on the hydrological dynamics of both, hillslope and catchment systems. Especially, a progressive extension of the arid season, as well as a concentration of rainfall in sporadic but more and more intense events is likely to occur. This increasing "rainfall erosivity" will be able to accelerate considerably the soil erosion process in this particular environment, in which the high "erodibility" of both, soils and substrata has to be added to the multi-secular man's activity (agriculture, forestry, sheep raising). Current climate variability and future climate change coming along with intensive landuse changes due to mechanization and social transformations result in consequent reactions of the system. Naturally, landscape systems with higher sensitivity react more directly and with a higher amplitude to small changes of the driving forces.
A part of the changing climate little attention was drawn to the substrates and related soils that underwent erosion and mass wasting processes. In this study we want to identify, localize and evaluate the dominant substrates and related soil characteristics. Therefore we utilized an integrative approach using a detailed terrain analysis, remotely sensed information and advanced stochastic modeling.

.

STUDY AREA

The study was carried out in Southern Basilicata. Fig. 1 shows the study area in orange and the coverage of the available satellite data. The landscape is characterized by marine terraces as described in detail by Brückner (1980) and Boenzi et al. (1999).
We focused on the area between the lower Basento River and the lower Sinni River, south east of Pisticci towards the Gulf of Metapont. Brückner defined 11 marine terrace niveaus up to an elevation of ca. 400 m asl.. The highest terraces can be observed along a line defined by the towns of Rotondella, Santa Maria d'Anglona, Montalbano Ionico, Pisticci, Porcellini, Montescaglioso and Ginosa.
The terraces formed on the grey-blue *Calabrino* clays with up to 1000 m thickness that cover cretaceous carbonates. The upper terraces are characterized by conglomerates indicating uplift and glacio-eustatic regression of the Calabrino Sea. Almost seven marine sedimentation cycles can be identified (Brückner 1982).

Fig. 1 - Study area and coverage of satellite data (yellow: Landsat; orange: ASTER)

Corresponding to the marine terraces also fluvial terraces formed by the main rivers draining towards the Golf of Metapont (see Brückner 1982). The soil of the area are strongly related to the topographic position and to the substrates along the fluvial and marine terraces. On the marine terraces mainly cambisols and luvisols are found whereas the fluvial terraces are dominated by fluvisols. On the steep slopes of the fluvial incisions regosols are found.

METHODS

It has been shown by several authors in the past that soils are related to the topographical position on hillslopes when geology and landuse can be considered uniform (e.g. Conacher and Dalrymple 1977). This two dimensional approach can be extended to three dimensions using digital elevation model information. Apart of the elevation itself also other terrain characteristics can be delineated such as primary (slope, exposition, curvature) and secondary topographic indices (topographic wetness index, stream power index, transport capacity) (Wilson & Gallant 2000). As shown by Pennock and Corre (2001) or Ventura and Irvin (2001) landscape can be segmented for further soil landscape modelling using combinations of topographic indices.
The topographic indices reflecting environmental driving factors were delineated with SAGA GIS (System for Automated Geoscientific Analyses see Conrad 2007), from a digital elevation model (DEM) with 30 m resolution (ASTER GDEM). The images were merged and pre-processed in order to correct and eliminate construction errors and manmade artefacts (Olaya & Conrad 2008). Subsequently the DEM was hydrologically corrected with the fill algorithm following Planchon and Darbox (2001).

In this study we delineated the topographic indices as basis for a subsequent soil landscape modelling. Apart of the digital elevation model a detailed filed survey was conducted in the Cavone River basin that provided characteristic soil information for different landscape segments. Furthermore landuse information was collected using Landsat images and performing a detailed landuse classification using a Maximum likelihood procedure (Landsat ETM+ (09.1999). For a more detailed assessment of the substrates and soils we performed a multispectral analysis of ASTER infrared bands to reveal the mineral composition of the surface (TIR, SWIR, VNIR; ASTER 07.2003, 06.2004)) Fig. 2 shows the general characteristics of some minerals.

A part of the independent environmental variables derived from terrain analysis and form the remote sensing we digitized a soil map (Busoni et al. 1986) to get the dependent variable to calibrate and fit the stochastic model. The soil map covers a small corridor between the Agri River and the Cavone River covering all marine and fluvial terrace niveaus. In order to assess the relations between the environmental variables and the soil types and characteristics we applied a boosted regression tree approach (Friedman, 1999); it employs a learning algorithm to identify a model that best fits the relationship between the attribute set (predictor variables; environmental variables) and the classified response variable which is the soil type and grain size distribution.

In this study the TreeNet software (Salford Systems) also known as stochastic gradient boosting model (Elith et al., 2008) was utilized. Gradient boosting constructs additive regression models by sequentially base fitting a simple parameterized function to current "pseudo"-residuals by least-squares at each interaction (Friedman, 1999). Particularly, the TreeNet model computes several hundreds to thousands of small classification trees, each one contributing to construct a portion of the model and refine on its predecessors.

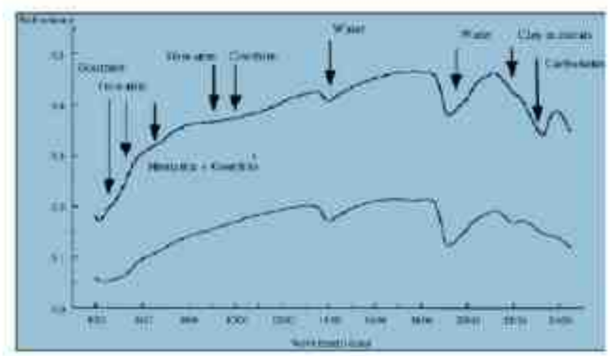

Fig. 2 - Relation of reflectance and wavelength for selected minerals

The advantages of using TreeNet model are related to different strengths: being not sensitive to data errors in the input variables; automatic variable subset selection; to handle data without pre-processing; resistance to outliers; automatic handling of missing values; robustness to dirty, partially inaccurate data; high speed and resistance to over-training (Friedman, 2002). Moreover, a recent comparison of methods shows that Random Forest and Boosted Regression Trees out-compete simple regression trees. (De'Aht, 2007, Märker et al., 2011). However, the methodology allows an assessment of larger areas and thus significantly improves the understanding of controlling factors.

RESULTS AND CONCLUSION

The analysis of Landsat images form 1999 and ASTER images from 2003 and 2004 allows the detection of changes in the landuse and landcover. Thus, also information about the vegetational effects on soil erosion can be derived. Moreover we performer a detailed terrain analysis yielding 32 topographic indices that describe different fluvial and slope processes and also give information on climatic, vegetation, geologic and structural characteristics of the study area. All topographic indices were utilized in the subsequent stochastic modelling procedure. To characterize pedogenesis and substrates we identified the mineral composition with multispectral analysis of ASTER infrared bands. Thus, we got information about the relative content of clay minerals and oxides such as: montmorillonit, vermiculit, smectit, illit, kaolinit and hematit, goethit. Fig. 3 shows the results for smectites and kaolinites as well as for hematites and goethites.

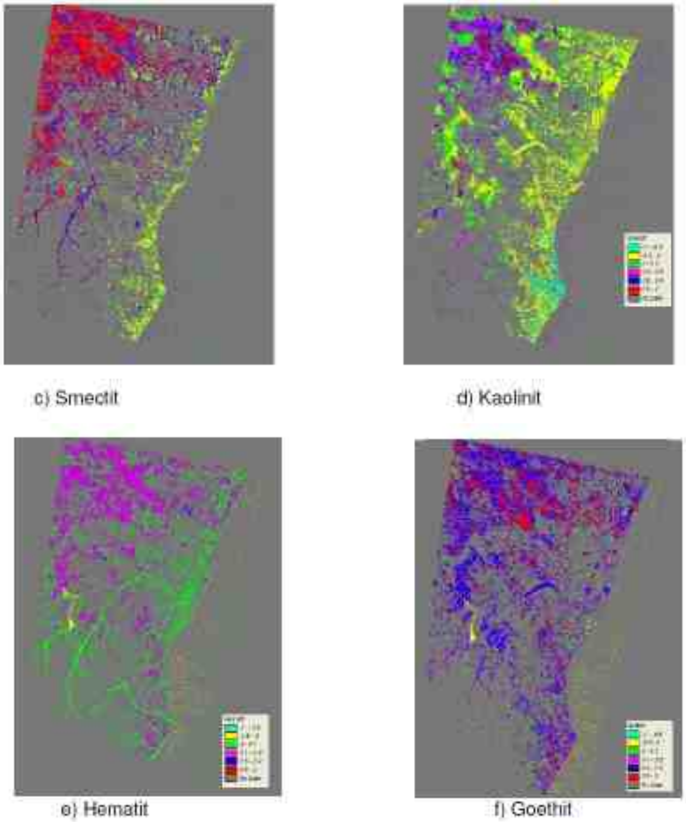

Fig. 3 – Relative content of clay minerals and oxides

The spatial distribution of the clay minerals and oxides give important information on the pedogenesis such as paleosoils rich in hematite as well as on soil hydrological processes such as infiltration characteristics in expandable clays and hence, in soil erosion processes.

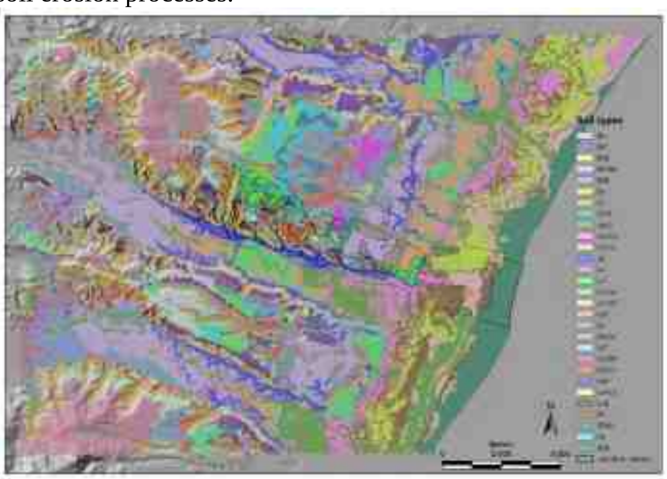

Fig. 4 – regionalized soil type map based on boosted regression tree analysis

Finally, the stochastic modelling allowed the regionalization of the existing soil map information to the entire area. For this study a boosted regression tree analysis was performed. Fig. 4 illustrates the resulting soil type map. Moreover, we also derived a texture class map for the top soil.

The integration of data derived from an advanced terrain analysis with remotely sensed information allows a detailed assessment of soil characteristics and other factors triggering soil erosion like landuse and landcover. Moreover we show that stochastic techniques such as boosted regression trees are very potential tools to perform a spatial up-scaling from detailed point or polygon features of soil characteristics and related processes.

INTRODUCTION

Quantitative Geomorphology is one of the most innovative and promising methods in landscape evolution research. In active tectonic areas, the creation and evolution of topography can be controlled by active fault segments and measured by means of morphometric indexes that mark the topographic surface response to tectonic impulses. A natural geomorphological system aims to an equilibrium condition where the energy necessary to erode, transport and sediment is minimized. This ideal state results in a typical and well defined geometry. Measuring how and where topography differs from this ideal model allows to understand the tectonic control on morphology.

To achieve this goal a reliable digital topographic model must be used. Currently Digital Elevation Models (DEMs) are the most used topographic databases and Geographical Information Systems represent the most appropriate tools to analyze this kind of data.

In this work we propose the results of some quantitative geomorphological analyses of High Tiber Valley Quaternary basin as a complementary technique to determine the spatial variations of disequilibrium due to tectonic impulses.

Moreover we compare two kinds of DEMs frequently used in these studies to highlight differences and potentialities.

THE STUDY AREA

The High Tiber Valley is a continental extensional basin in the northern part of Umbria region for about 70 km (fig. 1). The basin was formed starting from the lower Pleistocene when an extensional tectonic phase was superimposed on a previous compressional phase which formed the Northern Apennines ridge. As a consequence, several normal fault bounded intermountain basins were formed and filled with fluvial lacustrine deposits. The area has been also affected a by a regional uplift active since the upper Pliocene - lower Quaternary. The High Tiber Valley is one of the most significant intermountain basin of central Italy with a surface morphology resulting from the interaction between the extensional fault system active since the lower Quaternary (BARCHI *et alii*, 1998; BONCIO *et alii*, 2000), the fluvial processes of the Tiber drainage network and the regional uplift.

The area shows homogeneous passive structural factors (lithology) and clear evidence of neotectonic activity. In addition the drainage network is poorly organized and evolved but well hierarchized. This makes the study area an excellent test area for geomorphological analyses of river networks.

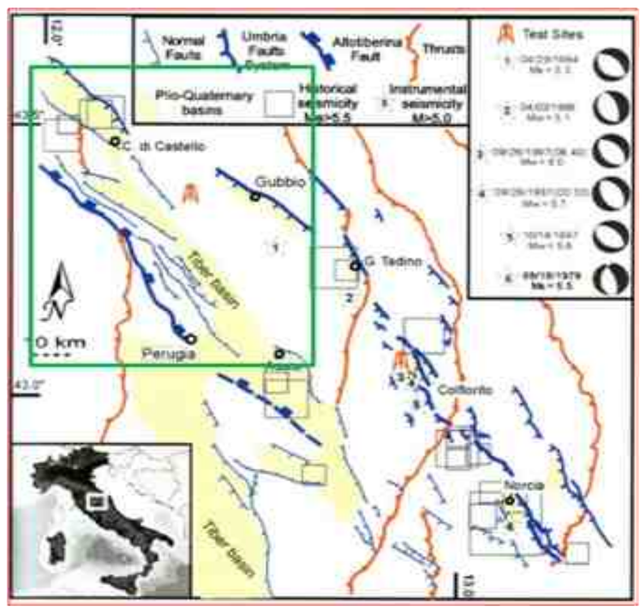

Fig. 1 – The study area (SACCUCCI, 2011 and references therein).

METHODS AND RESULTS

Shuttle Radar Topography Mission (SRTM) with a cell size of 90x90m (DEM 1) and a DEM derived from digitalization of contour lines derived from topographic maps (scale 1:25.000) with a cell size of 25x25m (DEM 2) were used. Although the DEM 2 has a better resolution, we demonstrate that the vertical accuracy has a lower quality compared to the DEM 1. Moreover, the smallest morphological element taken into account in the analysis procedure is represented in the 90x90m cell size. Finally

SRTM DEM is available for large areas without requiring loss of time for the data acquisition (like DEM 2).

We analyze 34 hydrological basins corresponding to Tiber river tributaries either on left side or on the right one. The GIS used is ArcGIS 10 (© ESRI) and Hydrological model supported with external tools: the CalHypso (PEREZ-PENA *et alii*, 2009) and Stream Profiler extensions (WHIPPLE *et alii*, 2007).

The drainage network is derived and hierarchized according to Strahler method. Drainage density (D_d) is calculated and compared in order to highlight significant differences in river distribution. The spatial distribution of values confirms the substantial homogeneous behavior of bedrock according to river responses.

Bifurcation ratio (R_b) and I and II Horton's Law are verified. Generally the values are close to equilibrium conditions but, where this is not verified, the disequilibrium evidences are limited to the highest hierarchical order, close to the confluence with the Tiber river. The hypsometric curves show two well different behaviors. We analyzed the basins draining similar lithologies (silicoclastic units). Within the analyzed basins, those on the right of Tiber river show a well distributed erosion with a concave-convex curve typical of equilibrium condition or with concave curves with erosion limited only to the highest part of the watershed. The basins on the left have hypsometric curves strongly convex (erosion in the medium-lower part of the basin) and a recurrent knickpoint close to the confluence. On the right the longitudinal profiles show a concavity index values lower than the ideal behavior ($\Theta < 0.5$) whereas on the left the rivers generally shows values higher than 0.5 according to hypsometric results. Knickpoints and steepness index (K_s) distributions highlight the same disequilibrium condition with high values close to the main water divided only for the right tributaries whereas the left ones have the K_s highest values close to the confluence. This anomaly is more pronounced in the southern part of the basin (Fig. 2).

The comparison with the DEM 25m demonstrates that the differences between the two drainage networks (deriving from DEM 1 and DEM 2) are proportional to the scale detail and do not influence the results.

In conclusion the quantitative analysis shows a general disequilibrium in the entire study area with substantial differences between the left and right side of High Tiber Valley. The drainage network is strongly influenced by the action of fault segments on the river left hand side and in the southern part.

The use of SRTM DEM is recommended for the high values of vertical accuracy and the large availability of this dataset that allows to compare the same analysis on large areas.

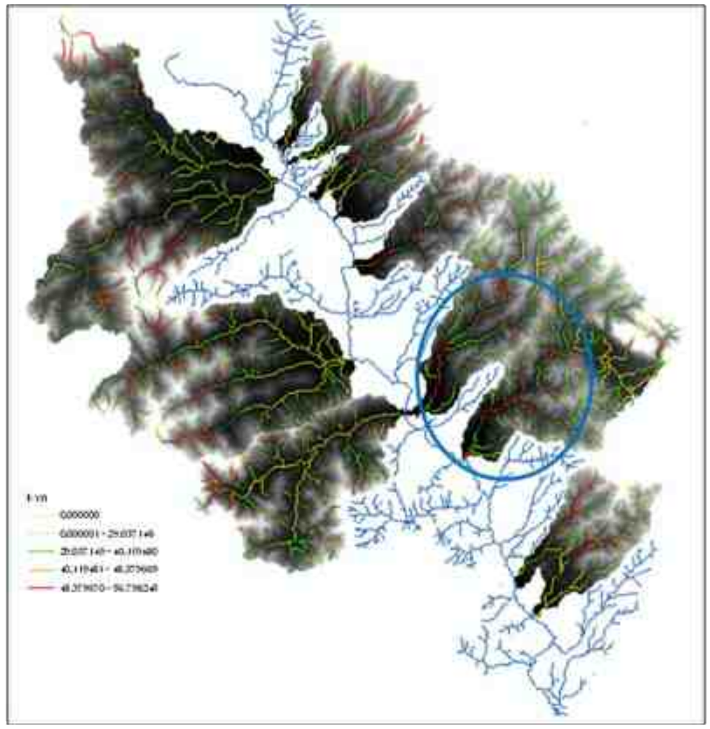

Fig. 2 – The Ks values distribution in the main basins. The circles highlight the anomalous values.

Deep Seated Gravitational Slope Deformations geomorphometry. The case of Schlinig valley (Eastern Alps)

NINFO A. (*), ZANONER T. (*), MASSIRONI M.(*) & CARTON A. (*)

Key words: *DSGSDs, hillslope geomorphology, LiDAR-DTM, morphostructures, InSar.*

INTRODUCTION

The Alpine regions are widely affected by slope instability, determined by various interactions between climate and local geological framework. Our research focuses on Deep Seated Gravitational Slope Deformations (DSGSDs), which are large mass movements with low rates of displacement (some mm/years) and involving wide portions of hillslopes with medium to high-relief slopes energy (> 500 m) (Zischinsky, 1966; 1969; Mortara & Sorzana, 1987; Varnes et al., 1989; Chigira, 1992; Cruden & Hu, 1993; Ballantyne, 2002). They may occur on all rock types although are more common on highly foliated metamorphic lithologies (Agliardi et al., 2009). Although DSGSDs are characterized by specific landforms, the most distinctive ones being double ridges, scarps, counterscarps, trenches (Zischinsky, 1966, 1969; Ter-Stepanian, 1966; Beck, 1968; Agliardi et al., 2001), these morphostructures can be classified in between landslides and tectonic landforms (Persaud & Pfiffner, 2004; Ustaszewski et al., 2008). In addition, depending on their stage of evolution and typology, DSGSDs can be masked by weathering and superficial erosion processes (Ballantyne, 2002) and the typical bulging at the hillslope foot of large mass movements can be not always present. For these reasons ready methodologies to unravel morphostructures related to DSGSDs are important and needed. Thus, we present procedures based on the calculation of morphometric indices from LiDAR-DEM, with the aim to improve the DSGSDs geomorphological identification and mapping. Our work has been focused on the Schlinig valley (Eastern Alps, South Tyrol) because it is affected by numerous DSGSDs types, evolving on various lithologies, which are in tectonic contact along a major alpine fault (Schlinig fault, Froitzheim et al., 1994). In particular, the orthogneiss of the S-charl nappe crop out in the right side of the valley, whereas in the left-hand slope the Permo-Mesozoic cover of the same nappe are overlaid by the Ötztal paragneisses.

METHODS

The *ground* DTM (2,5 m cell size) used for the analysis is freely available at the website of Bolzano Province Cartographic Service. We intentionally neglect possible noises and errors of raw downloadable data not applying any re-interpolation or smoothing process; this in order to see what can be obtained by an end user from a standard dataset. The obtained morphometric indices are: slope, aspect, curvature calculated along different directions, openness, wetness index, topographic solar radiation index, etc. Curvature were calculated with the biquadratic polynomial model, proposed by Evans (1972, 1980) and the multi scalar approach of Wood (1996), varying the *kernel* window size of the analysis. The profile convexity is defined as the variation of the curvature calculated intersecting the z plane and the *aspect* direction; $profc=(ad^2+ae^2+cde)/(d^2+e^2)(1+d^2+e^2)^{1.5}$

A detailed gemorphological survey was conducted to validated the interpretations coming from the computer analysis.

RESULTS AND DISCUSSION

Profc results the more appropriate to individuate and map DSGSDs morphostructures (fig. 1A), because is very sensitive to the gravitational processes acting along the maximum slope profile. This morphometric variable, calculated with a *kernel* window size of 125 m, results the more appropriate to identify the specific landforms related to DSGSDs (fig. 1B). *Profc*, calculated with a window size of 250 m, is useful to map the DSGSDs main sectors (double ridge and concave upslope area, bulging, etc.) and avoid the misinterpretation of DTM errors (fig. 1B). It is important to underline that the multiscalar curvature calculation also proves to be an appropriate method to identify and avoid data errors. These indices enhance the capability in recognizing DSGSDs morphological fingerprints and stage of evolution (fig. 1). A spatial and statistical analysis has been conducted to define the areal morphometric signature of DSGSD scarps and counterscarps (in red fig. 1A), normally identified with linear features.

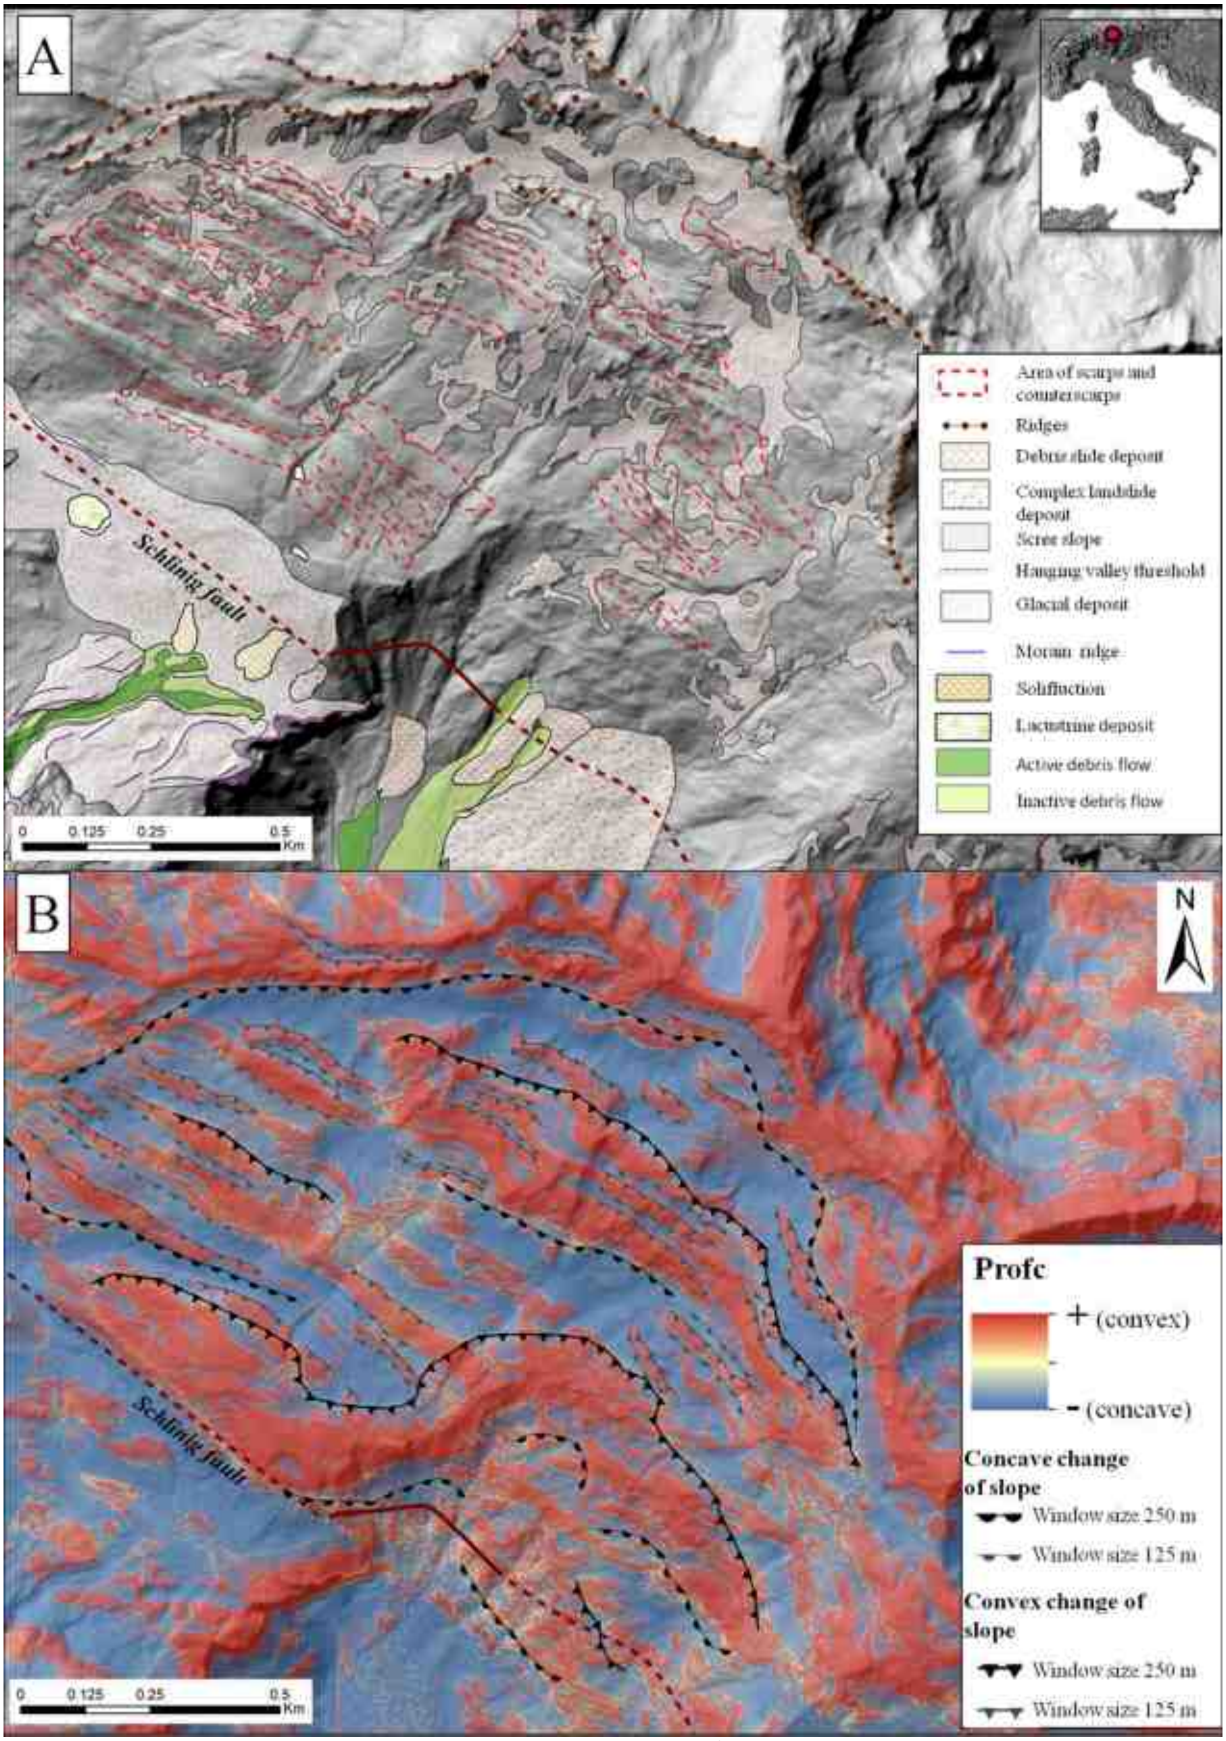

Fig. 1- A. Geomorphological sketch on hillshade. B. Morphometric sketch on *profc* kernel 50 and 100 in transparency.

The counterscarps, in the study area, present some specific characteristics: they are wide (20 – 70 m), long (100 – 700 m), with a mean surface of 11438 m^2 and an average direction perpendicular to the maximum slope. Their morphometry is characterized by a half concave profile that changes to convex through an intermediate low gradient area. The middle sectors of the counterscarps are the only "flat areas" (gradient < 9°) in the DSGSD and can be recognized through a slope classification. Morphometric indices are interpreted in integration with interferometric PS (permanent scatter) data, which provide precise measurements of the hillslopes displacements.

In particular, the eastern part of the DSGSD which is characterized by first order counterscarps (more sinuous and irregularly distributed) records an higher grade of mobility (15-20 mm/year) than the western sector (2-5 mm/year), which is instead affected by a pervasive set of regular spaced structures (fig. 1). Hence the geomorphometry of the gravitational morphostructures seem to be, at least in the analyzed case, indicators of hillslope stage of evolution and activity.

The results in Schlining valley can enable the identification of some specific landforms that can be used to recognized DSGSDs phenomena in other Alpine areas and eventually discriminate between different gravitational typologies (Lateral spreading, Rock-slides, and Rock-flows).

Spatial variability on the erosion rates and river profiles along the Calabrian Arc

VALERIO OLIVETTI (*), ANDREW CYR (**), PAOLA MOLIN (*) & CLAUDIO FACCENNA (*)

Key words: *Erosion rates, cosmogenic isotope, Calabria.*

INTRODUZIONE

Theoretical (e.g. GILBERT, 1877) and mathematical (e.g. HOWARD, 1994; WHIPPLE & TUCKER, 1999) models of rivers undergoing steady and uniform tectonic and climatic forcing predict smooth, concave-up channel longitudinal profiles. Deviations from this predicted longitudinal profile form, e.g. convexities or knickpoints, are commonly cited as evidence for disequilibrium conditions. The relationship between erosion rates and uplift rate provides further evidences of steady state or transient landscape. In this framework, in order to study the different landscape response to tectonic forcing we analyzed two regions in the Calabrian Arc, the Sila Massif and Messina region, through the comparison of the river longitudinal profile with the hillslope erosion rates calculated by ^{10}Be content in modern fluvial sediments.

The Sila Massif is characterized by a low relief upland morphological surface standing at an average elevation of 1200 m, and interpreted as a relict of an old landscape developed in stable, base level conditions (DRAMIS, 1992; MOLIN *et alii*., 2004).

The Messina trough interrupts the continuity of the arc and is constituted by a narrow and deep NNE striking topographic depression filled by lower Pleistocene to Holocene sedimentary deposits. The Messina strait is one the most seismically active region in the Mediterranean region.

The western flank of the Messina strait is composed of a NNE-SSW trending fault, responsible for the 1908 destructive earthquake (VALENSISE & PANTOSTI, 1992; MONACO & TORTORICI, 2000; CATALANO *et alii*, 2003).

(*) Dipartimento di Scienze geologiche, Università Roma TRE, Italy.
(**) U.S. Geological Survey, Menlo Park, California, USA.

METHODS

We extracted the longitudinal profile of 35 rivers draining the entire Sila Massif and 10 rivers from both the Peloritani Mountain and Aspromonte Massif, draining toward the Messina Strait. We conducted geomorphologic and morphometric analysis using ArcGIS and a free routine for MATLAB (Stream Profiler) (WOBUS *et alii*, 2006) to extract and analyze stream long profiles, to generate log-log diagrams of slope versus area data, and to calculate steepness and concavity indices.

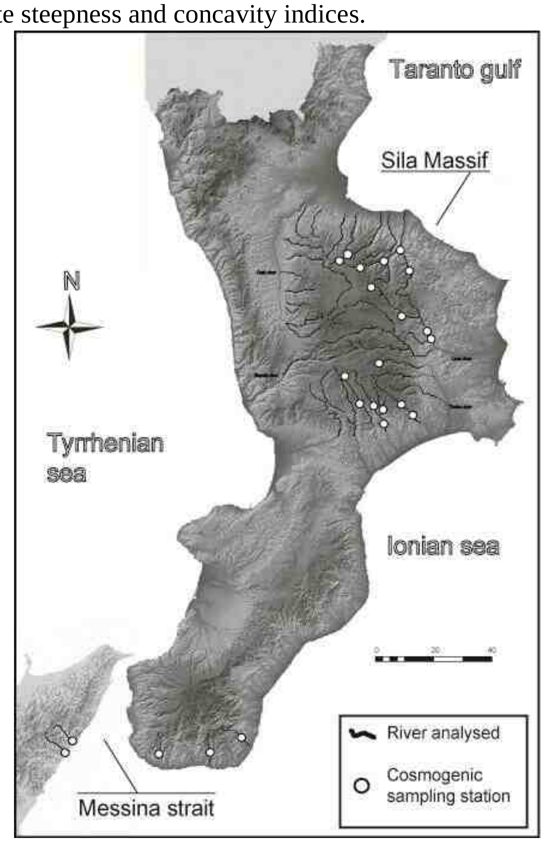

Fig. 1 – Map of the studied area with cosmogenic sampling location and rivers analysed.

Spatially averaged erosion rates have been obtained using cosmogenic nuclides such as ^{10}Be in quartz-bearing alluvial sediment (VON BLANCKENBURG, 2005). Beryllium-10 accumulates in quartz near the Earth's surface proportional to its local production rate and inversely proportional to the surface erosion rate.

UPLIFT AND EROSION ALONG CALABRIAN ARC

Long-term uplift rates across the region are constrained by raised marine shorelines associated with the Marine Isotope Stage (MIS) 5e high stand, which occurred approximately 125 ka. Uplift rate of the Sila Massif has been constrained by large number of marine and alluvial terraces orders. The resulting average uplift rate spans between 0.8 and 1 mm/yr (Cosentino & Gliozzi, 1988). Around Messina strait region, terrace elevations indicate non-uniform uplift rates, increasing from 1.07 mm/yr in northeastern Sicily (Bordoni & Valensise, 1998) to as high as 1.63 mm/yr on the eastern edge of the Messina Strait (Ferranti *et alii* 2006), and then decreasing eastward to as low as 0.63 mm/r (Bordoni & Valensise, 1998).

In the Sila Massif the analyzed river profiles exhibit a wide range of shapes diverging from the equilibrium concave-up form. Generally, the study river profiles show two or, more frequently, three concave-up segments bounded by knickpoints and characterized by different values of concavity and steepness indices. Cosmogenic data show a large variation in erosion rates. These variations as well as disequilibrium river longitudinal profiles indicate a landscape in a transient state in response to a strong uplift not yet counterbalanced by erosion.

In the Messina strait region, the river longitudinal profiles are full-equilibrated, with steepness and concavity indices almost constant. The k_{sn} values increase proportionally to rock uplift rates. This relationship is consistent with both theoretical predictions (e.g., WHIPPLE & TUCKER, 1999) and previous field studies (e.g., WOBUS *et alii*, 2006).

In the Messina Strait area, the cosmogenic erosion rates are higher than those relative to Sila Massif, indicating a good correlation with local rock uplift rates. The shape of river pr rofiles as well as erosion rates indicate the Messina strait landscape is in steady state conditions.

In conclusion, although the Sila Massif and the Messina Strait region (Peloritani Mountains and Aspromonte Massif), are characterized by similar climate and same lithology, their landscapes evolve differently in response to a slightly different rock uplift rates over at least the past 125 ky and probably to a different susceptibility to erosion as a consequence of rock deformation.

Morphometric and morphotectonic analysis of the Aventino-Sangro area (south eastern Abruzzi, central eastern Apennines).

TOMMASO PIACENTINI (*) & ENRICO MICCADEI (*)

Key words: *Abruzzo, Adriatic piedmont, Apennines chain, structural geomorphology, topography and morphometry investigation.*

ABSTRACT

A drainage basin scale topographic and morphotectonic analysis has been carried out in the south-eastern Abruzzi area, placed between the Apennines chain, the Adriatic piedmont and the coastal plain. The topography of this sector records the tectonic and geomorphic processes related to the recent evolution of the Apennines chain and the emergence of the Adriatic piedmont occurred at the end of Middle Pleistocene. The work led to the creation of the Morphotectonic map, that incorporate and integrate topographic investigations (morphometry of orography and hydrography on raster and vector data scale 1:25,000 - 1:10,000, 5m grid DEM), with photogeology analysis (scale 1:33,000), Quaternary continental deposits and structural geomorphological field mapping (scale 1:10,000), morphotectonic profiles drawing.

Orography analysis is based on a 5m DEM. Slope analysis, Energy of relief analysis and Hypsometry analysis were carried out. Hydrography analysis is based on 5m DEM and scale 1:25,000 topographic map. Longitudinal profile, drainage density, azimuth of the drainage network, patterns, hydrography parameters were analyzed (Schumm, 1956; Strahler, 1957; Avena et al., 1967; Ciccacci et al., 1986; Keller & Printer, 1996; Capolongo et alii, 2005; Picotti et alii, 2009).

Photogeology analysis was performed for all the Aventino Sangro valley on scale 1:33,000 aerial photos (Abruzzo Region Flight, 1987), for preliminarily mapping of main landforms (tectonic and structural landforms, fluvial landforms, slope landforms, etc.).

Structural geomorphology field mapping (scale 1:10,000) investigated bedrock, Quaternary continental deposits, main tectonic elements and morphotectonic elements (ridges, slopes, valley, hydrography forms and fluvial terraces) (Ciccacci et al., 1986; Ambrosetti et al., 1987; Panizza & Castaldini, 1987; Lupia Palmieri et al., 1996; Bigi et al., 1997; Molin et al., 2004; D'Alessandro et al., 2008; Picotti et al., 2009).

The field mapping integrated with photogeology analysis led to the creation of a morphotectonic map and Quaternary fluvial deposits and terraces map).

The comparison of topographic data and parameters with the evidence of geomorphological processes has been carried out by means of transversal morpho-lithostratigraphic profiles and long morphotectonic profiles, providing a contribution to define the main steps of the landscape evolution, its dominant morphogenetic processes and the relative timing.

The present drainage network of the area, similarly to those of the main Adriatic rivers, is characterised by general and local geomorphic markers of tectonics and uplift and by different types of anomalies: energy relief and hypsometry, drainage network morphometry and statistical azimuthal distributions, drainage pattern types, longitudinal profiles, fluvial terraces plan and vertical arrangement, morphotectonic elements.

The topographic and geomorphic investigations enable the recognition of morphotectonic features at basin scale, the detection of tectonic control on landscape, and the reconstruction of paleo-landscapes, providing a contribution to define the main phases of post orogenic landscape evolution of the piedmont area of the Apennines chain, resulting from the link of alternating morphotectonics and surface processes, uplift processes, local tectonics and alternating slope and fluvial processes.

Integrating geochronological methods to constrain the age of uplifted marine terraces, Ionian coast of Northern Calabria

GLORIA MARIA RISTUCCIA (*,****,°), ENRICO SANTORO (**), LUCILLA BENEDETTI (***), RÉGIS BRAUCHER (***), LUIGI FERRANTI (**), ANNA MARIA GUELI (****), CARMELO MONACO (*), GIUSEPPE STELLA (****) & SEBASTIANO OLINDO TROJA (****)

Key words: ^{10}Be, ^{36}Cl, cosmic rays, depositional marine terrace, expo sure ages, OSL.

The study undertook here regards part of the Taranto Gulf in northern Calabria (Fig. 1), which experienced rapid late Quaternary uplift due to a combination of lithospheric and crustal processes. Consequently, a spectacular flight of marine terraces is preserved along the coast, as a result of the combination between glacio-hydro-isostatic Quaternary cycles and tectonic uplift. Local (fault-induced) and regional (slab-related) uplift signals are embedded in the deformed paleo-shorelines profiles (FERRANTI *et alii*, 2009).

The uncertainty about chronology of terraces, however, hampers a correct estimate of the local and regional uplift rates.

The absence of the warm faunal assemblage characteristic of the Last Interglacial (Senegalese Fauna and, particularly, the Persististrombus latus [Gmelin, 1971]) along the central and southern part of the Taranto Gulf (Fig. 1b), stimulated the application of different absolute dating methods (BRÜCKNER, 1980; DAI PRA & HEARTY, 1988; AMATO *et alii*, 1997; CUCCI, 2004; ZANDER *et alii*, 2006; SANTORO *et alii*, 2009; CAPUTO *et alii*, 2010). Notwithstanding, agreement among distinct authors dealing with this issue is still missing due to poorly accurate or even conflicting chronological results.

In order to shed light on the terraces chronology we applied a method based on the integration of Optical Stimulated Luminescence (OSL) (WINTLE & MURRAY, 2006, and their references) and Cosmogenic Radionuclides Exposure (CRE) ages (PERG *et alii*, 2001). A relatively good control on the terraces inner margin distribution, and on the stratigraphic architecture of terraced deposits is already available (SANTORO *et alii*, 2009), and has been integrated with original work. Terraced surfaces have been identified through aereophotography analysis (1:17.000 scale) and morphological and sedimentological field surveys (1:10.000 and 1:5.000 scale topo maps and orthophotos, respectively).

The chemical preparation of the CRE samples was carried out at the CEREGE (Centre Européen de Recherche et d'Enseignement des Géosciences de l'Environnement, Aix en Provence, France) laboratory following the scheme proposed by STONE *et alii*, 1996 and BENEDETTI *et alii*, 2003. Terrestrial in-situ cosmogenic nuclides (TCNs) were measured by isotope dilution accelerator mass spectrometry at ASTER-CEREGE (France). The determination of the chemical composition of each sample as well as the density along the depth profile allowed to estimate correctly exposure ages through TCNs concentrations.

As regards the OSL, the preparation of the coarse grain (sand-size) samples was carried out at PH3DRA (Physics for Dating Diagnostic Dosimetry Research and Applications) laboratory, located in the Department of Physics and Astronomy, University of Catania (GIUNTA *et alii*, 2012). Luminescence dating assumes that mineral fractions can be used as natural dosimeters and the luminescence signal is reset by solar exposure before deposition of sediments. Measuring the radiation dose accumulated from these zeroing event (*Equivalent Dose*, *ED*) and the dose rate absorbed per year (*Annual Dose*, *AD*), as a result of the decay of radioactive elements present in the surrounding materials, the age of the sample can be calculated using the equation: Age (ka) = *ED* (Gy) / *AD* (Gy/ka).

For this study, between the different TCNs, we have chosen to combine the ^{36}Cl and ^{10}Be exposure methods. TCNs, stable or radioactive, derive from the interaction between cosmic rays of extra-terrestrial origin (electrically charged particles, between which the more abundant are protons and α-particles) and minerals present in the first meters of the lithosphere. The maximum TCNs concentration is time-dependent being linked to: a) exposure age; b) erosion rates; c) radioactive cosmogenic nuclides half-life. In general, applications of single nuclides are limited by the pervasiveness of erosion, inasmuch as both age and erosion rate cannot be obtained by a single nuclide measurement. Literature data suggest that the resolution of

the approach could be improved by combining a spallogenic nuclide with one that is also produced by thermal neutron absorption; an example is represented by the ^{36}Cl-^{10}Be couple. For the cosmogenic analysis, we sampled sediments from different remnants of a marine terrace (T4 in Fig. 1, following SANTORO *et alii*, 2009 nomenclature) preserved along the Pollino Mts. coastal sector. In order to determine exposure ages through TCNs concentrations and to better understand the erosion processes that have interested the marine terraces surfaces, twelve (five superficial and seven along a 3 m high depth profile) samples along the upper level of the fluvial-coastal depositional sequence (transitional conglomerates between beach and river systems) were collected (Figs. 1a and 1c).

This terrace, which has an average inner margin elevation of 114 m, was previously attributed to the MIS 5.5 (124 ka) based on ESR (FERRANTI *et alii*, 2009) and aminoacid racemization (CUCCI, 2004) dating. The presumed T4 age is optimal for the ^{36}Cl-^{10}Be couple which has a good resolution in a time range <300 ka. Furthermore, based on sedimentological analysis (SANTORO *et alii*, 2009), the terraced deposits are rich in calcite and quartz (the two target minerals for the production of ^{36}Cl and ^{10}Be, respectively) and were not affected by significant erosion. Generally, samples were collected where the integrity of the depositional sequence was evident and the soil cover was minimal. Indeed, high erosion rates and the shielding effect of post-emergence covers can greatly reduce TCNs production rates and cause a significant age underestimation. Furthermore, through ^{36}Cl and ^{10}Be depth distribution it was possible to determine the inherited TCNs component, which derives from the pre-depositional history of the sampled material and it is assumed to be equal to the ^{36}Cl and ^{10}Be concentrations in the deepest part of the depth profile (BRAUCHER *et alii*, 2009). For the OSL analysis, six uplifted beach bodies from five different terrace orders were sampled (Fig. 1a). To compare results between OSL and CRE ages, some of these samples were collected also from the sands immediately below the conglomerates sampled for TCNs depth profiles (Fig. 1c). All OSL samples were obtained by hammering opaque black PVC pipes (60 cm long cylinder with a diameter of 10 cm) to prevent light exposure during sampling, into freshly cleaned vertical geological sections. Quartz, the OSL target mineral, was extracted from the sediments and then mounted on single grains discs, used for luminescence measurements. Experiments have been conducted using a semi-automated Risø reader TL-DA-15 with EMI 9235QA photomultiplier with an attachment for *Single Grain technique* (BØTTER-JENSEN, 1997; BØTTER-JENSEN *et alii*, 2000). A calibrated ^{90}Sr/^{90}Y beta source delivering about 0.1 Gy/s to quartz was used for irradiation. BSL and GSL signals were obtained, respectively, with 41 blue LEDs (470 nm) and with a green Laser (532 nm). The stimulation units delivered ~30mWcm^{-2} for BSL and ~50 mWcm^{-2} for GSL at 90% power. Both BSL and GSL emissions were detected in the 280-380 nm region, using an Hoya U-340 optical filter. The single-aliquot regenerative-dose (SAR) protocol proposed by MURRAY and WINTLE (2000, 2003) was used to estimate the *equivalent dose* in the samples. *Dose rate* was calculated using radioisotope concentration, burial depth, elevation, geomagnetic latitude (PRESCOTT & HUTTON, 1988, 1994), and present day moisture. The concentrations of uranium, thorium, potassium and rubidium (PREUSSER & KASPER, 2001) were measured by the Inductively Coupled Plasma mass spectrometry (ICP/MS), performed at Actlabs Laboratory (Ontario, Canada).

Comparison between the OSL and CRE dating methods allows to improve the knowledge about terrace chronology, relative sea-level changes and quantitative estimates of local and regional uplift components in this key sector of Calabria.

Morphometric analysis in the offshore of the southern Taranto Gulf: unveiling the structures controlling the Late Pleistocene-Holocene bathymetric evolution

ENRICO SANTORO (*°), LUIGI FERRANTI (*), SALVATORE PASSARO (**), PIERFRANCESCO BURRATO (***), DANILO MORELLI (****)

Key words*: tilt, fault modeling, erosional marine terraces.*

The present study is focused on a morphometric analysis of high resolution multibeam data (10m, 5m and, locally, 2m resolution), that were acquired during the oceanographic TEATIOCA 2011 campaign along a sector of the Ionian margin of northern Calabria (Figs. 1a and 1b). The integration of morphometric analysis with sparker and chirp data allowed to unveil basic but robust information about: 1. hierarchy of the fault systems controlling the bathymetric evolution; 2. the interplay between tectonic and erosional processes in sea-floor modeling; 3. uplift rates; 4. tilting processes.

At the end of the Early Pleistocene, a tectonic change occurred in southern Italy (HIPPOLYTE *et alii*, 1994). At this time, NW-SE striking transpressional faults in the frontal part of the Apennines (Fig. 1a) were activated, as a consequence of the involvement of the foreland continental lithosphere in the collision (CATALANO *et alii*, 1993). Based on seismic reflection profiles and borehole data, DEL BEN *et alii* (2007) and FERRANTI *et alii* (2009) have shown that the on-land strike-slip fault zones continue off-shore and were active at least up to the Middle-Upper Pleistocene . Two major transpressive fault zones are known in the offshore: the Amendolara Fault (AMF) and the Spulico Basin Fault (SPBF), SW- and NE-verging, respectively (Fig. 1a). FERRANTI *et alii* (2009), through morphometric, structural and seismic data (Fig. 1a), proposed that compression is still ongoing.

In the Gulf of Taranto the Ionian slope is dominated by ridges and intervening basins which are the morphological expression of Pleistocene transpressive fault systems (DEL BEN *et alii*, 2007; FERRANTI *et alii*, 2009). The most prominent morphologic feature is the 45 km long, NW-SE Amendolara ridge characterized by three minor bathymetric highs: the Amendolara Bank (AMBK), the Rossano Bank (RBK) and the Cariati Bank (CBK) (Fig. 1a). In the northern sector, the Capo Spulico Ridge is a narrow E-W-trending crest. The AMBK is bordered by terraces and marine scarps that have a marked appearance in multibeam, sparker and chirp data (Fig. 1a).

The 10 m multibeam has been sampled at regular intervals of 1 km to generate 42 NE-SW cross profiles (Fig. 2a) which have been used to construct bathymetric swaths, illustrating changes in relief. To produce the swath, minimum, maximum and average depths have been compiled in an observation window 41 km long and 26 km wide. Such a window width insures that the maximum and

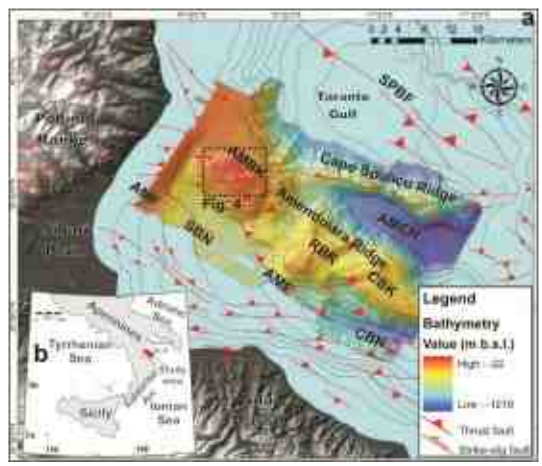

Fig. 1 – a) morpho-structural map of the southern Taranto Gulf. The multibeam data analyzed in this work for morphometric analysis are shown. Strike-slip faults in the Pollino range after Catalano et al. (1993). Offshore faults modified after FERRANTI et alii (2009). Faults: AMF, Amendolara Fault; SPBF, Spulico Basin Fault. AMBK, Amendolara Bank; RBK, Rossano Bank; CBK, Cariati Bank; SBN, Sibari Basin; CBN, Corigliano Basin; AMCH, Amendolara Channel; b) regional location of the study area.

the minimum elevations of the ridge and basins are captured. Bathymetric data were plotted against a NW-SE oriented section (A-B in Figs. 2a and 2b). Maximum and minimum elevation curves highlight a general southeastward deepening of bathymetry (Fig. 2b). A relief curve, derived by subtracting the maximum and the minimum elevations (Fig. 2b), reveals three areas (AMBK, RBK and CBK) where the sea-bed is relatively more incised in a way that is not immediately obvious from the smooth bathymetry alone. Such result is the submarine analogous to the regions of

anomalously higher relief on-land, which are commonly coincident with sectors of active incision in response to rock uplift.

The profiles crossing the Amendolara Ridge evidence the presence of an overall northeastward tilt of the offshore area (Figs. 2c and 2d). Along the AMBK and the CBK a segment of the shelf area and a paleo-planation surface are evidently tilted northeastward with similar gradient of 17 m/km and 19 m/km, respectively (Figs. 2c and 2d). This tilting component is also evident in sparker profiles that illuminate Middle Pleistocene-Holocene seismo-stratigraphic sequences regularly dipping in the same direction. Superimposed on this deep rooted tectonic signal, the relief distribution highlight three areas interested by relatively higher uplift rates.

The rose diagrams of the azimuth distribution of slope gradient and channel flow direction (Figs. 3a and 3b) shows that they have both a maximum in a NE-SW direction (Figs. 3a and 3b). This supports the contention that the bathymetry is primarily controlled by NW-SE trending structures (AMF and SPBF, Fig. 1a).

In order to investigate the relative importance of the AMF and the SPBF in the bathymetric evolution we focus our attention on the semi-quantitative estimate of erosive processes affecting the slopes. First of all, we determined the Amendolara ridge and Capo Spulico Ridge

fronts sinuosity (f_s; Figs. 3c and 3d) as the ratio between the length of the ridge-front along the foot of the ridge at the pronounced break in slope and the straight line length of the ridge front (KELLER & PINTER, 1996). f_s is an index that reflects the balance between erosional forces that tend to cut an embayment into a front, and tectonic forces that tend to produce a straight front coincident with an active range-bounding fault. The relatively straight shape of the southward facing ridge-fronts (f_s from 1.01 to 1.12; Fig. 3c) points to active tectonic uplift. On the other hand, the northward facing range fronts (f_s from 1.34 to 2.30; Fig. 3c) are more irregular and probably shaped by erosional

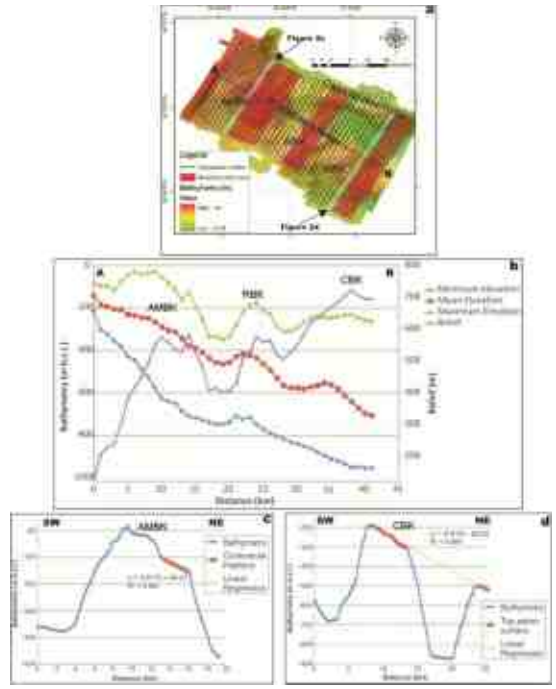

Fig. 2 – a) traces of the bathymetric profiles used to construct swath profiles (b); c – d) examples of bathymetric profiles (location in Fig. 2a).

processes. Furthermore, two ridge fronts are evident along the southern slope of the Cariati Bank (Fig. 3c). The more internal front (f_s: 1.12) is characterized by a more irregular shape than the southernmost front, which is conversely almost rectilinear (f_s: 1.01). We interpret the internal front as an earlier front linked to a structure no more active or interested by a decrease of the deformational rates,

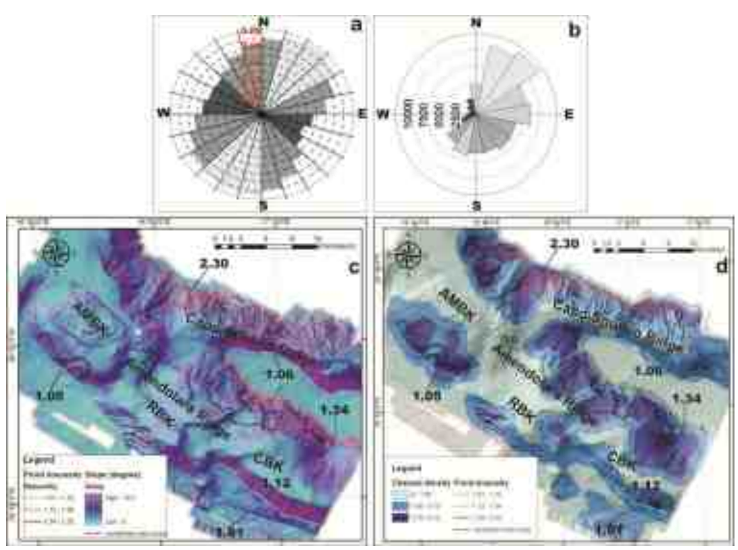

Fig. 3 – a-b) rose diagrams of the slope gradient (a) and of the channel flowing direction (b); c-d) morphologic maps showing landslide distributions, front sinuosity, slope degree (c) and channel density (d);

actually outpaced by erosional processes. The fresh appearance of southward facing ridge-fronts, as evidenced by the f_s index, suggests a more important role for the AMF in the recent morphological evolution of the area. This hypothesis is further supported by landslide distribution and the channel density map (Figs. 3c and 3d).

Based on multibeam, sparker and chirp data, 65 translational and rotational landslides were mapped; in figures 3c and 3d we report the distribution of the landslides main scarps in relation to slope (Fig. 3c) and channel density (Fig. 3d) maps. From figure 3c it is evident that slope acclivity is not the primary control of the landslide distribution. This is apparent if we look at the southern slope of the Capo Spulico Ridge and CBK which are characterized by the highest gradient and by the absence of gravitational processes (Fig. 3c). Landslides are almost totally localized on the northeastward slopes; we believe that this distribution is primarily linked to the northeastward tilt process that makes sediments prone to slide along north facing slopes.

One exception is represented by the AMBK southern flank were rational slides are probably related to the tectonic front activity.

Channel density was calculated as the ratio between the total channel length and the area of a circular cell with a radius of 100 m that encloses them. As already highlighted by landslide distribution and front sinuosity index, the northward facing slopes appear to be controlled by erosional processes. Probably, the mobilization of sediments through gravitational phenomena enhances the channel network development.

Summing up all the morphometric data, it is apparent that the AMF played a fundamental role in the recent bathymetric evolution of the area. The straight and regular southward facing slopes are linked to deformation and uplift rates outpacing erosional processes. On the other hand, the northeastward tilting process driven by slip on the AMF trigger gravitational and channelized erosion on the north facing slopes. The three higher relief areas highlighted by swath profiles reflects the AMF internal segmentation.

The only sector where an estimate of the uplift rates can be attempted is the AMBK where seven erosion marine terraces orders are preserved (Fig. 1c). In a first step terraces were identified by means of a statistical analysis of depth distribution along the AMBK top and the computation of a semi-logarithmic depth histogram. It is widely acknowledged that flat-lying morphological markers, such as marine terraces, show up as peaks in the depth histogram (PASSARO *et alii*, 2011). Inner margins (intersection point between abrasion platform and on-looking sea cliff) elevations were refined through a morphological analysis of multibeam data and, hence, corrected for the later Holocene cover draping the AMBK top through investigation of numerous chirp and sparker profiles (Fig. 1d). The eustatic origin of the terraces is supported by the absence of normal faults or landslides across the AMBK top. The absence of beach facies can be related to a later erosion by successive eustatic cycles and/or the disconnection between the AMBK and the sediment on-land sources. Furthermore, the several Low Stand System Tracts which were identified around the AMBK top were probably built up during eustatic low stands and emersion of the Bank as an island and the sub-

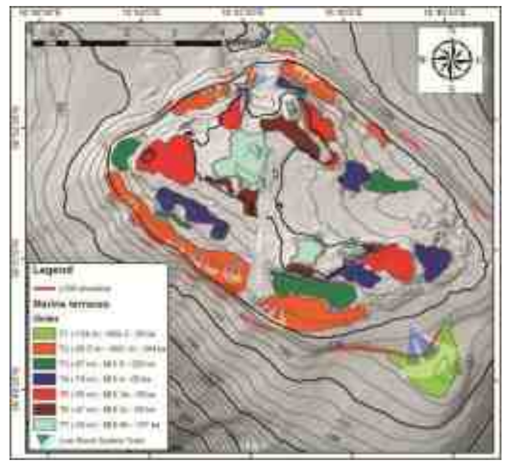

Fig. 4 – Morphologic map of Middle-Late Pleistocene marine terraces preserved on the top of the Amendolara Bank.

aerial erosion of eventually preserved beach facies. Because of the absence of direct chronological constraints, the terraces were dated indirectly by means of a trial and error approach. Uplift rates, ranging from -1 to 1 mm/a, were applied, with a 0.1 mm/a step, to theoretical marine terraces corresponding to the major glacial and interglacial cycles of the ~400 ka WAELBROECK *et alii* (2002) sea-level curve. We found that only an uplift rate of 0.1 mm/a fits the occurrence of the seven orders of eustatic terrace on the AMBK top. Both glacial and interglacial terraces are present: T1, MIS 2; T2, MIS 10; T3, MIS 8; T4, MIS 4; T5, MIS 3a, T6, MIS 3c; T7, MIS 6b.

By comparing the elevation of MIS 3c (~60 ka) terrace on the AMBK (T6, -47 m b.s.l., this work) and on the adjacent Pollino coast (T1 in SANTORO *et alii*, 2009, 16 m a.s.l.), we observe a decrease of the uplift rates from 0.8 mm/a to 0.1 mm/a in only 14.5 km. Therefore, it is apparent a strong NW-SE tilting component with a rate of 0.07 $m*km^{-1}*ka^{-1}$ in the last 60 ka. Differential uplift and eastward coastal tilting along the Ionian frontal sector of southern Apennines were already suggested by FERRANTI *et alii* (2009) to explain deep-seated slope gravitational deformation that deform marine terraces along the Taranto Gulf. Our analysis constitutes the first attempt to quantify this tectonic component. The sharp decrease in uplift rates could be explained by an eastward decrease of the regional southern Apennine uplift.

Age and properties of the summit palaeosurface of southern Italy

MARCELLO SCHIATTARELLA (*), SALVATORE IVO GIANO (*) & DARIO GIOIA (°)

Key words: *geomorphology, palaeosurface, southern Italy*.

INTRODUCTION

Long-term landscape evolution of an orogen results from the interaction between tectonic and geomorphological processes, largely controlled by regional uplift, fault activity and climate changes (WILLETT, 1999; WILLETT & BRANDON, 2002; WOBUS *et alii*, 2003; SCHIATTARELLA *et alii*, 2006; BISHOP, 2007). In the last decade, there has been a rise of interest particularly on the role of climate changes in landscape evolution (WHIPPLE *et alii*, 1999; BONNET & CRAVE, 2003; BURBANK *et alii*, 2003; WHIPPLE, 2009). In tectonically active areas characterized by a complex morpho-structural evolution, both relict and active landforms coexist as a result of exogenic vs. endogenic processes. Ancient landforms such as palaeo-landsurfaces represent non-equilibrium features (cf. BRACKEN & WAINWRIGHT, 2006) resulting by surface uplift and subsequent degradation due to erosion.

The term palaeosurface denotes any identifiable surface of demonstrable antiquity, often characterized by gentle topography represented by relics of an ancient erosional land surface, that evolved in response to particular combination of geomorphological processes (WIDDOWSON, 1997; BONOW *et alii*, 2006). The physical correlation of discrete remnants of palaeosurfaces allows to recognize extension and morphology of such ancient planation surfaces related to a former base level of the erosion (i.e. not in accordance with present morpho-climatic conditions), and they are identified in terms of attitude (i.e. characterized by little slope angles, not exceeding few degrees) and on the grounds of several markers of geomorphic processes acting in the past.

The reconstruction and dating of ancient land surface can provide useful information on morphotectonic evolution, whereas the nature of subsequent modifications by changing erosional and weathering regimes can reveal key aspects of subsequent environmental change (BORGER, 1997; SCHOENBOHM *et alii*, 2004). Hung land surfaces (i.e. terraced surfaces suspended with regard to the present-day thalwegs) are also markers of regional-scale neotectonic deformation and provide information on the rate and timing of uplift and erosion (SCHIATTARELLA *et alii*, 2006, 2008; MARTINO *et alii*, 2009). Recently, the relation between morphotectonic features and the fractal dimension of topography of Taiwan has been explored as well (SUNG & CHEN, 2004). It has been found that the fractal morphology may reflect some subtle changes in topographic properties of a landscape sculpted by surface processes, which in turn are influenced by tectonic activities. This property is perhaps more diffused than reported in that paper, because a fractal behaviour was also found in studies of coastal and fluvial features (RIGON *et alii*, 1994; TURCOTTE, 1999; DE PIPPO *et alii*, 2004; RINALDO *et alii*, 2006). The Hack's law relating the upstream length and the total drainage area at a given location is another evidence of fractal geometry in fluvial landforms. These statistical properties of river basins are irrespective of age even if real drainage basins evolve on a long-term time-scale. Furthermore, it was reported that the fractal dimension of the drainage network can also provide a method for assessing the degree of tectonic control on the geometry of fluvial networks (DEL MONTE *et alii*, 1999).

The purpose of this study is to better define the age of the summit palaeosurface of the southern Italian Apennines (i.e. "Paleosuperficie" *Auctt.*) by both morphostratigraphic and AFTA dating methods, with the aims of refining its use as a morphotectonic marker and distinguishing climate and tectonic contributions in landscape evolution.

DISCUSSION

The top of the mountains of southern Italy are often featured by erosional flat landforms representing the remnants of a wide palaeosurface attributed to the late Pliocene – Quaternary boundary. Apatite fission-track analyses collected in the last years furnished new chronological constrains in terms of its absolute age: this kind of data has been here used in combination with geology and morphotectonics to better define its evolution. AFT data from rocks belonging to different tectonic units of the axial zone of the southern Apennines (ALDEGA *et alii*,; MAZZOLI *et alii*, 2008) indicate a concordant final cooling age of ca 2.5-2.6 Ma (average value, SCHIATTARELLA *et alii*, 2009; GIOIA *et alii*, 2011), suggesting a widespread exhumation during the late Pliocene. This relatively young exhumation is likely related to erosional

(*) Dipartimento di Scienze Geologiche, Università della Basilicata, Potenza, Italia

denudation rather than tectonics (i.e. low-angle extension, as suggested by other authors for older stages, see SCHIATTARELLA *et alii*, 2006), thus implying a late Pliocene stage widely affected by intense exogenetic processes. It can be argued that such a regional denudation could be related to the summit palaeosurface morphogenesis. The attribution of those features to the late Pliocene is strengthened by the presence of lower–middle Pliocene clastic deposits outcropping at the top of the Maddalena Mts (SCHIATTARELLA *et alii*, 2003) and in the Mt. Marzano area, involved in the planation of the palaeosurface.

On this basis, we infer that both the cooling event and the erosion land surface now preserved at the top of the relief are evidence of the same episode of exhumation. It is worthy to note that the AFT cluster is comprised between 2 and 3 Ma, as well as mid-Pliocene sediments are the youngest deposit involved in the ancient planation process (Fig. 1). Curiously, also the new interpretation of these data in the key of land surface dating suggests that the transition period between the late Pliocene and the early Pleistocene represents the time-span in which the summit palaeosurface developed. Such a regional feature was displaced by the 1.8 Ma regional tectonic stage.

We have also investigated the statistical properties and the modalities of the "fragmentation" processes of the south-Italian

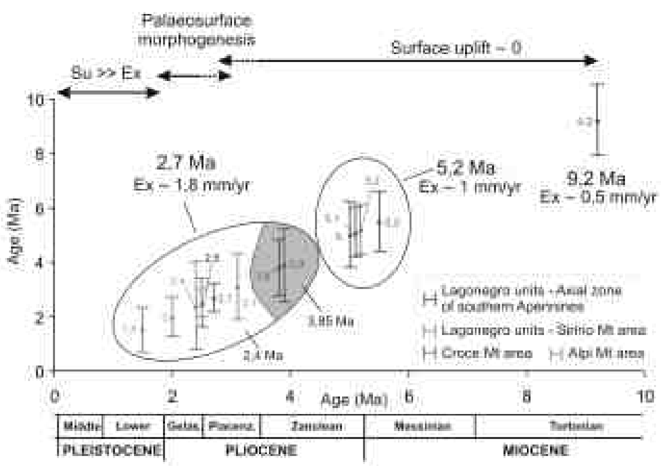

Fig. 1 – AFT data from the axial zone of the southern Apennines.

palaeosurface (i.e. the physical separation due to fault displacement and/or fluvial dissection) which led to the present-day arrangement of its morphological relics. Such a result may help to recognize regions with different tectonic histories and/or to emphasize the eventual role of other control factors. To this end, the morphometric properties of palaeosurfaces are extracted from a Digital Elevation Model (DEM) and maps of palaeosurfaces automatically derived using a recently published methodology (MARTINO *et alii*, 2009). The DEM used in this study is obtained by the Shuttle Radar Topography Mission (SRTM). In order to check the fit of the DEM-extracted flat surfaces with the real landforms related to erosional palaeosurfaces, the regional-scale automatic cartography has been compared with the geomorphological maps and schemes present in the literature relative to southern Italy and, overall, with a survey-derived map of land surfaces. To this aim, a local scale test-site (Mount Marzano – Maddalena Mts ridge) has been chosen to perform a more detailed comparison with the computer-aided cartography. In any case, a good correspondence between traditionally mapped and DEM-extracted land surfaces has been verified.

CONCLUSION

The statistical analysis of the properties of land surfaces of southern Italy has been carried out choosing two quite different test areas, but roughly characterized by the same climatic environment (Fig. 2).

The Sila Massif (Calabrian Arc) is the southernmost test

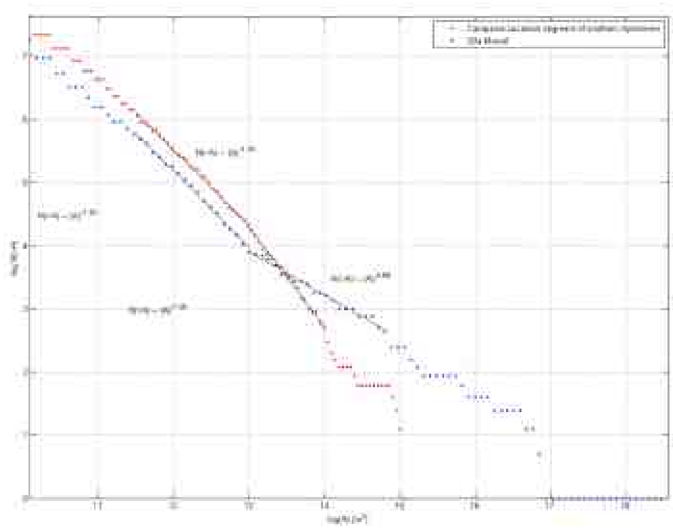

Fig. 2 – Cumulative frequency distributions related to the palaeosurfaces of the two test areas located at an altitude above 1000 m a.s.l.

area. It is characterized by wide and old land surfaces, at least Pliocene in age, probably inherited by pre-Tortonian flat landscape formed at sea level and weathered under tropical conditions (Scarciglia et al., 2005). During Quaternary times, the Sila Massif underwent a generalized uplift without internal block faulting. Consequently, the summit palaeolandscape of this area is loosely fragmented by recent tectonics and scarcely dissected by fluvial erosion (MOLIN *et alii*, 2004). The Campania-Lucania segment of the southern Apennines is much more morphologically articulated, due to the more closely spaced Quaternary faulting, associated with a higher and more pervasive fluvial dissection. The statistical properties of the palaeosurface remnants are here interpreted in terms of a common climate-driven fluvial erosion process and different tectonic activities in the two study areas. Neotectonic behaviour is expressed by an uniform block uplift in the Sila

Massif, with a major kinematic role of the fault-bounded borders, whereas the Quaternary activity of the dense fault network of the Campania-Lucania Apennines assign to this sector of the chain a strong non-homogeneity of the uplift pattern.

The topographic signature of tectonics and surface processes in landscape evolution: the case of the Iberian Chain (Spain)

VALENTINA NICOLE SCOTTI (*), CLAUDIO FACCENNA (*), PAOLA MOLIN (*) & MICHELE SOLIGO (*)

Key words: *dome-shaped topography, geochronology, Iberian Chain, landscape evolution, quantitative geomorphometry*.

ABSTRACT

Topography results from the interaction of tectonics that moves rock masses and surface processes that shape and lower them. In this study we investigated the recent evolution of the Iberian Chain landscape, an intraplate orogen located in the central-eastern Spain. It originated during the alpine orogeny in Upper Cretaceous-Middle Miocene. In the whole Iberia, the Iberian Chain represents a unique case of dome-shaped topography. Its central sector is dominated by an extensive planation surface which lies at an altitude of 1200-1600 m. This surface records a period of tectonic quiescence (Upper Neogene?) during which most of previous compressive structures were almost completely eroded creating a wide peneplain. In Late Pliocene (?)-Quaternary, this denudation episode was interrupted by the onset of an uplift that controlled the organization of the present fluvial network. The origin and evolution of the high-standing plateau in a relatively tectonically stable region is still a controversial issue.

To quantitatively characterize the influence of surface and tectonic processes, we studied the morphometry of the Iberian Chain. In detail, we analyzed the topography (map of local relief, swath profiles) and the hydrography (basin hypsometric curve and integral, basin asymmetry factor, river longitudinal profiles and relative geomorphic indices) of the Iberian Chain using the SRTM DEM as a main data source. Our results have been coupled with the incision rates of the High Tagus R. and Martin R. areas, calculated using fill terraces dated by the Uranium-series ($^{230}Th/U$) method carried out on calcareous tufa deposits. The values of incision rate are very similar throughout the range, indicating that, despite local small variation, a regional uplift affected the entire chain.

Our morphometric results indicate that uplift and rock-type erodibility are the main factors ruling landscape (topography and drainage pattern) evolution of the study area. Nevertheless, the accentuated low values of local relief and intrinsic concavity of the stream longitudinal profiles as well as hypsometric convex curves and relatively high integrals indicate the Iberian Chain landscape is in a transient state in response to a recent uplift. Indeed, the fluvial processes that so weakly incised this landscape are still far from counterbalancing the tectonics input. These results depict the Iberian Chain as a well distinct topographic unit with respect to the rest of Iberia.

Solar radiation and ground temperature as factors affecting the transition from glacial to periglacial processes in the Dolomites: the case of Cima Uomo glacier

ZANONER T. (*), SEPPI R. (**), CARTON A. (*) & NINFO A. (*)

Key words: *climatic factors, debris covered glacier, Dolomites, permafrost, topographic solar radiation*.

Glaciers of the Dolomites are mostly small and hosted in cirques. Most of them were progressively covered by large amount of debris throughout the retreating phase occurred after the Little Ice Age (LIA). This has allowed their preservation even at relatively low altitudes. In some cases, these ice-debris systems are currently developing under permafrost conditions, leading to interesting examples of transition from glacial to periglacial morphodynamic processes.

Cima Uomo glacier is located in upper Val San Nicolò (Dolomites, Trentino, Fig. 1) between 2400 and 2600 m of altitude. Visual observation of the surface morphology suggest that it probably consists of two separate ice masses completely covered by debris, although this should be confirmed by e.g. geophysical investigations. The lower part is approximately located close to the limit of the LIA moraines, whereas the upper one is located in the highest part of the cirque.

This glacier has been reported in several historical maps, where its evolution from clean to a debris-covered glacier can be observed. It has been mapped in two editions (1905 and 1925) of the D.Oe.A.V. map "Marmolada" at 1:25.000 scale.
Afterwards it has been mapped (still as a clean glacier) in the Italian cartography (I.G.M. map F° 11 II S.O. "Passo di Vallès" at 1:25.000 scale). From the first to the last edition of this map (from 1920's to 1960's) the bare ice reduction of the glacier is evident. In 1924, Castiglioni (1925) described it as a small glacier of about 20 ha, 8-9 of which covered by debris. The snout of the glacier was at an altitude of about 2420 m (lowest point of the glacial drift covering the snout). In the Italian Glacier Inventory, compiled in the '60s, the glacier is classified as extinct and few avalanche cones are reported in its place (Carton et al., 2009).

Presently, an evident large morainic ridge marks the maximum extension of the glacier at the LIA.

Fig. 1 – Location of the study area (on the left). On the right particular on Cima Uomo debris covered glacier in the year 2007 (picture of ARPAV – Centro Valanghe Arabba).

On the south-west part, the arch is advanced and closes the valley, reaching a small rounded relief. The north-eastern moraine has a S-shape and his higher portion marks a less advanced sector of the glacier. The geometry of the moraines fits perfectly with the map sketched by Castiglioni (1925).
On the more advanced lobe, some marked ridges and furrows are present, suggesting that the glacial debris is still in motion and a rock glacier-like landform is currently developing.

(*)Department of Geosciences, University of Padua
- Via Gradenigo 6, 35131, Padova (Italy)
(**) Department of Earth and Environmental Sciences , University of Pavia - Via Ferrata 1, 27100 Pavia (Italy).

This work has been carried out within the PRIN 2008 project "The cryosphere degradation in the central-eastern Alps. Study of the ongoing changes by analysing sample areas and key morphological units" (local head Prof. A. Carton).

The transition from a debris-covered glacier to an active rock glacier in the Dolomites has been recently described for the Croda Rossa glacier (Krainer and Lang, 2007; Krainer et al., 2010).

The evolution of Cima Uomo ice-debris mass is probably driven by permafrost conditions, as suggested by temperature measurements of the ground surface, performed with the BTS (Bottom Temperature of Snow Cover) and GST (Ground Surface Temperature regime) methods. In particular, GST data showed winter temperatures consistent with the presence of permafrost, also in the lower sector of the surveyed area (Fig. 2; see Fig. 3 for the location of the temperature data loggers).

Topographic and geophysical surveys are planned for the beginning of summer 2012, in order to investigate the dynamics of the debris and the extension and distribution of the residual ice in the ground.

Therefore, a specific investigation was carried out on the solar radiation of the study area. The topographic solar radiation was calculated in GIS using a DEM derived from a LiDAR survey carried out by the Autonomous Province of Trento between 2006 and 2008. The DEM has a cell size of 2 m. On this DEM (cell size of 2 m) was applied the hemispherical viewshed algorithm (Rich et al., 1994; Fu, 2000; Fu & Rich, 2002). The solar radiation is calculated using the coordinates, to asses the sun conditions (angle of incidence and duration) and considering local topography (relief shading effect). The calculation was performed using weekly intervals, summarized in an annual insolation value for every cell (Fig. 3).

Cloud cover was not taken into account because can be regarded negligible on an annual analysis (Cossart et al,. 2008).

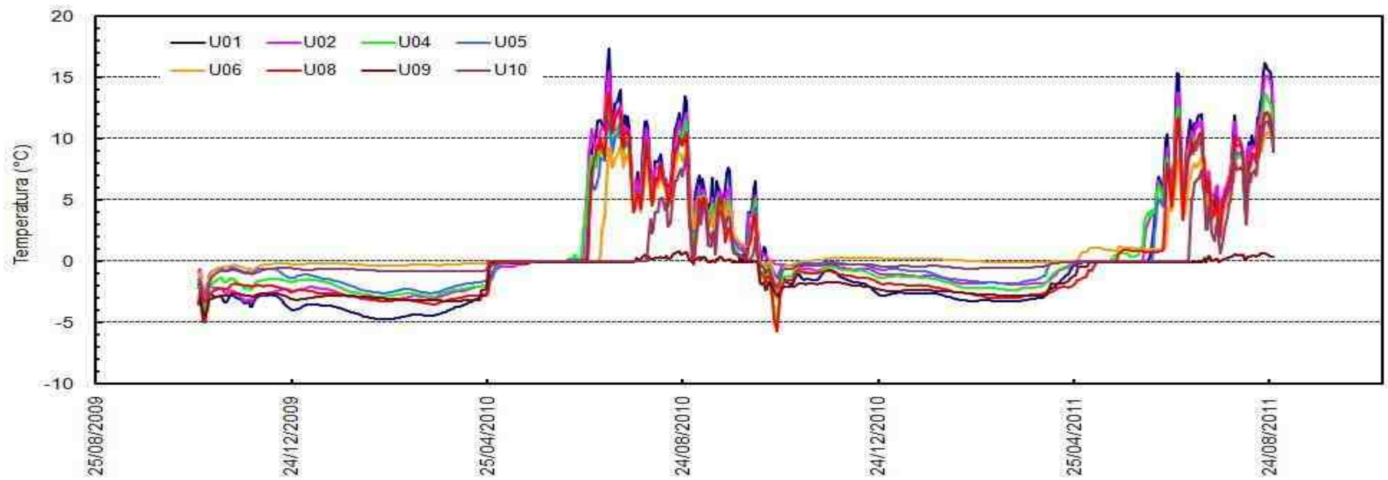

Fig. 2 – Trend of soil temperatures measured from 29/10/2009 to 24/08/2011 by thermometric probes (U01, U02, U04, U05, U06, U08, U09, U10). The trend is typical of a soil affected by permafrost.

In particular, several (14) large boulders will be surveyed for the second time, to measure their displacement over two years (2010-2012). Since most of the small cirque glaciers in the Dolomites are shaded by near-vertical rockwalls, the amount of solar energy locally available for melting the ice is one of the main factors controlling the evolution of this kind of glaciers. On the other hand, the energy balance at the ground surface determines the existence of permafrost conditions, thus controlling the transition from glacial to periglacial morphodynamics.

Incoming solar radiation is the result of a complex interaction of energy between the atmosphere and the surface. Recently, much progress has been made towards the creation of accurate physically-based solar radiation formulations that can accurately model this parameter over topography for a large range of spatial and temporal scales.

)

and 2011. In several cases, the same measurement point has been surveyed in the three consecutive years. Eight data loggers (U01, U02, U04, U05, U06, U08, U09, U10) for continuous GST measurements were placed at different elevations and on different morphological units in autumn 2009.

In this study, we present a first attempt to correlate the major climatic parameters with the ground surface temperature. In particular, here we analyze the relationships between solar radiation and ground temperature, in order to better understand which are the factors controlling the morphodynamic processes of these environments in a framework of climate change.

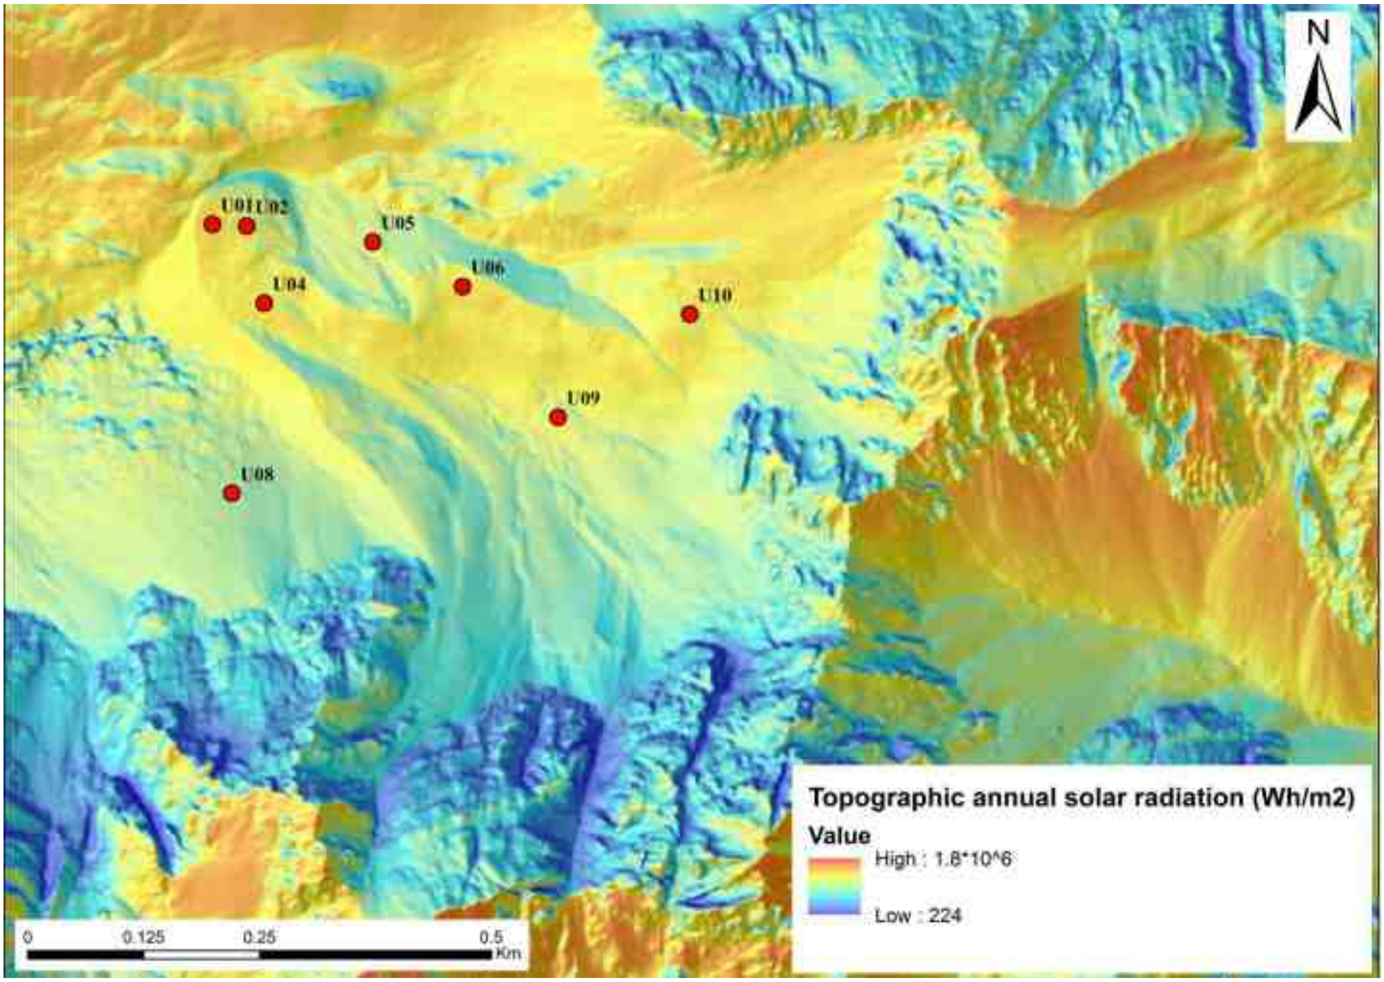

Fig. 3 – Topographic annual solar radiation drapped over a hillshade of study area. The red dots indicate the location of the thermometric probes.

Thematic mapping of the Tyrrhenian coast between Villa San Giovanni and Palmi (Reggio Calabria, Italy)

G. BIANCHI FASANI (*), F. BOZZANO (*), A. BRETSCHNEIDER, C. ESPOSITO (*), S. MARTINO (*), P. MAZZANTI (*), A. MONTAGNA (*), A. PRESTININZI (*) & G. SCARASCIA MUGNOZZA (*)

Key words: *Calabria, thematic maps.*

INTRODUCTION

In this paper we present some thematic maps referred to a strip about 30 km long and 3.5 km wide along the coastal area between Villa San Giovanni and Palmi (Reggio Calabria, Italy):

1. the geological map (1:10,000 scale) (fig. 1);
2. the landslide inventory map (1:10,000 scale) (fig.1);
3. some engineering-geological detailed maps (up to 1:10,000 scale) (fig. 2);
4. the landslide susceptibility map (1:10,000 scale)

All the above mentioned maps are the result of several scientific projects (PRIN 2006: "Integration of in-shore and off-shore geological and geophysical innovative techniques for coastal landslide studies", Principal Investigator F.L. Chiocci - Research Unit: "The engineering-geology model as a tool for the dimensioning of gravity-induced coastal instability", responsible F. Bozzano; POR Calabria 2000-2006: "Studio e sperimentazione di metodologie e tecniche per la mitigazione del rischio idrogeologico", Principal Investigator G. Scarascia Mugnozza - task 3: "Movimenti di massa e sismotettonica") and consulting activities, which have been carried out by the authors' affiliation structures in the period 2001 – 2012. Each activity, both research and consulting, has been carried out with a specific aim such as, for example, engineering-geological support to planning activities of some infrastructures, slope stability studies, managing and monitoring of unstable slopes.

(*) Dipartimento di Scienze della Terra; Centro di Ricerca CERI – Sapienza Università di Roma.

THEMATIC MAPPING: CRITERIA AND RESULTS

The geological map and the landslide inventory map derive from the collection of single spot maps realized in different periods, in some cases with the collaboration of other researchers, framed in different activities, finally unified based on uniform criteria. The final scale of such maps is that of the smaller scale spots, that have to be considered the lower limit and, thus, the reference point for a unified map. In addition, some related maps have been produced by other authors such as the "Map of slope instability evidences along the coastal seafloor between Scilla and Palmi" at 1:50,000 scale, and the "Landslide inventory map of the coastal area between Scilla and Palmi" at 1:10,000 scale. (by RU3 and RU2, respectively, of PRIN 2006, see reference above).

Datasets of in-site geological, geomorphological and geomechanical surveys, aerial photo interpretation, borehole stratigraphies, results of geotechnical laboratory test were collected, stored and used in a GIS environment. Beyond the production of the above listed thematic maps, GIS geoprocessing utilities allowed us to combine different kind of information in order to elaborate derived maps, the main one being the landslide susceptibility map. The latter is the result of an analysis performed in order to point out the relationships among the high occurrence of falls and roto-translational slope instabilities and the potential predisposing "environmental" factors. Use was made of the Frequency Ratio model, whose reliability has been proved for susceptibility assessment purposes (e.g.: YILMAZ 2009, LEE & SAMBATH 2006). The main advantage of this method relies on its complete implementation within a GIS environment. Ten different types of factors were used to calculate the frequency ratios: lithologic units, land-cover units, distance from faults, morphometric (slope, aspect and curvature) and hydraulic (topographic wetness index) parameters derived from an available 20m resolution DEM. Subsequently the landslide susceptibility index (LSI=ΣFR) was evaluated. A validation of the prediction results was performed by partitioning the total area into two separated subareas, using the space partition criterion defined by CHUNG & FABBRI (2003).

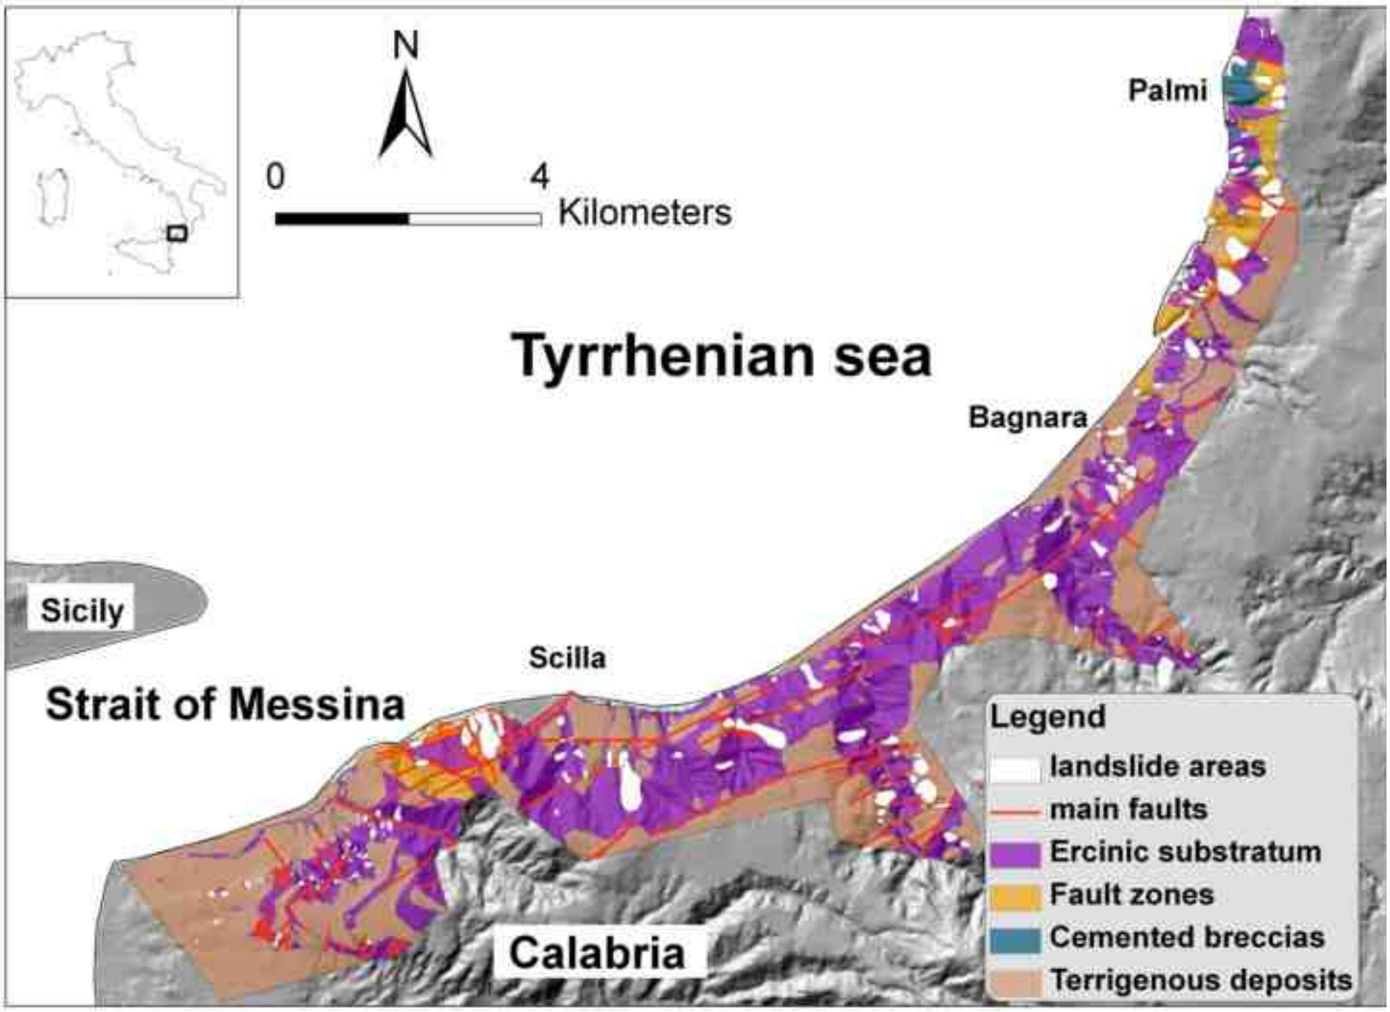

Fig. 1 – Simplified sketch derived from the geological map and landslide inventory map.

Specific experimental activities have been devoted to the geomechanical characterization of jointed gneiss, largely outcropping in the studied area and often involved in landslides. Due to the limited accessibility of significant rock mass outcrops, the geomechanical data, acquired according to standard I.S.R.M. methodology, are clustered in some sectors of the whole study area. An original approach (namely I.S.D. classification of rock mass) has been developed in order to make a zonation of the rock mass quality mainly in terms of jointing density. Such a method has been experimented astride the above mentioned clusters, where the interpolation of geomechanical data is reasonable if the geological setting is taken into account. It allowed to realize very detailed (up to 1:1,000 scale) engineering-geology maps. An example of such type of map is reported in fig. 2. The rock mass zonation according to the I.S.D. classification system is a crucial approach to the slope stability analyses by means of finite difference numerical methods, such in the case of Scilla (BOZZANO *et alii*, 2011) and S. Trada slopes (BOZZANO *et alii*, 2012), affected by large landslides in 1783 (seismically triggered landslide) and 2008 (rainfall triggered landslide) respectively.

All the thematic maps, that are going to be published, as well as the scientific papers (MAZZANTI & BOZZANO, 2011; BONAVINA *et alii*, 2005; BOZZANO *et alii*, 2009; 2011) and technical reports referred to the study area represent a powerful tool for supporting land-use planning analyses at different scales

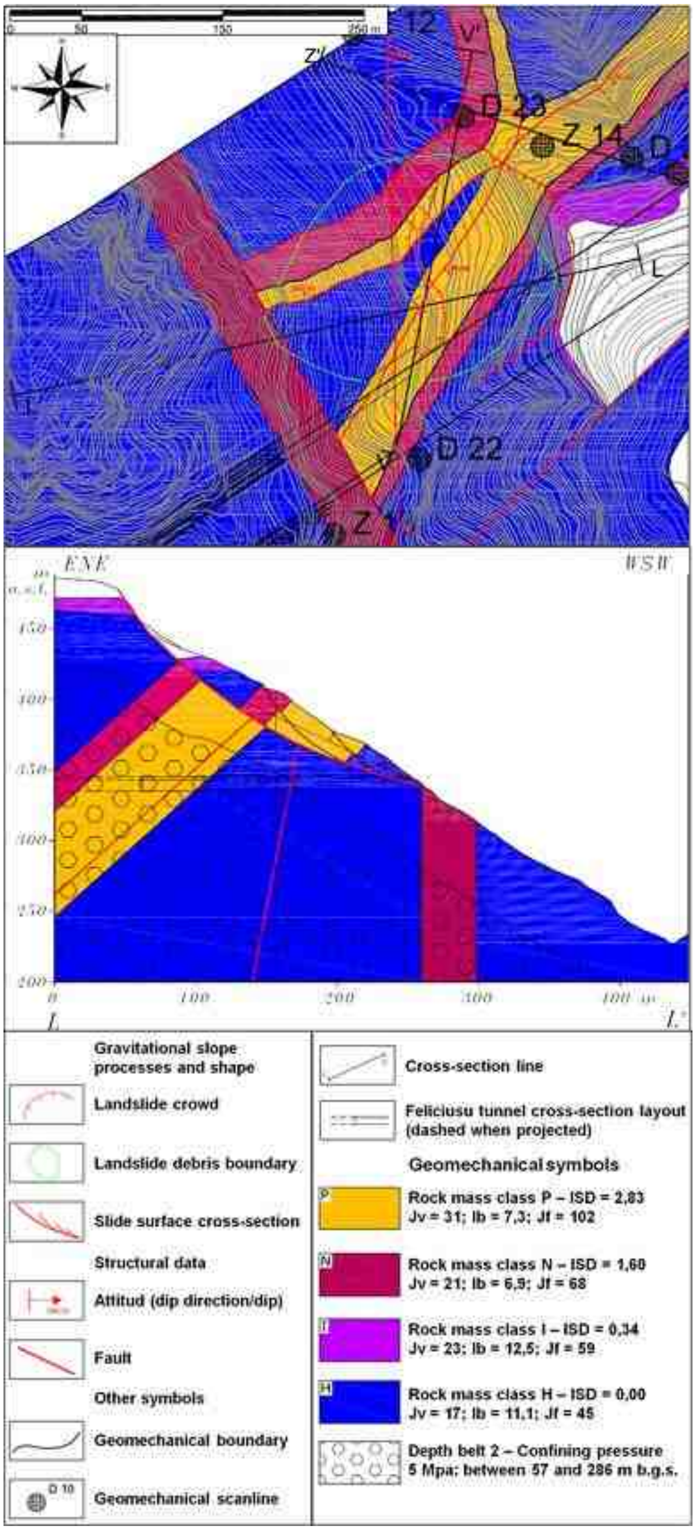

Fig. 2 – Engineering-geology map and cross section of the slope affected by the "Feliciusu" landslide.

Geomorphological mapping in Italy from the first essays to present

ALBERTO CARTON (*)

Key words: *Geomorphological mapping*.

The geomorphological mapping provides a overview of landscape forms and tells as about their genesis and evolution. The geomorphological mapping is also used as an essential tool for territorial study. Systematically used for a long time in other countries, in Italy has not yet found an "official" use by the management of territory. However the many initiatives promoted by regional and local authorities and many experiences in the context of geomorphological research, have emphasized the importance of the geomorphological map as other thematic maps normally used.

Aim of this work is a “trip” along the main stages of geomorphological mapping evolution in Italy, from the early essays. It’s important to note that the evolution of Italian geomorphological mapping was "experienced" by the entire scientific community of the physical geographers. The experience of everyone in different geographical and morphogenetic areas were, from time to time, made available to the community. They were compared to each other, with the aim of identifying common principles for the realization of geomorphological maps, to be used for basic and applied research.

A highly innovative period that brought to a qualitative leap in geomorphological mapping in the whole world is that of the sixties. At that time also in Italy were published the first examples of geomorphological maps like that of Bosco del Cansiglio (Castiglioni, 1960), of the Bressanone basin (Castiglioni 1963-64), of a territory of Calabria and Lucania (Panizza 1966, 1968) and Olona valley (Nangeroni, 1967).
Among the many issues discussed about these and subsequent geomorphological maps the use of colors and the scale of the map long engaged the researchers. The choice of color in particular followed different criteria from time to time. In the early essays (Panizza 1966, 1968) the colour had a chronological significance, later (Panizza, 1972) it was used to distinguish the processes. In some cases it was used to distinguish the forms of erosion from the forms of accumulation (Tessari, 1975-76).

Important stages, in the evolution of geomorphological mapping in Italy, were the meetings that took place within the group "Geomorphology" of the National Council of Research, the “Working Group on Physical Geography” and the "Gruppo Nazionale Geografia Fisica e Geomorfologia”.

Researches carried out in small areas of Alps and northern Apennine and on the whole Po Valley, conducted by a team of researchers of several Italian universities, have enabled to refine the methods of study of several issues. Even today the geomorphological maps then produced are taken for example and especially the acquired experiences have brought to a considerable unification in the graphic language. In particular, the implementation of the geomorphological map of the Po Valley, has resolved many problems related to the medium scale representation.

The increased costs of printing, which preceded the advent of computer graphics, the need to produce correct maps from the scientific point of view, and the growing demand from institutions and professionals to produce geomorphological maps useful for application pushed the Italian researchers to produce in the beginning of the ‘90s geomorphological maps simplified to two colors that enhanced the hazard of morphogenetic processes (GNGFG, 1993).

Outside these common experiences, many researchers developed a geomorphological mapping for special issues. So were published geomorphological maps that describe particular environments or individual categories of forms and processes such as maps of coastal evolution, of volcanic areas, of karst, of landslides, of the submarine geomorphology, of glacial forms, of Antarctic areas etc. Given the peculiarities of the subjects time by time dealt, peculiar legends were often set up, aligned with the basic principles, but with a greater availability of symbols as for example the legend for karst areas (Bini et alii, 1986).

With the start of the program of survey and mapping for the “Geomorphological Map of Italy”, in 1994 the Sector Geomorphology of the National Geological Service along with the "Gruppo Nazionale Geografia Fisica e Geomorphologia” of the National Council of Research prepared the guidelines for the survey and mapping at scale 1:50.000 to be used in the whole country. The document included all the experiences hitherto made. However, only four geomorphological maps of Italy (1:50.000 scale), are printed (fig.1).

The advent of GIS has finally produced a great qualitative leap forward as regards both the scientific and technical aspects. Overlapping LIDAR images, or simply orthophotos, on the topographic map has made much faster and more precise the operation of carryover of the symbols. The wide database that can be associated with digital mapping, return in full all the information that a geomorphological map should give and, if necessary, it can present the data unbundled. Data loaded into a GIS can also be corrected and updated, so the complex operations for the realization of a geomorphological map, do not end with the press of the paper, but become points of start for other uses. Finally, informatic maps are less expensive and can be diffused to a greater number of users.

Geological and geomorphological model for wide area monitoring of environmental risk

SABATINO CIARCIA (*), LUCIO AMATO (°), ANTONELLO CESTARI (*) & DAVIDE SALA (**)

Key words: *wide area monitoring, SAR, Strait of Messina*.

INTRODUCTION

In the Strait of Messina has been defined a wide area monitoring project related to environmental risk by "Società Stretto di Messina".

Within this project has been defined a geological/geomorphological model for supporting measurement locations and defining landscape evolution scenarios.

In particular, we referred to the past landslides, bibliographic data derived but *in situ* checked, and to a landscape evolution model for slope instability of surface coverage.

The first data were used to check the previous instability, by means the latters, instead, we tried to evaluate, through a physically model, certain areas of territory where there were geological and geomorphological conditions for the neoformation landslides input.

The used geomorphological model is based on shape recognition through DTM and detailed aerial images grid analysis.

The aim of the proposed model was to provide a tool that allows to monitor the present status of the territory and replicate it, semiautomatically, where significant anthropogenic morphological changes occur (Fig. 1).

GEOLOGICAL SETTING

The main geological elements that characterize the Strait of Messina area, are related to the Sicilian-Maghrebian Chain deposits and Calabria-Peloritani successions.

The Maghrebian-Sicilian Chain is formed by a SE verging thrust system comprising tectonic elements originating, starting from the Middle Miocene, by the deformation of Neotetide oceanic realm, related to Mesozoic-Tertiary sedimentary covers belonging to the Apulian continental margin, including shallow-water platform carbonates as well as pelagic basin successions.

The Calabria-Peloritani Arc constitutes the connection between the Maghrebian-Sicilian chain and the southern Apennines, representing the innermost orogenic element, and is formed by several tectonic units, representative of different portions of a former continental crust, associated to its Meso-Cenozoic sedimentary covers, encompassing ophiolite bodies.

Fig. 1 – study area an topographic map.

In the examined area, the substrate is represented by a Hercynian crystalline basement, covered by Meso-Cenozoic sedimentary successions. The oldest outcrops rocks, of Paleozoic age, widely exposed throughout the Calabria-Peloritani Arc, are mainly metamorphic source (gneisses, amphibolites, etc..), comprising more or less rare granitoid. The pile is topped by unconformably Tortonian-lower Messinian coarse clastic sediments, mainly deriving from the crystalline source-rocks.

The succession passes, upward and discontinuously, to

(*) TECNOIN S.p.A. Consultant
(°) TECNOIN S.p.A. Technical Manager
(**) TECNOIN S.p.A. General Manager

Messinian evaporitic deposits (evaporite limestones, gypsum, diatomites, etc.) followed by Lower Pliocene limestones and whitish marls ("Trubi"), in turn overlayed by Middle Pleistocene sandy-pelitic and calcarenites alternances.

The stratigraphic framework upwards provides the widespread presence of a ubiquitous unit on both sides of the Messina Strait; these are the Messina Gravels, a Middle Pleistocene detrital succession. The sedimentary series is capped by clastic deposits related to the Upper Pleistocene marine and river terraces, disposed on several altitude orders and, locally, by recent and current alluvial or beach deposits.

LANDSCAPE EVOLUTION PROCESSES

From a geomorphological point of view, the study area, at the basin scale, both for the Calabrian sector that for the Sicilian one, is defined by the substrate dislocation processes, by means of a discontinuity system, due to the tectonic lineations, mainly NE-SW directed.

For the definition of landslides inventory, as already noted is perimetered, by both the Calabria and the Sicily study sector, have been used the Basin Authority "plans excerpt" elaborate, the technical bibliography, the SIA and the IFFI project data (Fig. 2).

Sicily Sector

In total, 141 landslide areas were identified, partly classified with the original data, in part reclassified. The landslide total area is approximately 2 km² equal to about 2% of the total geomorphological context (in part this surface is given by the superposition of landslides identified from different sources).

Calabria Sector

In total, 48 landslide areas were identified. Data derived from PAI of Calabria Basin Authority and IFFI inventory of APAT. The total area of the landslide is about 1 km ², equal to about 4% of the total geomorphological context.

The landslide inventory was reported in fig. 2.

GEOMORPHOLOGICAL MODEL

The geomorphological model was built from field-surveyed, geomorphological map and a grid-based automatic landform recognition from DEM, with control of expert judgement (DRAMIS *et alii*. 2011, GUIDA *et alii*, 2009).

The geomorphological map derived from model was reported in fig. 3

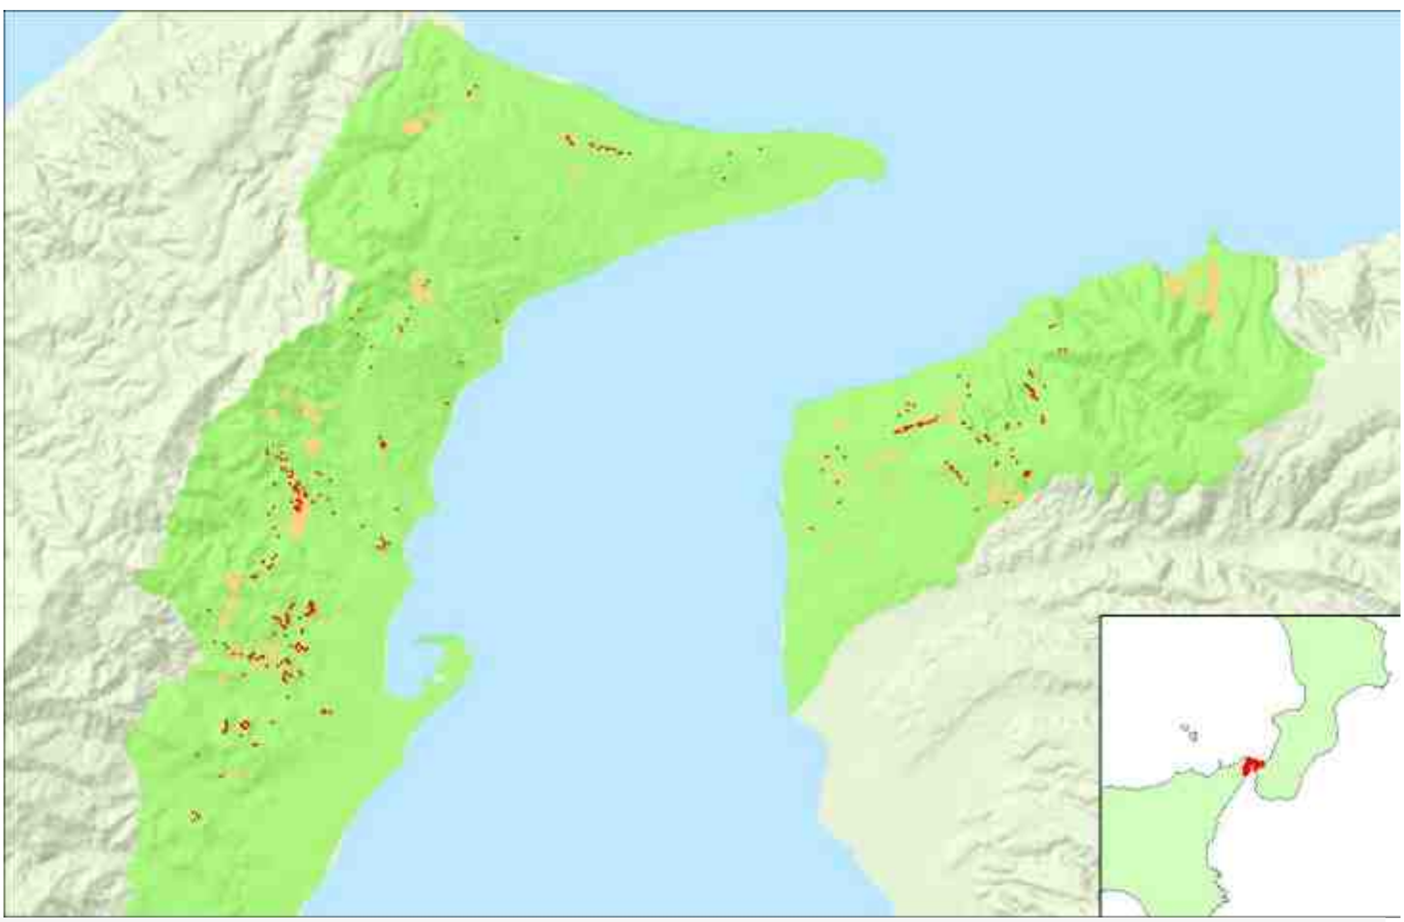

Fig. 2 –Study area, historical landslides and monitoring points.

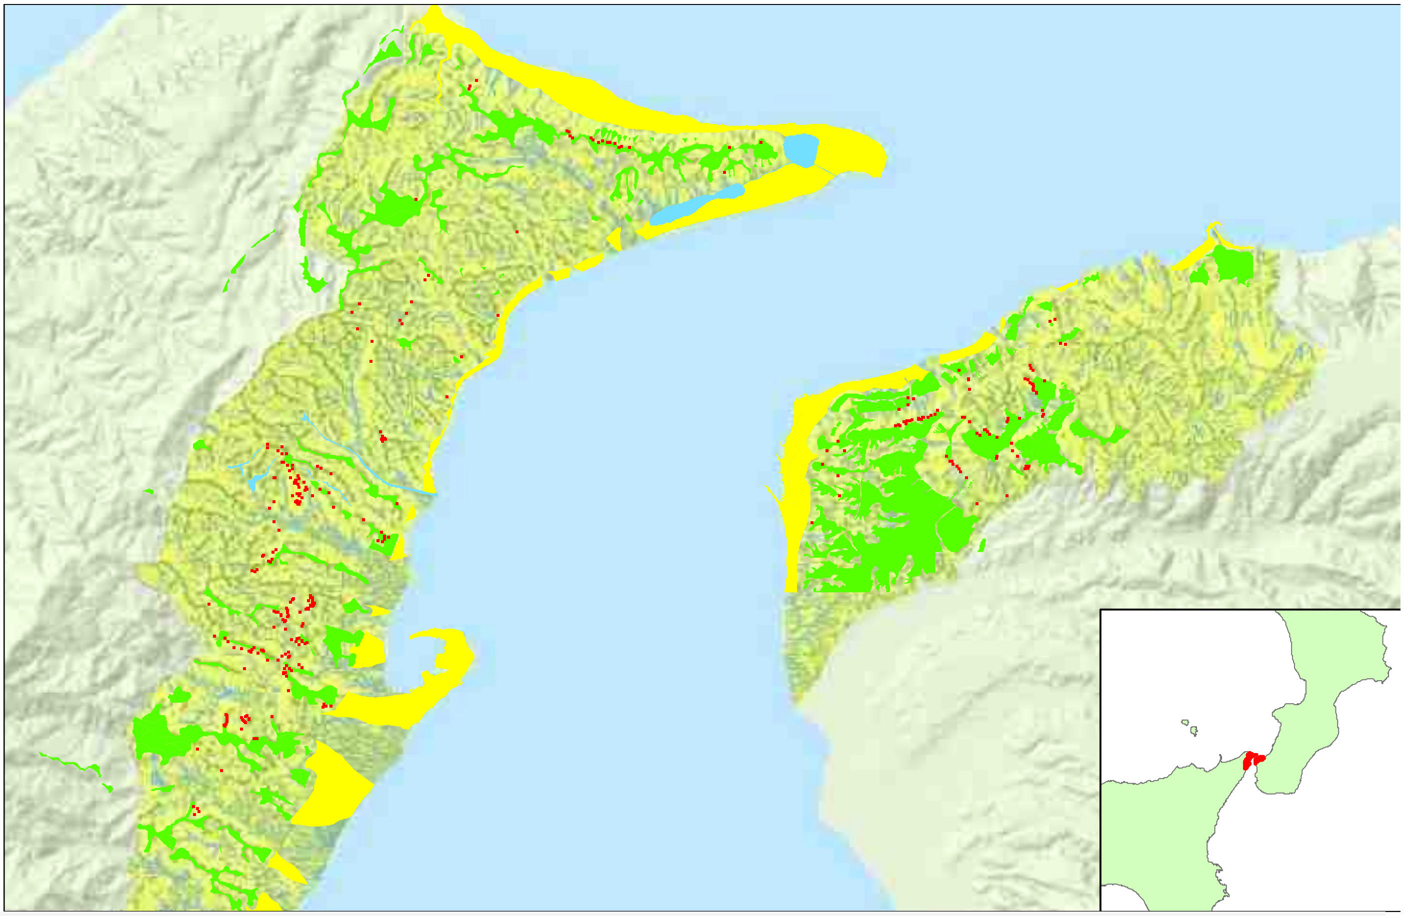

Fig. 3 – Landscape evolution model of hillslope and monitoring points.

Geomorphology and GIS analysis for mapping landslide in the Camastra basin (Basilicata, South Italy)

MASSIMO CONFORTI (*,°), STEFANIA PASCALE (°), VITTORIA PASTORE (°), MARIANGELA PEPE (°),
FRANCESCO SDAO (**) & AURELIA SOLE (°)

Key words: *Geomorphology, GIS, landslide inventory map, Basilicata, South Italy.*

INTRODUCTION

Landslides play an important role in the evolution of landscapes. They also represent a serious geo-hazard in many areas of the world. Also, large areas of the Italian territory and, in particular, the Basilicata region, are on the whole very susceptible to landslide (POLEMIO *et alii*, 1996; CANIANI *et alii*, 2008; PASCALE *et alii*, 2010), due to the combination of its peculiar geological, morphological, climatic characteristics and very often by human activity, e.g. increasing urbanization, agricultural and deforestation (GULLÀ & SDAO, 2001).

Landslide inventory maps are very important to document the extent of landslide phenomena in a territory, to investigate the distribution, types, pattern, frequency of occurrence and to study the spatio-temporal evolution of landscapes dominated by mass-wasting processes (GUZZETTI *et alii*, 2012). Also, a landslide database is most important information source for evaluate landslide susceptibility, hazard, vulnerability and risk (VAN DEN EECKHAUT & HERVÁS, 2012).

The objectives of this study were the identification, types and mapping of the landslides in the Camastra watershed (Basilicata, South Italy), that can be assumed as representative of the morphodynamics processes typically acting in the widespread sites of the Basilicata region.

The work was carried out through a geomorphological study and the collected data were processed and managed in a Geographic Information System (GIS).

GEOGRAPHICAL, GEOLOGICAL AND GEOMORPHOLOGICAL FRAMEWORK

The Camastra watershed, right tributary of the Basento River, is located in the central-western sector of Basilicata (South Italy) between 4492925N and 4470270N latitude, 5626208E and 5886976E longitude (Fig. 1). The overall area of the basin is about 361 km^2, with altitude ranging from 444 to 1835 m a.s.l. The average slope gradient in the study area is about 13° but in the most places, the gradient is higher than 30°. The hydrographic network in general has a sub-dendritic pattern which often is structurally controlled (Fig. 1).

The climate is typical Mediterranean with average annual precipitation of about 840 mm and the rainfalls are concentrated, in the period autumn-winter. The mean annual temperature is around 13°C.

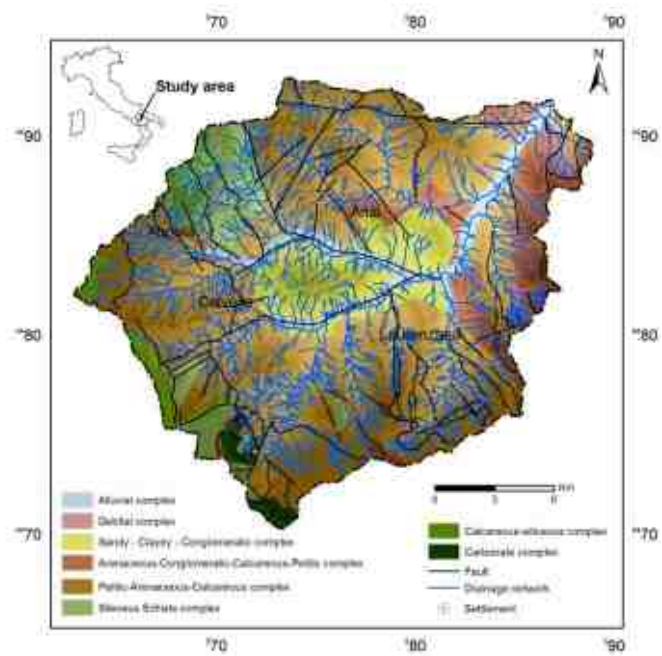

Fig. 1 – Location of the study area and geolithologic map of the Camastra basin.

From a geological point of view, the Camastra basin is placed in the external sector of the southern Apennines chain. The southern Apennines chain consists of a stack of several tectonic units made of Mesozoic-Paleogene successions and their flysch-like Neogene cover, tectonically superposed onto the buried part of the Apulian Platform shallow-water carbonates (MOSTARDINI & MERLINI, 1986; CASERO *et alii*., 1988; CELLO & MAZZOLI, 1998). This complex fold and thrust belt mainly formed as a result of Neogene deformation of the former Adriatic passive margin during Europe-Africa plate collision (MAZZOLI & HELMAN, 1994, and references therein). The belt consists of

(**) Dipartimento di Strutture, Geotecnica, Geologia Applicata, Università della Basilicata, Potenza, Italy

This work performed under the project "Combined landslides and flood risk assessment along the road network of Potenza Province (Basilicata)".

ocean-derived units, shallow-water carbonates of the Apennine Platform Units and pelagic and hemipelagic basinal sediments of the Lagonegro Units. Another important tectonic unit widely outcropping in the area, is the "Sicilide Complex" (OGNIBEN, 1969).

The lithologies outcropping in the Camastra basin were grouped into eight ''lithological complexes''. On the basis of both the occurring lithotypes and of the relative abundance of each lithotype within each complex, the detected complexes were named, respectively, carbonate complex, calcareous-siliceous complex, siliceous-schists complex, pelitic-arenaceous-calcareous complex, arenaceous-conglomeratic-calcareous-pelitic complex, sandy-clayey–conglomeratic complex, detrital complex and alluvial complex (Fig. 1).

The geomorphological setting of the study area is strongly controlled by geological and structural conditions. The western and north-western part of the basin, where, mainly, carbonate rocks outcrop, are dominated by a mountainous landscape with high relief characterized by steep slopes, more than 30° in average, and narrow V-shaped valleys, often controlled by fault systems; steep slopes also developed along fault scarps and dissected ridges made of resistant rocks (Fig. 1). The middle and eastern sectors, where rock erodibility is higher, are characterized by a hilly morphology with low-gradient slopes; nevertheless, the presence of more competent rocks (calcareous and/or sandstone) locally determines high-gradient slopes or sub-vertical rock faces. These latter landforms notably emerge from the surrounding terrains, given their greater resistance to erosion. Also, many places of middle and eastern sector of the basin, are characterized by homoclinal ridges as hogback and cuesta landforms and often characterized by breaks in slope and strike-valley due to structural controls. The landscapes show an undulating topography, gentle slopes, wide, and slightly incised valleys, where clayey lithologies crop out. Finally, recent alluvial fans and fluvial terraces are observed along the main river valleys.

In the study area, the main geomorphic processes are related to mass movements and running water processes (diffuse and/or linear) that essentially control the present-day landscape evolution (CANIANI *et alii*, 2008; PASCALE *et alii*, 2010; DE BARI et *alii*, 2011). The hillslopes are often deeply gullied as a result of erosion caused by ephemeral streams. In many sectors of the study area, badlands (*calanchi*) affect clayey sediments, producing typical stream dissected morphology, with very steep gullies separated by narrow ridges. Moreover, along badland slopes micro-piping and rilling processes operate, whereas landforms similar to small pediments are often development at foot slopes.

LANDSLIDE INVENTORY MAP

A detailed landslide-inventory map of the study area (Fig. 2), was carried out integrating the stereoscopic interpretation of multi-temporal aerial photographs, dating to 1954, 1990, 2006 and 2010, and detailed field survey. The mass movements were reported on the 1:25000 scale topographical map.

The slope instability due to gravity consist of both landsurfaces affected by severe creep and/or solifluction and of landslides. Mass movements are widespread in the study area, and many settlements and man-made infrastructures (e.g. roads and/or houses) are periodically damaged and/or destroyed by landslides activity (Fig. 2). The spatial distribution, size and typology of landslides are largely controlled by the geological and geomorphological context, including structural factors (alternating weak and hard rocks), tectonic setting, local relief and fluvial downcutting. A total number of 949 landslides were detected an mapped in the Camastra basin (Fig. 2), which covered an area of about 85.3 km^2 and correspond to 23.7% of

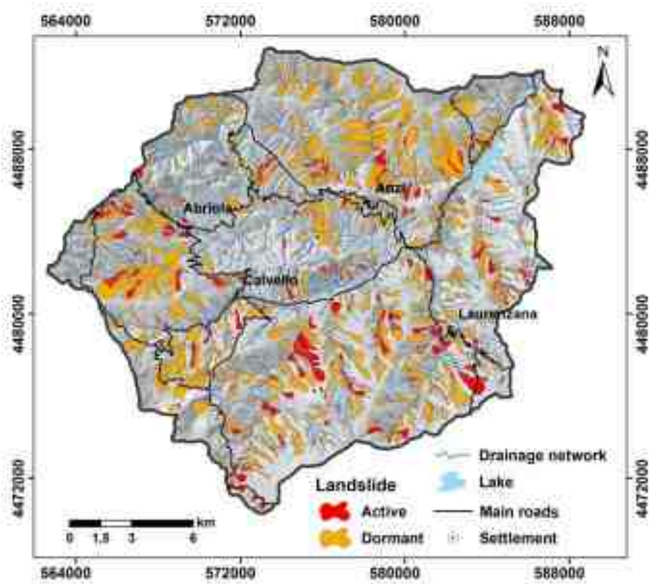

Fig. 2 – Landslide inventory map of the Camastra basin.

the total area. The minimum, mean and the maximum landslide areas are 0.004, 0.084 and 1.023 km^2 respectively.

Multi-temporal aerial photo interpretation and field surveys provided data for distinguishing between active (25%) and dormant (75%) landslides. Additionally, this diachronic analysis showed that landslide deposits may have quickly been reworked by slope-wash processes and/or reshaped by anthropogenic activity. Some active landslides represent a reactivation of pre-existing dormant landslide (Fig. 2).

By simplifying the Varnes (1978) classification, the landslides were mapped on the basis of the type of movement as follows: falls (1.1%), slides (34.4%), flows (10.4%) and complex landslides (48,7%).

Falls affect mainly steep slopes carved into strongly fractured and weathered hard rocks, locally leading to the development of talus slope where steep scarps grade into a straight profile downward. However, small rock/earth falls occur along the outer edge of fluvial valleys. Landslides mainly occur on slopes cut in the pelitic-arenaceous-calcareous complex, sandy-clayey–conglomeratic complex, detrital complex, though they are relatively diffused also where the arenaceous-conglomeratic-calcareous-pelitic complex crop out. Rotational and complex landslide also affect siliceous-schists complex. Field surveys show that the flow-type landslide bodies can be affected by a series of small mudflows, particularly during heavy rainstorms. Most part of the detected landslides occur on slopes bordered downslope by streams displaying clear field evidence of ongoing downcutting processes. In addition, creep and/or solifluction correspond to about 3.2% of the unstable area. The geomorphological survey has also highlighted the occurrence, in the studied area, of hillslopes affected by a large number of small and shallow landslides mainly of the flow and/or slide type; because they were difficult to be drawn at the scale of the map, the term “landslide area" was introduced. These landforms occupy to 2.2% of the slope instability recognized in the Camastra basin.

Finally, the triggering landslide factors are manly represented by heavy rainfall, less frequently by earthquakes and, in many case by human activity (POLEMIO M. & SDAO F., 1996; GULLÀ G. & SDAO F., 2001). In particular, it was observed that during heavy rainstorms, many slopes can be affected by a series of small mud-flows and/or earth-slide.

CONCLUSIONS

This study has demonstrated that landslide are the mainly denudation processes in the Camastra basin (Basilicata, southern Italy). In fact, mass movements affect more than 23% of the study area. Due to the lithological and morphological features of the area the complex landslide are the most common type of mass movement in terms of frequency and spatial distribution.

Finally, the geo-database build by means GIS software and the landslide inventory map obtained, may provide the basis for further analyses, representing a useful tool for land management as well as the initial step for the assessment of geomorphological hazard and risk.

Application of "GmIS_Unisa" geomorphological mapping system to regional planning.

DOMENICO GUIDA (*), VINCENZO SIERVO (**), ANTONELLO CESTARI (**) & VINCENZO PALMIERI (°)

Key words: geomorphological mapping, regional planning, GIS, landform recognition.

INTRODUCTION

Geomorphological mapping provide a full objective landforms description, from which to derive landscape evolution on regional planning time scales.

From DEM-based geomorphometrical analysis and object-oriented remotely sensed imagery processing are obtained landform of Montalto Uffugo (CS) municipality.

Geomorphic models was built with landform ("object") related with various kinds of class relationships (geometric, temporal, physical, geological and hierarchical).

An object-oriented geomorphological mapping system, in use at Salerno University in several national and regional projects on engineering geomorphology, landscape ecology and hydrology, was applied (GmIS_UniSa).

The model output thematic map, rappresentative of landscape evolution in response to depositional and erosional processes, fulfill the requirements of regional planning rules.

By generalization and decomposition procedures of geomorphological objects are achieved smaller scale models (regional planning, hazard management) and large scale models (site development, process monitoring).

"OBJECT-ORIENTED" GEOMORPHOLOGICAL MAPPING SYSTEM

The geomorphological mapping model can be symbol-based or area-based: the first will indicate in symbolic form the processes and forms (qualitative analysis), with the latter defining a relief zonation in homogeneous areas characterized by unique geomorphological conditions defined by physical and geometrical parameters (quantitative analysis).

The adopted geomorphological model, derive the symbol based geomorfological map from geometrical property of landform (object boundary, centroid in a full coverage map).

These models should:

- increase typology, quality, quantity and combinations of manageable and representable geomorphological data. In particular, the information associated with each "object" should be flexible enough to allow the representation of all related attributes (e.g. the terrace edge of fig. 1, besides being a linear entity, is also part of the polygon which defines the terrace itself and the underlying river bed);
- interact with the analysis and data representation of other disciplinary sectors at different scales;
- conform with spatial data transfer standard (SDTS) in order to promote and facilitate the transfer of digital spatial data between dissimilar computer systems (GOODCHILD *et alii* 1999).

The most significant efforts in geomorphological mapping can be summarized in the following aspects: data

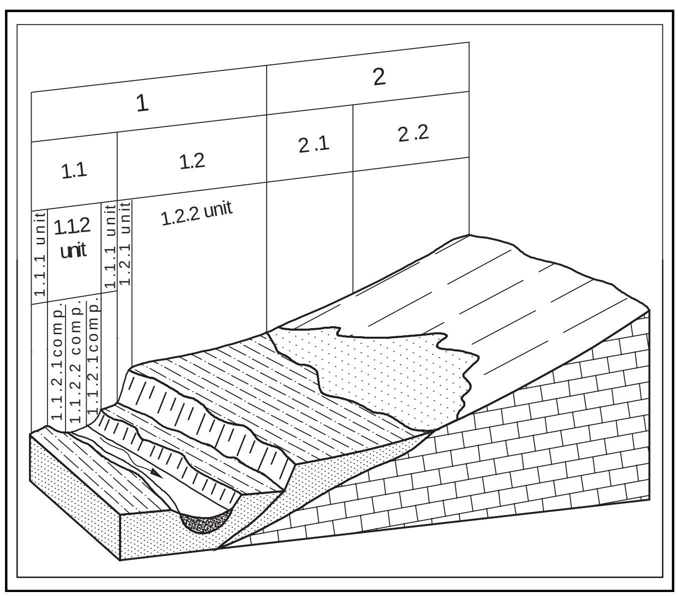

Fig. 1 – Nested hierarchic sequence of landforms (mod from DRAMIS ET AL., 2011)

interoperability, hierarchical and multiscalar; full-coverage mapping, object-oriented data management (DRAMIS *et alii*, 2011).

Full coverage object-oriented geomorphological mapping may be performed by intercomparison between: a) expert judgment supervised e b) fully automatic un-supervised.

The first procedure is based on a “traditional” field-surveyed, geomorphological map and a grid-based automatic landform recognition from DEM, with control of expert judgement.

The second procedure is based on grid segmentation techniques, allowing the partitioning of DEMs or remotely sensed imagery, into non-overlapping regions (segments) representative of geomorphic entities, verified on field or with landscape evolution physical model.

With this procedure the geomorphic map are designed with “non subjective” and “repeatable” landscape form better achieving boundaries recognition and geometric relationships.

THE SALERNO UNIVERSITY GEOMORPHOLOGICAL MAPPING SYSTEM

A GIS-based, full coverage, object-oriented geomorphological mapping system has been developed at the Department of Civil Engineering and at the Great Risks interUniversity Consortium (C.U.G.Ri), Salerno University (Italy), and has been applied in several projects on engineering geomorphology, landscape ecology and hydrology (CASCINI *et alii*, 2005; BLASI *et alii*, 2007, GUIDA *et alii*, 2009).

The GmIS_UniSa adopts the "Expert Judgment supervised" procedure, the approach based on "traditional", gradually implements the results of the recognition and delineation of forms through the analysis of DEM grid or object-based, controlled by the operator's judgment expert.

The different taxonomic levels is organized in terms of “nested topologic entities” (closed polygons, open lines, and punctual symbols) supported by an attribute list. Moving upward toward smaller scales, polygons may change to lines or symbols.

Moving downward, symbols may change to lines or polygons, lines may change to polygons, while polygons may be decomposed into smaller features.

The Salerno University mapping procedure includes the following steps (fig. 1).

- Production of a “traditional” field-surveyed, symbol-based geomorphological map, normally at scales ranging between 1:5,000 and 1:25,000, in relation to the mapping project purpose, focusing on morphography, morphometry and morphogenesis. The data source is a detailed field survey supported by aerial

"V-shaped" incision; 8. torrential stream-bed; 9. torrential terrace strongly influenced by lateral contributions; 10. complex landslide: slide-rapid earthflow; 11. soil creep; 12. complex landslide: translational slide-earth flow; 13. complex landslide: rotational slide-earth flow; 14. active earth flow; 15. quiescent earth flow; 16. landslide fan; 17. landslide scarp

photo interpretation (1a); the legend is a symbol-oriented list of significant relief features (1b);

- Aerial photo interpretation, at a scale close to that of the survey base toposheet, to produce a full-coverage geomorphological map from expert judgement. At this stage the geomorphological features are delimited and coded in a nested structure with boundary lines at different reliability levels.

- Primitive topological transformation of the mapped units supported by attribute list.

- Construction of an object-oriented, GIS-based geomorphological map.

- DEM-based geomorphometrical analysis, automatic multiscale landform recognition, and object-oriented remotely sensed imagery processing.

CONCLUSIONS

Was built on the territory of Montalto Uffugo (CS) municipality the geomorphological model according to the specifications of the "GmIS_Unisa" mapping system.

From the model was produced the full coverage geomorphological map shown in figure 2, compared with a geomorphological symbolic map.

The geomorphological map has been given a summary of the thematic map required by the provisions of regional planning.

Oro-Hydrographic Map of Western Europe

DOMENICO GUIDA (*), ALBINA CUOMO (*), ANTONELLO CESTARI (**), FRANCESCO DRAMIS (°), PAOLO PARON (°°), VINCENZO PALMIERI (°*) & VINCENZO SIERVO (**)

Key words: *orography*, *geomorphometry*, *mountain ordering*, *Europe.*

INTRODUCTION

Mountains are recognized as land sectors with elevation generally higher and with more prominent geographic features than their surroundings (SMITH & MARK, 2003) and their importance derives by the worldwide distribution, human occupation and environmental influences.

Historically, the scientific disciplines studying mountains are qualitative orography and quantitative orometry or mountain geomorphometry (HENGL & EVANS, 2009). In this paper, as in the previous one by CUOMO *et alii* (2011), "orography" will be used in a broader geomorphological meaning, as the landscape spatial expression resulting from the balance between relief creation and sculpting by constructive and destructive processes, working over different spatial/temporal scales. Many disciplines, such as topo-climatology (CUOMO & GUIDA, 2010a), regional hydrology (CUOMO & GUIDA, 2010b) and landscape ecology, request objective and quantitative approaches to detect and map orography in order to support landscape analysis and environmental modelling. This abstract, referring to the definition and mapping method of CUOMO *et alii* (2011), illustrates the obtained orographic map of Western Europe and describes the resulting analysis from an original procedure to regionalize ordered orography by critical lines (channels) connecting selected key saddles.

MATERIALS AND METHODS

The method used to build-up the map is based on the orographic parameters, describing the mountain terrain as a whole: *mountain prominence* and *order*, and their *parent relationship* (Fig. 1).

Mountain prominence is a first-order derivative of elevation representing the height above all surrounding terrains or the relative elevation of a summit; more precisely, the elevation difference between a peak and the saddle connected to the lowest contour that encircles it and does not contain higher peaks. One of more used methods is based on the well known

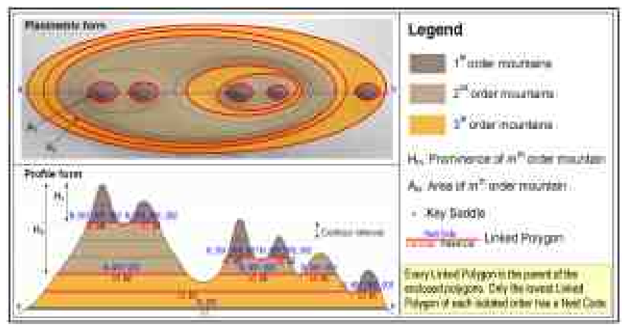

Fig. 1 – Scheme of order, prominence, area and parent relationship of the ordered mountains (modified from Yamada, 1999).

concepts of key saddle and key contour. Mountain order, as proposed by YAMADA (1999), is defined by the contour lines on a topographic map in which each mountain is represented as sets of closed contour lines. These sets include only a single closed contour line for each elevation "*unless a saddle (or pass) that divides the mountain has a height that exceeds the contour interval*" (YAMADA, 1999). Yamada definition of mountain orders is similar and complementary to that defined for stream orders by STRAHLER (1952).

The mountain parent relationship establishes a partonomic relation between topographic points and lines; the parent of each peak is the higher peak whose base contour surrounds the given peak and no other peak. Such peak is referred to as the topographic parent. The two other systems of defining parent peaks are called "line parent" and "source parent", and both are used more often than the topographic parent. One of the more used procedures to partonomically aggregate nested mountain orders is the island parentage or encirclement parentage.

The procedure proposed by CUOMO *et alii* (2011) automatically provides the identification of those contour lines or groups of contour lines encircling any positive (mountains) or negative (depressions) orographic volumes, using and processing polygons instead of polylines. Once the procedure has derived the polygon set, it identifies all the polygons that are not encircled by any other polygon, calling them base

(°*) ARCADIS – Agenzia Regionale Campana Difesa Suolo, Via Uldarigo Masoni, 12, 80141 Napoli, Italy

polygons and, starting from these, it derives the relative parent relationship. In other words, adopting a bottom-up procedure, any specific base polygon is the parent of all the enclosed polygons; if out of all these there are two or more polygons at the same elevation, the procedure marks them as linked polygons. At this point, the procedure considers that these are the parents of all the enclosed polygons, until there are again more than one polygon at the same elevation. Obviously, between the linked polygons there are n-1 saddle where n is the number of polygons (Fig. 1).

The map (at the 1:3,500,000 scale) is based on a CGIAR-CSI DEM with a 250 m horizontal resolution (http://srtm.csi.cgiar.org/) (JARVIS *et alii*, 2006). Based on the above background, concepts and materials, the applied methodology works with a GIS-based procedure, including five computer routines and several operational steps. The 1st outine provides the contour generation from the source DEM and the related contour lines table, comprising the contour line type and the contour line level fields. The 2nd routine provides the polygon generation and related polygons table following four steps: the 1st step consists of a nested polygonization of those contour lines that surround an orographic volume; the 2nd step works on the previous nested polygons to construct the polygon parent relationships; the 3rd step extracts the summit polygons from nested polygons. Finally, the 4th step localizes and extracts the summit or peak points within the summit polygons and creates the peak points table. The 3rd routine manages the same steps for those contour lines that don't surround an orographic volume, allowing to identify the hollow contour polygonization and depression polygons, to recognize the immit polygons and, finally, to localize and extract the immit or pit points within the immit polygons creating the pit points table. By means of the 4th routine, various types of saddle points were localized and extracted. Finally, the 5th routine provides the mountain orders from the polygons and calculates the mountain prominence by difference from contour value of each linked polygon and the elevation of the highest peak point within it. As described in CUOMO *et alii* (2011), the above method was addressed to derive the mountain ordering and prominence and, then, their parent relationship in order to perform the digital orographic map of peninsular Italy.

Actually, the hierarchical mountain ordering and related orographic dataset and mapping are only one consequence of the adopted methodology. More generally, it is an attempt to give a logical systematization and practical finality to a series of orographic entities, as contour lines, polygons, peak points, saddles, pits, etc…, by using the Morse Theory as reference, concerning the study of the relationship between a function's critical points and the topology of its domain (RANA, 2004). So, the simplified procedure seeks to extract and select only those critical points (pit, peak and saddle points) with orographic relevance in the real world, represented by a DEM. Following the Morse Theory, over a generic surface between these points, the relation: peaks - saddles + pits = 2 (Euler-Poincarè formula) is valid. This formula holds (only) if the given surface is topologically equivalent to a sphere (without boundary) and if there are no degenerate critical points over it. Over a surface with boundary (as a DEM) it is also necessary to introduce a global virtual minimum (vm) outside of the boundary, so that the outgoing directions from surface boundary are only descending. With these assumption for a generic DEM, if all the critical points are non-degenerate, the given formula can be written as: peaks - saddles + pits = 1. Once obtained these critical points "…*referred to in physical geography as the fundamental topographic features*" (RANA, 2004), it is possible to derive the critical lines that are special lines which connect critical points. There are two types of critical lines: ridge lines, that start from peaks and terminate at saddles; channel lines, that originate from saddles and terminate at pits. In the procedure proposed in CUOMO *et alii* (2011), the contour lines were used to distinguish the polygonal features and, consequentially, the point features too. In that way, not all the critical points present over the surface were extracted, but only those considered as significant, because their prominence is greater than the contour interval.

Following the previous considerations, notwithstanding the adopted simplifications, the method ensures the topological integrity and, then, the validity of the above formula for each base polygon. The effort is to give a hierarchical organization to these critical points and lines in order to obtain a simplified version of topological network for surface zoning or landscape regionalization.

CONCLUSIONS

The method extracts the parent relationships of the ordered mountains, by integrating the concepts of mountain prominence and extension from a 250 m cell grid digital elevation model (DTM) from CGIAR-CSI.

The resulting orographic entities are hierarchically codified into a proposed orographic taxonomy, derived by a multiscale comparison analysis at continental, national and regional scale, including six nested orders: orographic unit, complex, group, range, chain system and chain block. These orographic entities are bounded by an original procedure of regionalization, starting from a simplified application of the topological data structure analysis of RANA (2004). These nested orographic entities are shown on a general oro-hydrography map at the 1: 3,500,000 scale, obtained by intersecting nested orography boundaries, selected hydrography as critical lines connected to key saddles, as critical points. The resulting map is a prototypal, objective, hierarchical oro-hydrographic regionalization at continental scale of the Western Europe (Fig. 2). The orographic entities are hierarchically termed into an original taxonomy modified from CUOMO & GUIDA (2010a), and CUOMO *et alii* (2011).

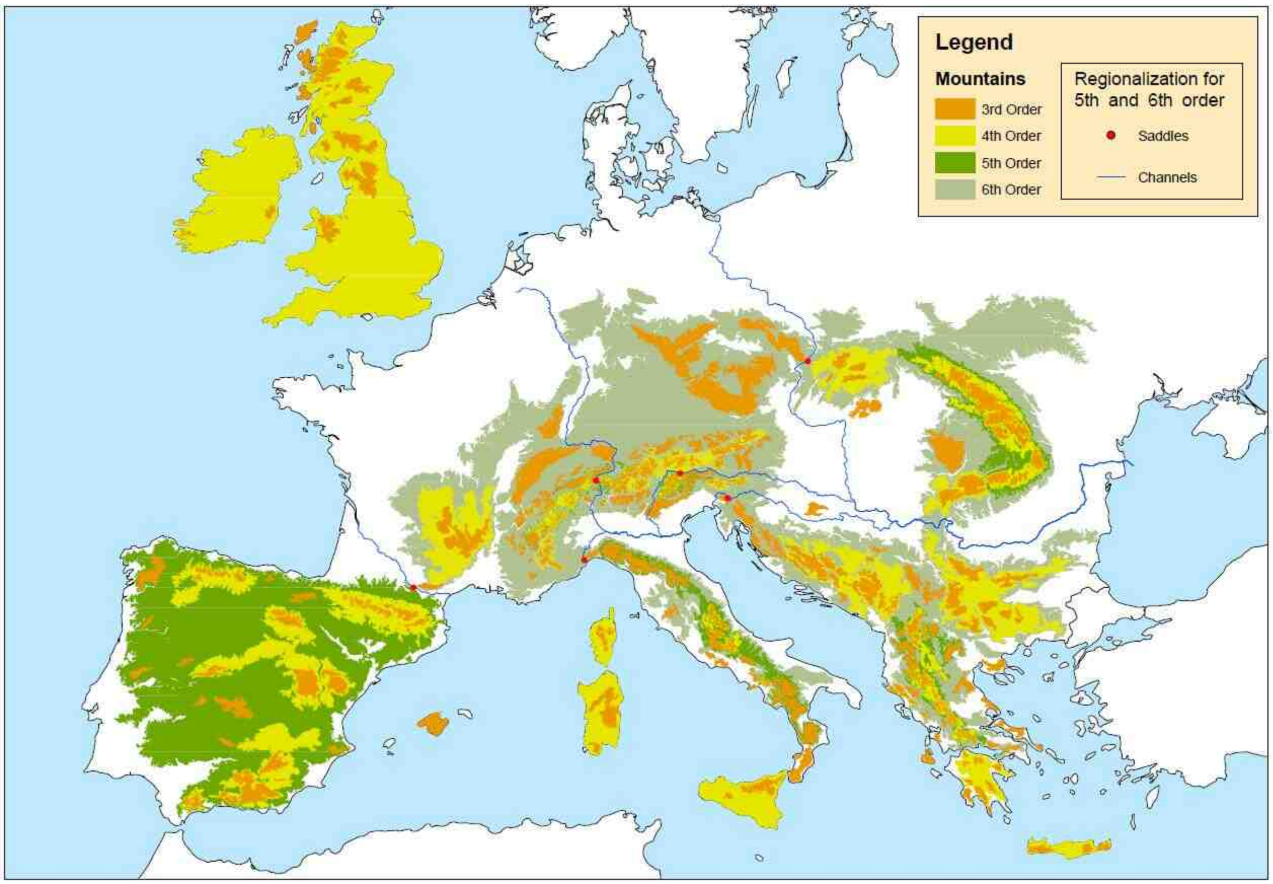

Fig 2: Simplified oro-hydrographic map of Western Europe (without first and second order mountains)

The oro-hydrographic map of Western Europe can have applications in regional topo-climatology (Cuomo & Guida, 2010b) to point out the role of the multi-scale orographic barriers in controlling the distribution, frequency and intensity of extreme orographic precipitations as well as the orographic signature of relief in disciplinary, multi-scale eco-regional researches.

A GIS-based geomorphological mapping of the Calore River alluvial plain in Benevento area (Campania, Italy)

VALENTE ALESSIO (*) & MAGLIULO PAOLO (*)

Key words: *Geomorphological mapping, GIS, River alluvial plain, Campania, Italy*.

INTRODUCTION

In this work the physical landscape of an alluvial plain in terms of processes, forms and evolution is represented by reducing the use of symbols in favor of geometric entities properly mapped. These entities are processed by means of a GIS, which is able to handle large amounts of spatial data, as well as to offer solution to many of the problems occurring during the production of comprehensive geomorphological maps.

The information of the spatial database, derived from field survey, cartographic analysis and interpretation of aerial photographs, are managed and represented in a multiscalar hierarchical structure. In this way, the change in scale naturally caused a change in detail of the provided information. Obviously the importance of interpretation increases with decreasing scale.

This mapping approach can be the basis for correct choices in terms of environmental planning, also according to recent indications provided by European and national standards.

MAPPED AREA

The segment of the River Calore that flows in the mapped area, is East-West elongated in the Benevento Plain, an intra-chain large depression located to the East of the carbonate massif of Camposauro Mount (southern Apennines). In this depression clayey and sandy-arenaceous deposits of the Ariano Group (Upper Zanclean - Piacentian: CHIOCCHINI, 2007) widely outcrop. They overlap calcirudites with calcarenites and marly interbeddings ascribed to Argille Varicolori Formation (Oligocene-Miocene: CHIOCCHINI, 2007). On this substratum gravelly and sandy alluvial deposits (Middle Pleistocene-Holocene: CHIOCCHINI, 2007) unconformably rest. These latter constitute the substratum of discontinuous river terraces occurring on both the sides of the Calore River, at altitudes ranging between 80 and 200 m

The Calore River starts about 50 km to the south of the examined area and ends about 40 km to the west, where it joins the Volturno River. It flows down for some 115 km, mostly in the province of Benevento. The catchment area is about 3000 square kilometers, with an average altitude of about 545 m. (MAGLIULO *et alii*, 2009)

In the mapped stretch, the Calore River receives as major tributaries: the Ufita and Tammaro rivers on the right side, and San Nicholas Creek and Sabato River to the left. The sinuosity is 1.25. Side bars, often alternate, migrating downstream, and a single active channel are present. These features allow to classify it as a pseudo-meandering river. The evolutionary trend is towards a single-thread river with a good stability, and low values of liquid and solid discharge (MAGLIULO *et alii*, 2009).

THE GIS-BASED GEOMORPHOLOGICAL MAP

The qualitative and quantitative information derived from field surveys, literature data and interpretation of topographic maps and aerial photograps can be stored into a proper GIS database. GIS allows easy processing of data and flexibility in the cartographic representation.

Using GIS, the space can be described by a series of "objects", each of which discretized by points, lines or polygons with associated attributes (position, topology, etc.). In this way, the different "objects", at different scales, can occupy the same space but with different attributes, e.g. genetic, morphometric and chronologic ones (MCDONNELL, 1996) .

Therefore, any geomorphic system, such as the alluvial plain in question to be investigated and dealt with analytical methods, needs a multi-scale breakdown in terms of more simple sub-systems, while maintaining the structural congruence, the functional coherence arising from the behavior of all the interrelations between the various components and the proper relationship allometric.

Each sub-system, delimited by certain geometrical elements and/or shaded, requires a description of detail, which may involve, in turn, further breakdown. For each degree of

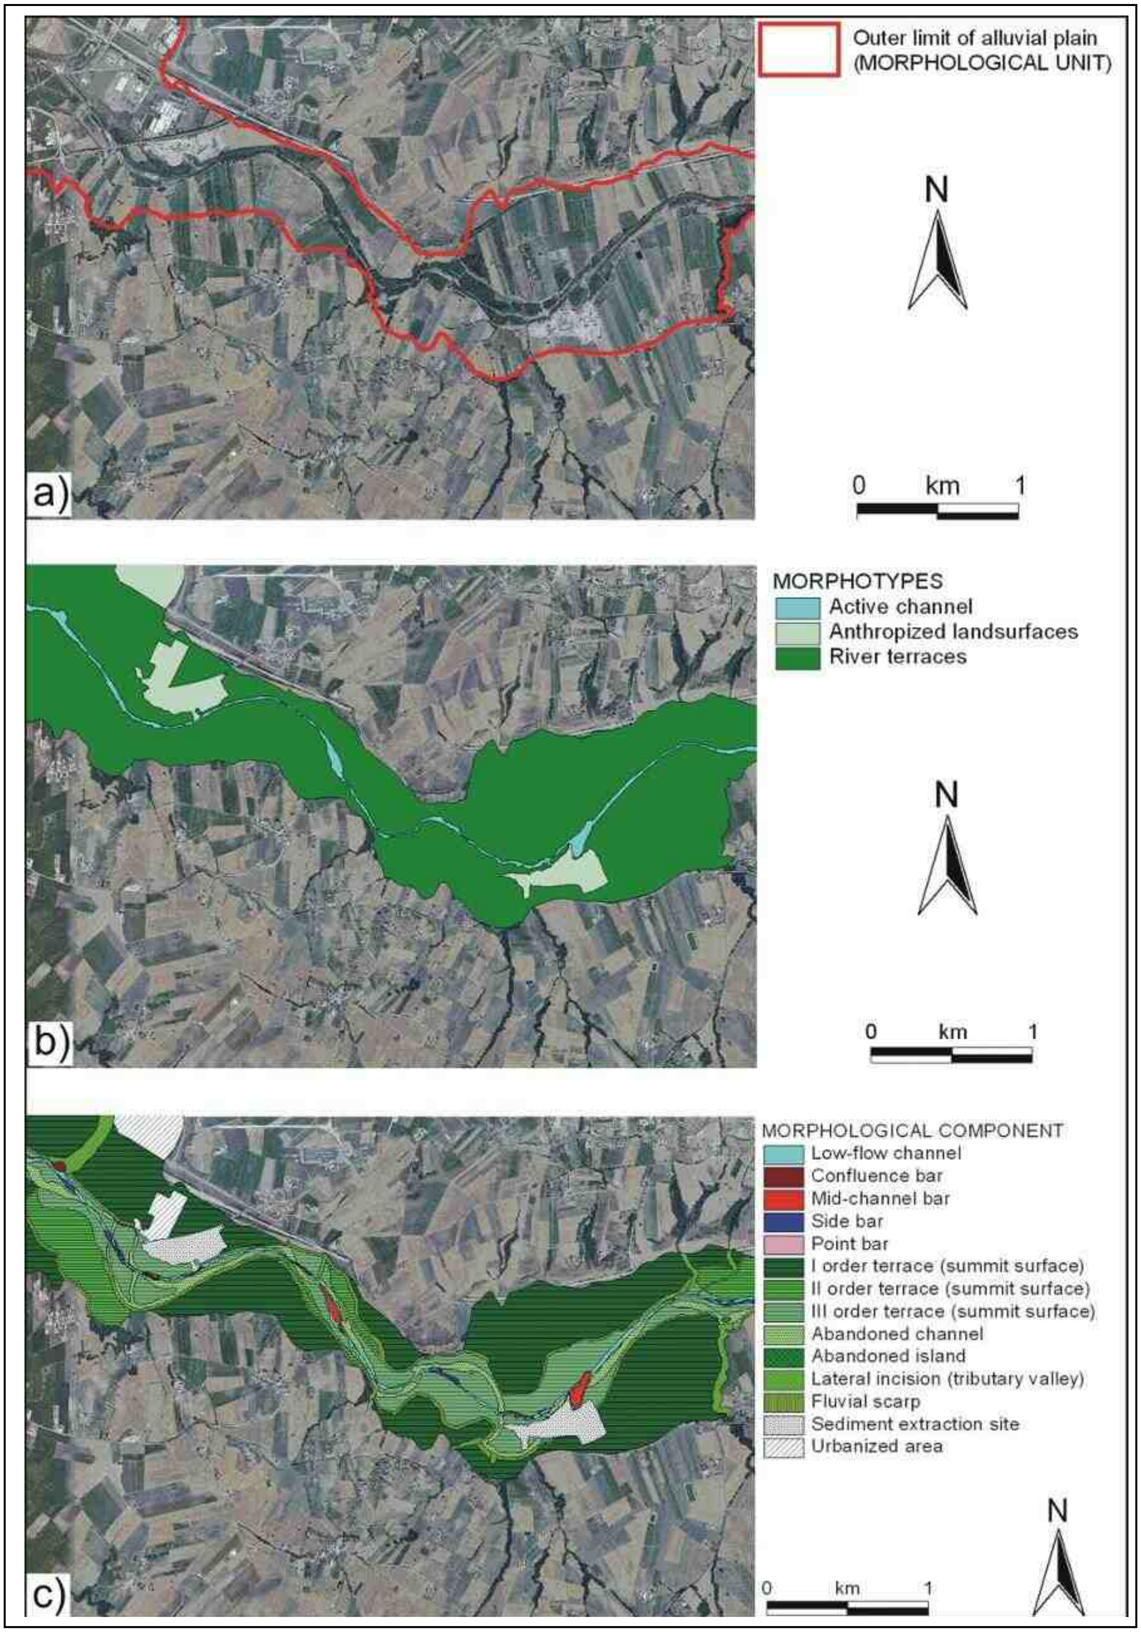

Fig. 1 – Example of a stretch of the GIS-based geomorphological map. In order to improve the view the adopted scale in the hierarchical sequence is left the same.

disaggregation and subsequent increase in the retail knowledge, correspond to a different scale of data representation, appropriate for environmental planning purposes.

In order to make visible the representation of geomorphologic "objects" of the alluvial plain, we have chosen to ignore higher hierarchical levels of the sequence proposed by GUIDA *et alii* (2009) which included categories represented the small scale maps (i.e., less than 1:100.000). More precisely, it was felt that the characters of the alluvial plain of the Calore River were better represented at the lower hierarchical levels, also for the availability of the topographic map at 1:25.000 scale and orthophotos at 1:10.000 nominal scale, which were an useful support to the GIS software used for the representation of the geomorphological map as "objects".

Therefore, once identified the alluvial plain as Morphological Unit, i.e. an entity that includes a variety of morphological forms characterized by morphometric parameters considered discriminator and resulting from specific geomorphic processes, we proceeded to a further subdivision, aimed to a more detailed description. Thus, were recognized and mapped the Morphotypes, considered as the geomorphological entity where landforms derived from "the dominant geomorphic processes acting over evolutionary stages defined on the local geological structure under the action of climate and its variations" are present (VERSTAPPEN & VAN ZUIDAM, 1968). More precisely, in the studied sector of the alluvial plain, we have been recognized as morphotypes: the active channel, the river terraces and the forms of anthropogenic origin. The "river terraces" morphotype includes the most recent orders (<117 m a.s.l.), as highlighted by the analysis of recent geological maps (CHIOCCHINI, 2007). Among these terraces, the surface formed by the alluvial deposits on which Roman structures were established from the first century B.C. are included (D'ARGENIO *et alii.*, 2001). Therefore, this morphological unit excludes the terraces older than the Upper Pleistocene (?) - Holocene, which fall into different morphological unit (e.g, hillside).

A further distinction with respect the one recognized at this scale, i.e. between 25,000 and 10,000, and described earlier will be observed in the Morphological Components Map, adequately mapped at a scale between 1:10,000 and 1:5000. The active channel is subdivided into the low flow channel and fluvial bars of different types. A greater complexity affected the breakdown of the terraces into Morphological Components, as at least three orders of summit surfaces were recognized and mapped, together with the outer scarps, the traces of abandoned channels and the lateral incisions. As regards the recent terraces, D'ARGENIO *et alii* (2001) reported that the distinction was possible only at a scale of 1:5000 or smaller. Worthy to note is the fact that the mapping of both these surfaces and outer scarps facilitates decision making regarding the areas subject to flooding and possibly to mitigate the risk. Finally, it is possible to differentiate anthropized landsurfaces into areas strictly related to urbanization from those used for specific purposes, such as the sediment extraction sites

CONCLUSION

The adoption of the proposed multi-scale hierarchical structure and the identification and characterization of the alluvial plain of the River Calore allowed to define uniquely the forms in the landscape, as well as the spatial expression of certain geomorphic processes. This exclusiveness therefore facilitates the understanding of the evolutionary trend by giving clear, unambiguous instructions for solving problems that planning and land management needs.

The objectives of this mapping approach is to improve understanding of relationships between forms and processes, and changes in the river system, also through geochronological attributes.

Investigation of marine and continental layers in a stalactite older than 1 million years (Custonaci, north-western sector of Sicily)

FABRIZIO ANTONIOLI (°), PAOLO MONTAGNA (°°) (°°°)(*) , ANTONIO CARUSO (**), ROSARIO RUGGIERI R.(***), VALERIA LO PRESTI (**), SERGIO SILENZI (+), NORBERT FRANK N. (°°°), ERIC DOUVILLE (°°°) & CATHERINE PIERRE (++)

RIASSUNTO

Ricerche su una stalattite a livelli marini e continentali più antica di un milione di anni, Custonaci, Sicilia NW.

Questo lavoro si basa sul ritrovamento, in una grotta carsica, a 100 metri di quota a Custonaci in provincia di Trapani, di una stalattite di notevole interesse paleo climatico, ricoperta da coralli marini, la cui sezione rivela la presenza di 3 Iatus che denotano una interruzione della deposizione di carbonato continentale presumibilmente in seguito a trasgressioni marine. Il carbonato, datato attraverso la metodologia ^{230}Th/U MC-ICPMS (Neptune^{Plus}), ha fornito una età più antica del limite temporale massimo di applicabilità del metodo (~ 600 ka). I coralli, che ricoprono il livello continentale più giovane, analizzati usando il rapporto ^{87}Sr/^{86}Sr, hanno fornito una età di 1.1±0.2 Myrs. Alcune considerazioni sui risultati delle analisi δ^{18}O sui livelli continentali dello speleotema indicano una deposizione durante il MIS 27-31.

KEY WORDS*: speleothem with marine and continental layers, coral overgrowth, submerged cave.*

INTRODUCTION

A stalactite overgrown by scleractinian corals was collected from a karstic cave located along the northwestern Sicilian coast between Trapani and San Vito Lo Capo at 100m above the sea level. The Custonaci coastal area consists of four major marine terraces identified by **A**NTONIOLI *et alii*, 2002, with the youngest terrace (about 16 m above sea level) attributed to MIS 5.5 on the basis of the Senegalese fauna (*Strombus bubonius*). From a morphogenetic point of view the cave is a flank margin cave subsequently invaded by the sea due to the retreat of the cliff, then colonized by marine organisms, and finally raised during the Pleistocene tectonic with the development of typical karst forms such as domes and channels due to acid water condensation, and calcite deposits. The cave is also partly encrusted by coral growth.

RESULTS

The speleothem section (Fig.1) shows three hiatuses that are considered to represent three different sea level transgressions older than the coral overgrowth. Several pieces of the continental layers of the stalactite were analysed for ^{230}Th/U using a multi-collector ICPMS (Neptune^{Plus}) and all the ages resulted to be beyond the upper limit of the ^{230}Th age range. Small fragments (3-5mg) of the thecal wall of three corals were analysed for ^{87}Sr/^{86}Sr ratio and the strontium ages were then calculated from the regression curves LOWESS look-up Table version 4: 08/04 (revised from **M**CARTHUR *et alii*, 2001.

The age of the corals is 1.1±0.2Myrs (mean ± 2SD), supporting the ^{230}Th/U ages of the continental layers beyond the upper limit of the U-series chronometer.We measured the δ^{18}O of the continental layers at 1 mm spatial resolution and the comparison with marine and continental records suggests that the calcite of the stalactite was precipitated during MIS 27-31.

CONCLUSIONS

The stalactite from Custonaci thus represents a unique paleoclimatic and paleo sea level archive together with the Bahamas flowstone (**L**UNDBERG AND **F**ORD 1994) and the Argentarola speleothems (**D**UTTON et allii, 2009. The sandstone deposits on which the oldest terraces are carved below the cave are related to the "Sintema di Marsala" (CATALANO *et alii.*, 2010) and are attributed to the Late and Middle Pleistocene, in agreement with the age of the coral overgrowth on the sampled speleothems.

The land bridge between Europe and Sicily over the past 40 kyrs: timing of emersion and implications for the migration of *Homo sapiens*

FABRIZIO ANTONIOLI (°), VALERIA LO PRESTI (°°), MAURIZIO GASPARO MORTICELLI (°°), MARCELLO A. MANNINO (°°°), KURT LAMBECK (*), LUIGI FERRANTI (**), LAURA BONFIGLIO (***), GABRIELLA MANGANO (***), GIAN MARIA SANNINO (°), STEFANO FURLANI (+), ATTILIO SULLI (°°), MARIA RITA PALOMBO (++), SIMONE PIETRO CANESE (X)

ABSTRACT

Il Ponte continentale tra Europa e Sicilia: ipotesi di emersione e durata nel corso degli ultimi 40 Ka e implicazioni sulla presenza di *Homo Sapiens* in Sicilia.

The submerged Sill in the Messina Strait, which is located at a depth of -81 m m.s.l., represents the only possibile connection between Calabria and Sicily during the last lowstand, when the sea level was at about -126 m m.s.l.. This multidisciplinary research aim at documenting times and modes the bridge between Calabria and Sicily was emerged, during the last 40 ka BP. The analysis carried out on morphobathymetric, lithological and relative sea level change (both isostatic and tectonic) data allow to hypothesize the continental bridge emerged at least between 21.5 ka and 20 ka cal BP. Moreover, considering erosion processes due to very strong marine currents, it could be emerged for a longer time span. This hypothesis is supported by anthropological and mammalofauna data, together with ^{14}C dating on *Equus hydruntinus* from San Teodoro Cave.

Key words: *Strait of Messina strait, continental bridge, relative sea level change.*

INTRODUCTION

The relative sea level change within the Messina strait and the migration of its shorelines is of interest for understanding of the possible *Homo sapiens* or other mammals (not able to swim) dispersal out of Italy.

The current lowest bathymetric altitude of the sill between Calabria and Sicily is about -108 m and an accurate examination of the glacio-hydro-isostatic and tectonic movements that affected this coastal area are crucial for an estimation of if, when and how long the continental bridge between Europe and Sicily was emerged during the last 40 ka. The aims of this paper are therefore to:

- Make an accurate review of published geology, tectonic and marine geophysical data (most of which came from SELLI *et alii*,1981).
- Examine the field evidence of relative sea level rise around the Strait of Messina during last Interglacial, LGM and Holocene.
- Compare the field evidence with predictions from geophysical model over this time range.
- Calculate the tectonic contribution taking in account the glacio-hydro-isostatic component.
- Propose a palaeogeographic reconstruction for the last 40 ka, using a detailed bathymetric data for the sill area.
- Calculate the possible erosion of the sill bedrock using a new model that estimates the palaeotide in the Messina Strait, during LGM.
- Perform a review all available data on the presence of *Homo sapiens* in Italy and Sicily.
- Perform a reconstruction of whether and when the "Sill" connected Europe and Sicily allowing the crossing by *Homo sapiens* and other mammals.

RESULTS

Our research confirms that the area of the "Sill" in the Messina strait is made up of gravel lithologies related to the "Ghiaie di Messina formation" (SELLI et alii 1981; CHIOCCI et alii 2008) .

Multibeam surveys (high-resolution swath bathymetry acquired by the IAMC-CNR Research Institute, Naples, Italy; Tonielli R., Chief, During 2001-2002), cores, seismic profiles, ROV images, geological (CHIOCCI *et alii*,2008, LENTINI *et alii*,2000) and geomorphological considerations allow us to assume that the considerable morphological differences of the

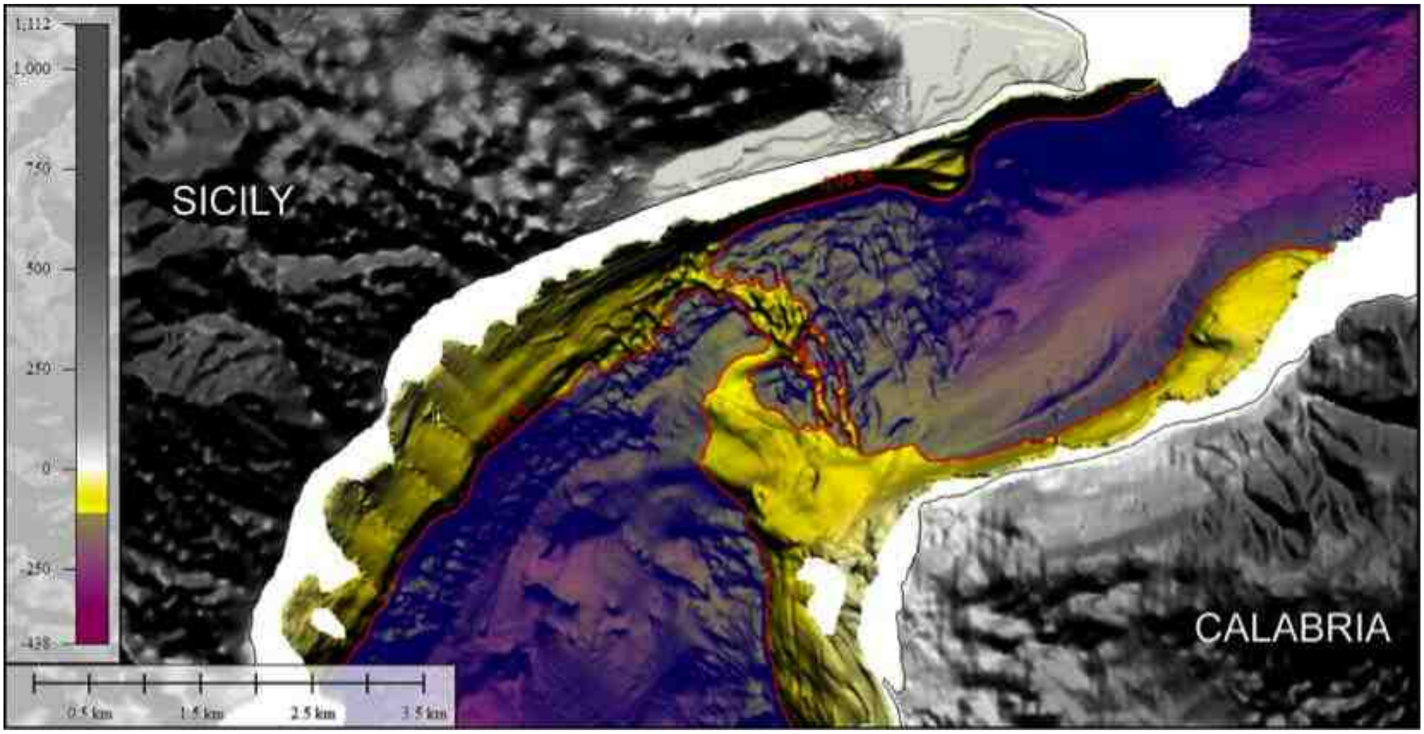

Fig. 1 – A multibeam image of the Sill showing the connection during LGM at -108 metres.

Sill, made up of "pillars" (10-15 meters width, 15 meters high) on the Messina side, contrasting with flat morphology in Calabria area, could be due to the effects of currents and the "vertical waves" described by CASAGRANDE *et alii*,(2009).

We carried out two numerical model simulations in order to compare the present day tidal currents with those occurred during the lowstand of MIS 2: the model predicts that the marine tides in the past exceeded 7 m/s. On the basis of tectonic considerations (FERRANTI *et alii*, 2010) we assume an uplift rate of about 0.9 mm/yr over the last 40 ka. Based on these data, we hypothesize that an emerged land bridge was present between Sicily and Calabria during a minimum time span from 21.5 to 20 ka cal BP, allowing for the first time the dispersal towards Sicily of some, no-good swimmer continental species.

Research carried out at San Teodoro Cave (North Sicily, BONFIGLIO *et alii*, 2008, MANGANO *et alii*, 2011) together with some considerations concerning the dating and the presence of *Homo sapiens* in Italy and Sicily (MANNINO *et alii*, 2007, 2011) and new ^{14}C dating of *Equus hydruntinus* from San Teodoro cave a slender horse first recorded in the Italian peninsula, including Mercure basin since the late Middle Pleistocene, (PALOMBO 2009), support our hypothesis. Taking into account also the erosion brought about by strong marine tides, the time window of the Sill emersion should be expanded a few thousand years during LGM.

Evidence of relative sea level change and vertical motion of the land along the coast of Calabria inferred from maritime archaeological indicators

MARCO ANZIDEI (1,4), FABRIZIO ANTONIOLI (2), ALESSANDRA BENINI (3), ANNA GERVASI (1,4), IGNAZIO GUERRA (4), PAOLO BALDI (5), MASSIMO FABRIS (6)

ABSTRACT

Calabria is one of the most complex regions of the Mediterranean basin, which experienced large earthquakes and uplift and is still undergoing to active tectonics. Along its coasts, are located several archaeological sites of roman and pre-roman age, that can be used as powerful indicators of the relative vertical movements between land and sea since their construction. In this paper we show and discuss data on the relative sea-level change as estimated from maritime archaeological indicators of the last ~2.3 ka BP existing along the Tyrrhenian and Ionian coasts of Calabria.

The palaeo sea level has been obtained measuring the functional elevation of the significant archaeological markers. The latter is defined from the elevation of specific architectural parts of an archaeological structure with respect to the local mean sea level at that location and at the time of its construction, and provides the basis for determining sea-level change. It depends on the type of structure, its use and the local tide amplitudes. The minimum elevation of particular structures above the local highest tides can also be defined. The elevation of the investigated sites was then compared against the latest predicted sea level curve for the Holocene valid for this region. Since the Tyrrhenian coast is affected by significant and continuous vertical tectonic uplift during Pleistocene, our data show the counterbalance between coastal uplift and relative sea level change caused by the glacio-hydro-isostasy, acting since the construction of the maritime settlement. The sum of these movements determined an about null relative sea level change at Briatico. These data are in contrast with other part of the tectonically stable areas of the Mediterranean and provide the evidence that crustal uplift continued in the last 1806±50 yr at a rate of 0.65 mm/yr. Conversely, the Ionian coast of Calabria between Punta Alice and Crotone, shows archaeological indicators submerged up to -6 m. The high value of the relative sea level change in the eastern coasts of Calabria, can be addressed to the vertical regional tectonics and local effects, besides the signal caused by glacio-hydro-isostasy. These combined effects are causing a fast retreat of the coast as evidenced by the paleoenvironmental records and aerial photogrammetric data, the latter available for the last 60 years.

Field surveying of intertidal limestone erosion susceptibility in the Gulf of Trieste: the "GeoSwim Project"

STEFANO FURLANI (*) & FRANCO CUCCHI (*)

Key words: *coastal karst, coastal geomorphology, tidal notch, Istria.*

INTRODUCTION

Limestones exposed on coasts are often eroded into a shape of a notch if the rock is near vertical while, pinnacles and potholes can be recognized if the rock surface is near horizontal (TRUDGILL, 1985). Since these features are most well developed in the mid-intertidal zone, it may be deduced that whatever processes are responsible for these forms are focused in this zone.

Since the Eastern Adriatic coast is widely interested by the outcropping of coastal limestones, we show preliminary results of a coastal field surveying directed to evaluate the susceptibility to "erosion" in the intertidal zone, through the surveying of structural and morphological parameters along the NE Adriatic coast, in the sector between Sistiana and Duino, in the Gulf of Trieste.

We have collected 7 morphological/structural parameters in correspondence of 2 m vertical transects in several sites, roughly following some of the parameters suggested in TRUDGILL (1988). In particular, intertidal slope, limestone bedding, RQD, exposure, structural orientation, structural profile, bottom depth. Moreover we observed the micromorphology, the surface texture, the occurrence of loose materials and the percentage of biological covering, which represent the results of the marine action. The collection of intertidal data (topographical and morphological) was carried out by an individual snorkeler surveyor or by a couple of them.

We analyzed the aforementioned parameters in order to highlight the susceptibility of the intertidal zone to coastal erosion in the Northern part of the Gulf of Trieste.

(*) Dipartimento di Matematica e Geoscienze, Università degli Studi di Trieste

Lavoro eseguito nell'ambito del progetto GeoSwim.

STUDY AREA

From a geological point of view, the study area lies on a carbonate platform belonging to the provisional and informal "Trieste Karst Limestones Formation", spanning from lower Aptian to Ypresian (CUCCHI et al., 1987; TIRELLI *et alii*, 2008). The top of the carbonate sequence is composed by limestone marls couplets. It is followed by a turbiditic succession (Flysch of Trieste) dated as Lutetian (BENSI et al., 2007; Tirelli *et alii*, 2008), which is exposed in underwater position at the base of the coastal slope, in the inner Gulf of Trieste and is involved in minor NW-SE thrusts (TIRELLI *et alii*, 2008; FURLANI *et alii*, 2011a).

From a geomorphological point of view, the area is interested by near vertical limestone plunging cliffs, which descend to the sea bottom, ranging from -1 to -7 m m.s.l.. A submerged tidal notch has been surveyed by ANTONIOLI *et alii* (2007), while FURLANI *et alii* (2011b) reported the relative lacking of well-developed intertidal morphologies due to the tectonic setting of the area.

Fig. 1 – The roof of the submerged tidal notch in the Gulf of Trieste is at an depth corresponding to the mean spring low tide.

MATERIALS AND METHODS

Ten intertidal transects, 250 m from each other, have been measured and analyzed in the Gulf of Trieste, from Sistiana to

Fig. 2 – Intertidal coastal limestones along the Gulf of Trieste.

Duino. The surveying has been carried out by a team of swimming geomorphologists, using simple portable topographical instruments (invar rod, underwater compass, ultrasonic depth meter, etc).

In correspondence of each transect, 10 parameters have been visually estimated and then measured. The surveyed parameters are the following: intertidal slope, limestone bedding, RQD, exposure, structural orientation, structural profile, bottom depth and biological zonation (following Trudgill, 1979) are the preparing parameters, while micromorphology, surface texture and biological covering are the morphological results occurring along the coast.

RESULTS AND DISCUSSION

The studied coast ranges from very inclined to vertical and the slope roughly corresponds to limestone bedding. RQD range from 25-50 to 75-90. Following the ACFOR classification, the biological covering ranges between 11 to >30 according to biological zones and sites.

The analysis of the parameters suggested that in the studied area the susceptibility to coastal erosion is homogeneous, with some peaks in the Eastern sector, due to the lower depth of sea bottom and to local variation in exposure. The homogeneity is largely influenced by the lithological setting of the study area, which is characterized by mechanically homogeneous hard limestones.

When the Sicily Channel was an archipelago

EMANUELE LODOLO(*)

Key words: *Adventure Plateau, paleogeographic markers, seismic profiles, transgression, sea-level changes, geo-archeology*.

Past sea-level positions have been generally reconstructed in locations where they form recognizable morphologies above the modern coast. Quaternary, fossil shorelines reflect the diversity of the present-day coast, because the shorelines are generally preserved after a change in sea-level.

Three main types of paleo-shorelines are recognized: erosional (e.g. marine terrace, notch), depositional (e.g. beach-ridge) and constructional (e.g. coral reef terrace). In addition to geomorphological signatures, archeological remains (artefacts that are now submerged, like towns, production structures, landing places, ports, etc.) provide very useful details to support the reconstruction of the ancient coastlines (Antonioli and Leoni, 2008; Auriemma and Solinas, 2009, among others). These paleogeographic reconstructions however, are more difficult and often imprecise in tectonically active areas, where the vertical movements can not be overlooked.

Although the geometric description of fossil shores and their associated deposits provides critical information for interpreting sea-level histories, dating is also required. A variety of techniques have been used, depending on the time of origin and nature of the relict shoreline, and both relative and absolute dating are applied. These data and techniques have been used to propose a number of Quaternary paleogeographic maps for the Italian coasts (e.g. Lambeck et al., 2004a and 2011; Antonioli et al., 2009 and 2011), and for several sites in the Mediterranean region (e.g. Lambeck et al., 2004b; Lambeck and Purcell, 2005; Anzidei et al., 2011a and 2011b; Furlani et al., 2012).

For shallow sea areas far from the coast, the reconstructions of ancient sea-level are much more difficult, because the geomorphological markers are often covered by a more or less thick sedimentary layer, and available geophysical data are scarce. The large amount of seismic profiles (Fig. 1) now made available (ViDEPI website), enables the identification of areas of shallow water affected by the phenomena of marine transgression. These eustatic changes have left a mark on the profiles with well-defined and easily identifiable reflections. Through identification of transgressive reflections on seismic profiles (Fig. 2) it was possible to map the areas that were once raised. It has been done in the Adventure Plateau, which represents the north-westernmost carbonate platform of the Sicily Channel.

(*) Ist. Naz. di Oceanografia e di Geofisica Sperimentale (OGS) - Trieste

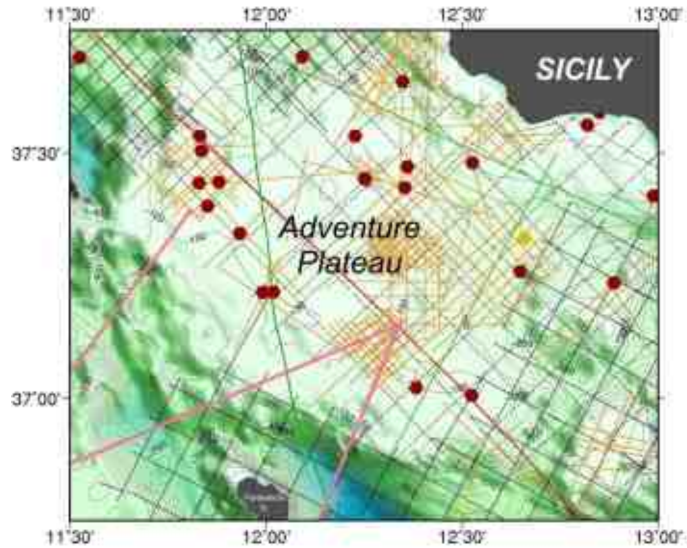

Fig. 1 – Bathymetric map of the Adventure Plateau, with superposed all the available seismic profiles to date. Coloured dots indicate oil wells and gravity piston cores.

What has emerged is a series of islands, whose dimensions are comparable to the size of Malta, possibly separated by very shallow channels and/or lagoons (Lodolo, 2010 and 2011). But until that time these areas have emerged? To answer this question, we need to make two points: (1) determine the resolving power of available seismic lines, and (2) determine the rates of accumulation of sediments.

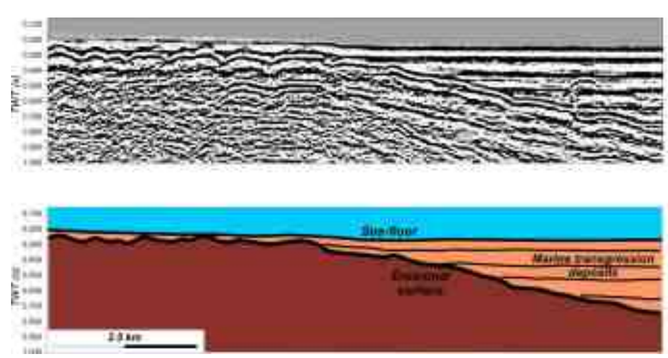

Fig. 2 – Seismic example of marine transgression in the Adventure Plateau, where a high-amplitude and continuous reflection (the erosional surface), and a sequence of transgressive deposits, are well recognizable.

Seismic resolution is the ability to distinguish two neighboring reflections. The resolution depends on the wavelength of the sound which propagates through the medium, and is generally ¼ of the value of this wavelength. The speed of the acoustic waves in relatively young and weakly consolidated sediments is about 1600 m/s, and in medium resolution seismic surveys (the most common data), the wavelength is about 40 m. We are not therefore able to identify in a seismic section of this type a sediment package if its thickness is less than 10 m. In other words, if above an erosional surface we do not see other reflections, does not necessarily mean the absence of sedimentary cover on top of it, but simply that its thickness is below the threshold of 10 m.

In the Sicily Channel, sedimentation rates are quite different among the shallow banks, the bathyal platforms, and the deeper troughs. Data from ODP Site 963, and some gravity cores, both located in the central-eastern part of the Adventure Plateau, show that the sedimentation rates range from 0.3 to 0.52 mm/yr, respectively, if we consider exclusively the uppermost part of the recovered sections. Knowing the thickness inferred from seismic profiles, one can determine the time the surface above sea-level began to sink, because gradually flooded by marine transgression. Moreover, it should be noted that depositional features generally are inadequate to estimate accurately the heights of former sea-levels, because of uncertainties on sediment compaction, precise position of the deposits above or below sea-level, and tidal changes.

Starting from the average sedimentation rates provided by the available cores, we can roughly estimate that the areas mapped as islands in the region of the Adventure Plateau, now lying at depths ranging from 50 to 70-80 m, have been raised at least up to about 11000-12000 years ago. This coincides approximately with the value of rising mean sea-level calculated from the Last Glacial Maximum, and imply a negligible vertical subsidence due to tectonics in this sector of the Sicily Channel.

The presence of large emerged areas in the Sicily Channel until the Upper Paleolithic has important geo-archeological implications. The region represented a bridge between Africa and Europe, and was a privileged way of communication and commerce for the people living on its shores. It is easily conceivable that these areas were occupied by human settlements. Perhaps their remains are now buried under the sea beneath a relatively thin blanket of sediment.

Underwater surveys in the reconstruction of Upper Pleistocene – Holocene sea level changes in the Taranto seas

MASTRONUZZI G. (°), ARTUSA C. (*), FONTOLAN G. (#), LONGO D. (*),
MILELLA M. (**), PIGNATELLI C. (^), PISCITELLI A. (**)

Key words: *underwater surveys, sea level changes, Upper Pleistocene, Holocene, Taranto.*

INTRODUCTION

The coastal region where is the city of Taranto is characterized by the presence of two articulated landforms shaped on the Mesozoic carbonate basement, deeply tectonized, covered in transgression by Cenozoic calcarenite and clay deposits of the Bradanic cycle: ì - a flight of sub-horizontal surfaces sloping seaward (BELLUOMINI et alii, 2002; ZANDER et alii, 2006; SAUER et alii, 2009); ìì - an articulated bay (MASTRONUZZI & MARZO, 1999). The first corresponds to the series of marine terraces whose shaping is due to the interaction of regional uplift and variations in sea level during the Middle and Upper Pleistocene (i.e.: BELLUOMINI et alii, 2002). The second is part of the drainage network articulated in rectangular pattern that is engraved on the previous surfaces and filled by the sea (MASTRONUZZI & SANSÒ, 1998).

The lower surface, ranging between 5 and 25 m above present sea level, is modeled on silty-calcarenitic sediments with Persististrombus latus (= Strombus bubonius) and Cladocora caespitosa and tropical fauna which suggest an age of about 125ka corresponding to MIS 5.5 (BELLUOMINI et alii, 2002; PEIRANO et alii, 2004; 2009). This interval time is currently called Tyrrhenian; it should assume the name of Tarentiano because of the particular geological representativeness of the entire area (ANTONIOLI et alii, 2008).

The sea surface was about 7 m higher than the present one (FERRANTI et alii, 2006). In particular, deposits in facies of beach and dune have been recognized at the highest altitudes; it suggests that the position of the related shoreline should have been in correspondence of the present 20-22 m a.p.s.l.; it means that an uplift of about 0.12 mm/a is request (Ferranti et alii, 2006).

The bay is formed by two inlets, named Mar Grande and Mar Piccolo - this in turn divided into two areas -, separated by a narrow peninsula where there is the Ionic capital. It corresponds to a rias, part of the drainage network fed by groundwater from the Murge carbonatic plateau; it was engraved during the Last Glacial Maximum (Mastronuzzi and Sansò, 1998; 2002; Mastronuzzi, 2006; Pignatelli et al., 2009) and filled by the sea during the Holocene transgression (Antonioli et al, 2009). Today, in the bays the water depths are different: in the Mar Grande, in direct contact with the Gulf of Taranto and the Ionian sea, it reaches 40 m; in the Mar Piccolo, closed and bounded, it does not exceed 15 m in the inlet in communication with the Mar Grande, and 9 m of the inner one.

NEW DATA

In the years 2005-2008, surveys were conducted by means of multibeam, side scan sonar and sub botton profiler, in the context of the following projects: ì – Archeomar, Ministero dei Beni Culturali; ìì – Sviluppo Italia Aree Produttive SpA Roma. A large number of vibrocorer have been also affected.

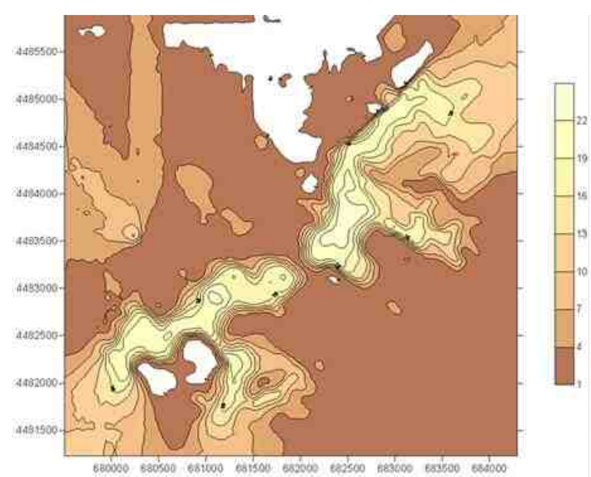

Fig. 1 – Map of the thickness of the sediments.

(°) Dip. di Scienze della Terra e Geoambientali, Università degli Studi "Aldo Moro", Bari Italy.

(**) Environmental Surveys s.r.l., Taranto, Italy.

A particular thank to the Ministero dei Beni Culturali and to Sviluppo Italia Aree Produttive SpA Roma that financially supported the geophysical surveys .

By means of the multibeam surveys, the bathymetric reconstruction permitted to reconstruct the 3D model of the two basins. Based on the interpretation of the data sub botton profiler, in correlation with data from the vibro coring, a map of the present thickness of the sediments has been produced. The application of these technologies confirmed what was already obtained from the study and reconstruction of the submerged landscape by means of the digital analysis of historical maps. In particular, it has been traced the detailed limit and the trend of the current shore platform, extending from the shore line until the isobath 9 m. from this depth In the Mar Grande, is etched the submerged deep valley, rest of the distal part of the LGM drainage network.

Fig. 2 – Core 678 from the Mar Piccolo.

CONCLUSION

The integrated analysis of the geophysical, stratigraphic and geomorphological data highlights the Holocene transgression that leads to the deposition of a considerable thickness of sandy-clay sediments, up to about 10 m thick, representing the body of marine terrace current in accumulation. They cover a sub-horizontal transgression surface shaped on the Plio-Pleistocene clays.

The comparative analysis of sedimentary bodies and present depths confirm the current evolutionary model of the Tyrrhenian; in this time, between the sea surface and the bottom of that sea a depth equal to the difference between the shoreline and the recognized top of the sediment.

The boulder berm of Punta Saguerra (Taranto, Italy): a morphological imprint of the Rossano Calabro tsunami of April 24, 1836

MASTRONUZZI G. (°) & PIGNATELLI C. (^)

Key words: *boulder berm, rocky coast, sea storms, tsunami, Apulia.*

INTRODUCTION

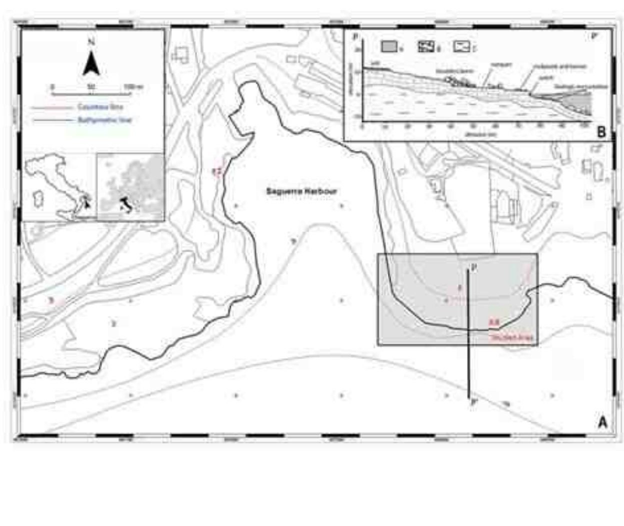
Many Authors have described the presence of mega-boulders along coasts around the world as one of the main evidence of the impact of catastrophic waves of either geological (tsunami) or meteorological (hurricanes, storms) origin (i.e.: MASTRONUZZI & SANSÒ, 2000; NOORMETS Et Alii, 2004; SCHEFFERS & SCHEFFERS, 2007; WILLIAM & HALL, 2004; KELLETAT ET ALII, 2005; HALL et alii, 2006; GOTO et alii, 2010). At present, the diatribe about the individuation of the type of mechanism responsible for their placement is still open: the presence of mega-boulders along the coasts is always evidence of a tsunami impact is a matter of debate (i.e.: MASTRONUZZI et alii, 2006; SWITZER & BURSTON, 2010). Nevertheless, the local morpho-bathymetry, litho-structural features and the local wave climate, all together condition the effect of a wave impact, whatever its generating mechanism may be. A recent survey highlights that, locally, a tsunami can also be characterized by a wave some ten meters high, but this is not the normality (LAVIGNE et alii, 2006); more frequent is the possibility that an impacting wave can run inland, rising along the coastal slope and defining a run-up of some ten meters. On the other hand, a tsunami is characterized by an impressive energy connected not only to the wave height but also to the wave period and its length; the possibility to release energy corresponds to its capability to pickup in charge while transporting a large quantity of heterometric material as the March 11, 2011 Japanese tsunami shown to all the world.

In the Mediterranean basin, the cause of the displacement of the boulders is generally ascribed to a tsunami impact (i.e. MASTRONUZZI & SANSÒ, 2000; MORHANGE et alii, 2006; VÖTT et alii, 2006; SCICCHITANO et alii, 2007; MOAUCHE et alii., 2009), although, in some cases boulder dislocation is directly recognised to be caused by the recent impact of storms generated by strong winds (MASTRONUZZI & SANSÒ, 2004; BARBANO et alii, 2010).

Based on the available data, it has been possible to improve a hydrodynamic equation that permitted the Authors to evaluate the maximum flooding possible, starting with the size of the deposited boulders as a consequence of a tsunami impact (PIGNATELLI et alii, 2009). Together, local census data, surveys and knowledge of the areas in which boulders were accumulated by a tsunami, are extremely important in the definition of a tsunami coastal hazard and in the redaction of the map of coastal risk.

NEW DATA

A new extended boulders accumulation has been identified along the rocky coast of Punta Saguerra (= Cape Saguerra), located not far from the city of Taranto, along the Ionian coast of the Apulian region (Southern Italy), whereas isolated boulders have been recognised in other near localities (Fig. 1). In the following pages the detailed survey of the features of the main accumulation and its chronological attribution are presented and discussed in order to identify its generative event. An extended berm of calcarenitic boulders is recognisable at Punta Saguerra, a few kilometres south of Taranto (Apulia, Italy) while isolated boulders are sparse in other near localities.



(°) Dip. di Scienze della Terra e Geoambientali, Università degli Studi “Aldo Moro”, Bari Italy
(^) Geo Data Service s.r.l., Taranto, Italy

This research has been financially supported by the Project S1 2007/09 “*Analysis of the seismic potential in Italy for the evaluation of the seismic hazard*” dell’Istituto Nazionale di Geofisica e Vulcanologia – Dipartimento Protezione Civile (Responsabili del Progetto: Salvatore Barba, Carlo Doglioni; Resp UOL Bari Prof. G. Mastronuzzi) and by Research Project Bari University 2009 “*Modellizzazione e valutazione del rischio costiero da eventi parossistici*” (Resp. Prof. G. Mastronuzzi).

Fig. 1 – Ubication of studied area.

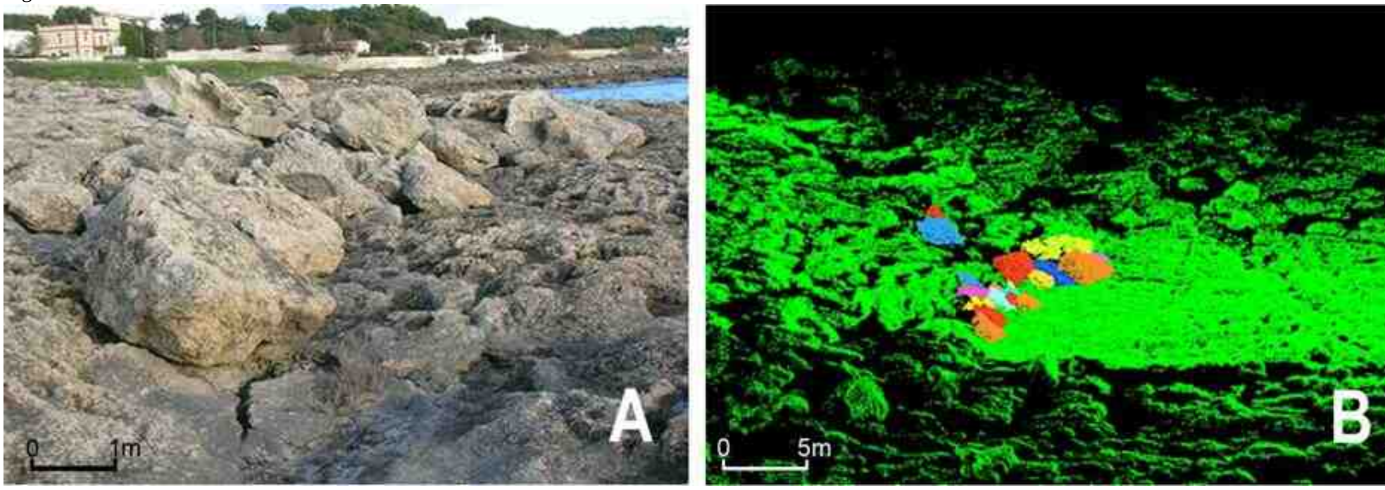


Fig. 2 – The berm of Punta Saguerra (A) and its laser scanner survey (B)

The berm is at 2-5 m above present sea level (a.p.s.l), on a rocky headland gently sloping toward the sea; it is separated from the coastline by a large terrace.

A detailed study of its stratigraphy and its morphology has been performed in order to define its depositional mechanism; in particular, integrated DGPS and Laser Scanner surveys have provided precise details of each boulder (Fig. 2): position, size and distance from the shoreline. The accumulation is constitute of boulders up to 30 tons, which locally are arranged in rows of embricated patterns. The surfaces of the biggest boulders are characterised by biogenic encrustations and by solution potholes that indicate their intertidal/adlittoral/spray zone provenience (Fig. 3). Based on direct observations of each boulder (size, shape, weight and long axis azimuth), together with hydrodynamic equations it is possible to hypothesize the extreme event – geodynamic or meteorological – which was responsible for this singular accumulation.

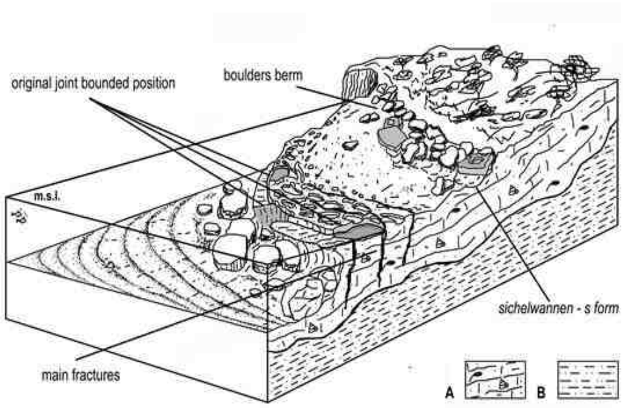

Fig. 3 – Block diagram of the Punta Saguerra berm.

CONCLUSION

Together AMS age determinations on *Vermetid* spp. sampled from boulder surfaces (Tab.1) and chronicle data suggest that the accumulation may be attributed to the tsunami generated by the strong earthquake that occurred on April 24, 1836, the epicentre of which has been localised near Rossano Calabro, along the Ionian coast of northern Calabria.

ID Sample	Type	14C Age	Error	ΔR	Calibrated Age (AD)	1σ	2σ
Baia d'Argento LTL1178A	*Vermetids*	413	± 40	121±60	1889 -1947	0,11	
				121±60	1813 -1955		1
Baia d'Argento LTL1179A	*Vermetids*	489	± 60	121±60	1853 -1952	1	
				121±60	1801 -1953		0,06
				121±60	1702 -1951		0,90
Baia d'Argento LTL2209A	*Vermetids*	426	± 35	121±60	1888 - 1954	1	
				121±60	1811 – 1954		1

Tab. 1 - AMS radiocarbon age determination of some samples collected at Punta Saguerra. The calibrated ages were obtained by using Calib 6.0 software (Stuiver & Reimer, 2010)

This conclusion seem to be invocated also by the only available chronicles related to the Taranto coast, written by Baffi (1929), almost a century later: "…*dopo una primavera molto piovosa ed un'orribile tempesta accaduta il 17 aprile 1836 nel golfo tarentino seguirono pochi giorni sereni fino al 24 Aprile 1836 … Verso mezzanotte dell'istesso giorno gli* *animali mostrarono soverchia inquietudine, il mare divenne grosso e tempestoso e sopra di esso fa' vista una meteora di color fuoco, in quel punto accompagnato da cupo rumore un terremoto durò 20 secondi e dopo 3 minuti replicò violentemente…*"

Palaeoenvironmental reconstruction of the Last Glacial Maximum coastline on the San Pietro continental shelf (Sardinia SW)

PAOLO EMANUELE ORRÙ (*) GIACOMO DEIANA (*), MARCO TAVIANI (°), SAMUELE TODDE (*)

Key words: *Sea level, LGM, continental shelf geomorphology.*

INTRODUCTION

First informations about the presence of submerged Holocene paleogeographies in the south-western Sardinian continental shelf is due to the Project PLACERS during N/O Bannock campaigns in 1980s (CARBONI ET ALII 1979; ORRÙ & ULZEGA 1989).

Recently, within the Project MAGIC, during the cruises "SARDEGNA 2009" and "SARDEGNA 2010" – Nave Universitatis (CoNISMa), geomorphological evidences of LGM sea levels, have been found off San Pietro Island (south-western Sardinia) at a depth between 130 and 110 meters BSL.

In particular three different geomorphological contexts have been noticed:

1. Paleo-cliffs up to 50 meters high, carved in the volcanic substratum and tied up to tectonic lineations oriented NNW-SSW and NE-SW, have been recognized 10 miles off Capo Sandalo. On the rock cliffsides it is possible to make out rotational landslides and on the basement some big falls and toppling blocks.
2. 12nm off Punta Geniò, by a fault moving ENE-SSW which interrupts the continuity of the paleo-cliffs line, a paleo-ria until ending in a inner bay paleo-lagoon. In this place a dredging has taken some samples of dark-grey sandy silts containing a littoral and marine thanatocoenosis.
3. 5 miles off Cala Fico, a fossil paleo-valley, almost totally filled by sediments dating back to the last sea level rise.

Methods used: side scan sonar surveys EG&G 272 T (100-500 kHz), RESON 8160 multibeam ecographic soundings/ multibeam sonar survey, HD seismic surveys through Subbottom CHIRP (500 Hz/13,5 kHz) e Sparker APPLIED ACOUSTIC CSP20200 (10/500 J); circular and rectangular heavy dredge have been used for the samples.

Detailed Multibeam surveys and Remote Operating Vehicle inspections have been put in place on the top and on the sides of the paleo-cliffs, where *Pseudolithophyllum expansum* is highly caked (deep Coralligenous – Cp) and colonies dark caves (GSO) and deep rocks biocenosis (RL) can be observed; in RL are abundant *Corallium rubrum* colonies.

GEOLOGICAL SETTING

Sardinian western continental margin is characterized by the setting of high-angle fault system (Oligo-Miocene), whereas a wide rifting system have been produced in intra-backarc Apennine-Maghrebian belt (CERCHI & MONTADERT, 1982.) Morpho-structurally, the Sulcis Escarpment is made up of a straight fault system, which borders the Sulcis margin on south-western side and gives rise to escarpment and intra-platform basins .(CARBONI Et alii, 1979).

The ignimbrite sequences, which are widely spread in the rift ASL, represents the basement. The Miocene sequence can be made out in pre-evaporitic Tortonian marls (basis for inclined reflectors, Burdigalian (LECCA, 2000), sometimes carved by the erosion surface, tied up to the Messinian eustatic fall (CHERCHI & MONTADERT, 1982).

From morpho- structural poin of view the continental shelf can be considered as split into two parts, a proximal sector, where we can find some ignimbrites outcrops of ignimbrites, is characterized by wide mega-cuestas and by volcanic morphotypes: calderas, craters, necks and dykes.

The distal section, sub flat, is regularized by the Miocene sedimentary series to the base and by the sequence prograding Plio-Pleistocene consists of several inclinated sistems tracts (LECCA, 2000).

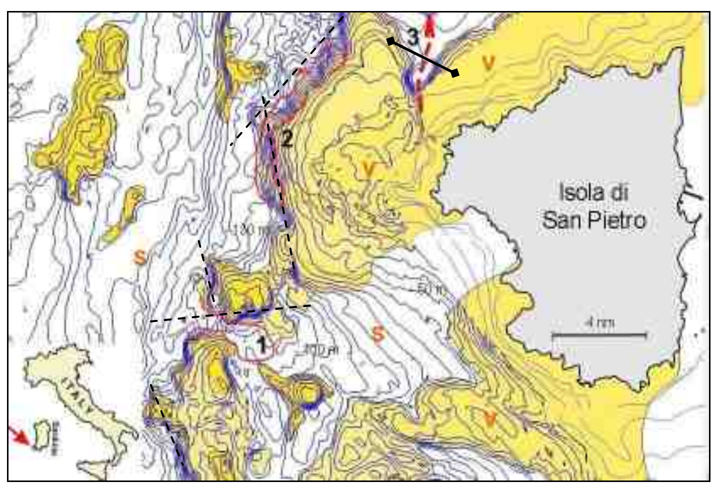

Fig. 1 – Location area of studied area. V) Tertiary acid vulcanites, Ignimbrites; S) Plio-Quaternary sediments. 1) palaeo-logoon where it has been dredged the LGM thanatocoenos; 2) paleo-cliffs and rotational landslides, 3) Fossil palaeo-valley - Trace of seismic profile

DISCUSSION AND NEW DATA

Paleo-cliffs and rotational slides (Fig.2)

The paleo-cliff lines shows several gravitative morphologies, caused by backwards erosional processes; the lithological feature of these cliffs implies a long-term evolution and polycyclic elaboration, which had likely started in late Middle Miocene and continued during the Plio-Pleistocenic transgressive phases. However, the erosional and gravitative morphologies, we can now observe, are mainly due to the last stage of low sea level fluctuations (MIS 2). During this stage, physical alteration processes on the rock surface, due to periglacial weather conditions, played an important role.

The tectonic lineations that control the o orientation of the cliff walls, have caused also rotational slides and here it is possible to distinguish separation walls and tilted slide deposits. Similar morphologies can be observed along the present coastline between Capo Altano and Porto Paglia, where the same volcanic lithotypes crop out.

On the bottom of the edges are extended abrasion platforms fossil, partially hidden by the drape of the Holocene sediments.

The Ignimbritic laves often lay on cineritic and volcanoclastic levels, this has favoured processes of differential erosion that, together with an full fracturing, has brought to the evolution of gravitational movements with falls and toppling-falls of bloks of very large volume (V>100 k m^3).

.

Cala Fico's palaeo-valley (Fig.3)

In the correspondence of the Cala Figo Ria, tectonically controlled, a 3 miles offshore a elongated depression morphology can be observed. Seismic surveys have shown that the broad inlet, that reaches offshore a 2 nm crosswise width, is the top of a fossil paleo-valley, carved both in volcanic rocks and a stratifies sequence of Middle Miocene.

The erosion surface reaches a depth of 200 meters BSL in the most distal seismic profile, and this fact, together with the analysis of the seismic facies, let establish a connection between the erosion surface and the Messinian phase continentality phase. (CERCHI & MONTADERT, 1982)

A wavy reflectors prograding sequence, ascribable to Plio-pleistocene sedimentation lays on this surface in unconformity.

The last continental erosional phase has carved during MIS 2 the pre-existing deposits until -123 m (LGM).

The following water flow of the paleo-valley (late Pleistocene-Olocene) can be distinguished in a units lower reflectors and tilted slightly wavy, which can be grasped as alternation of medium and big grains of littoral and deltaic sands; the semitransparent seismic facies units summit, with parallel riflections, which can be linked to silty sands and sandy silts of littoral and lagoon depositional environment. Similar paleo-valley have been found both in the Gulf of Palmas and the Gulf of Cagliari, where the Holocene series have been thoroughly sampled. (ORRÙ et alii, 2004)

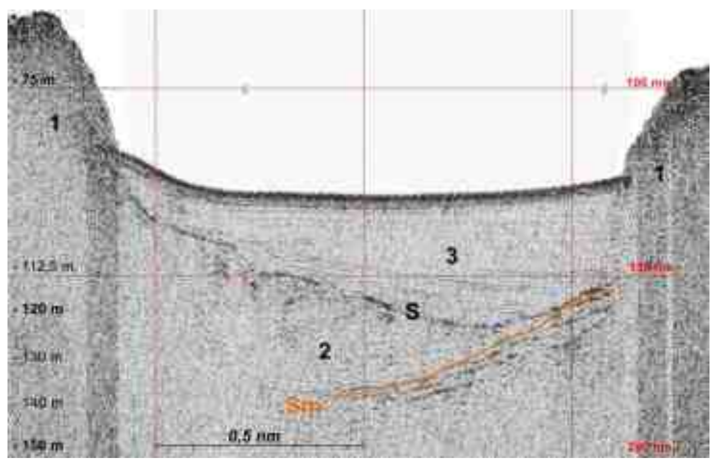

Fig. 3 - 100 J Sparker profile - Cruise MAGIC "Sardegna 2009" R/V Universitatis: 1) substrate volcanic, Ignimbrites of Cala Vinagra; Sm) Messinian subaerial erosional surface, 2) Plio-Pleistocenic sedimentary sequence, S) subaerial erosional surface of LGM (MIS 2), 3) sedimentary sequence in parallel plane reflectors. Late Pleistocene-Holocene).

The palaeo-lagoon (Fig.4)

Recorded by Multibeam surveys, the digital terrain model (DTM) of the seabed lets identify a paleo-ria, that interrupts the continuity of the rock frames which can be found at 130 m BSL; the inner bay doesn't follow the trend noticed in the present rias (e.g. Cala Fico) instead of a narrowing, it spreads in a wide amphitheatre, which goes up until reaching 120m BSL. In the lower area, filled now by fine sediments, there might have been a paleo-lagoon during the lower sea level of MIS 2, but it is

Fig. 4 – Thanatocoenosis dredged between -125/120 m : 1) Glycimeris sp ; 2) Mytilus cf galloprovincialis*; 3*) Mytilus cf edulis; 4) Cerastoderma sp; 5*)* Pitar cf rudis*;* 6) Venus cf casina*; 7)* Acmaea virginea

unclear whether this morphology is the outcome of erosion processes or whether it is part of a volcanic caldera or a submerged crater, as others nearby. The specimens of the seabed, taken here through a dredging, has brought up a black-grey sandy silt full of mollusca thanatocoenosis of littoral, lagoon and shallow wather habitat and some open shelf species, which haven't been thoroughly classified yet.

Some fossils have been analyzed through a C14 dating test in Beta Analytic, Miami USA: the results let us relate at least some thanatocoenosis species to a lagoon sea level during the LGM.

Beta-310989 – D2 - ***Mytilus galloprovincialis*** 15360±280 BP cal.
Beta - 310992 - D5.- ***Acmaea virginea*** 19100±270 BP cal.

Are currently under analysis the benthic foraminifera and the pollen content, in order to define both the littoral-marine paleo-environment of the LGM and surrounding coast area. (LÓPEZ CORREA M., et alii, 2010)

Sea level changes and geoarchaeology between Malfatano Bay and Piscinnì Bay (SW Sardinia) in the last 3 ky

ORRÙ P.E. (*), MASTRONUZZI G. (°), PIGNATELLI C. (°°), PISCITELLI A. (^), SOLINAS E. (**)

Key words: *Sea level, LGM, continental shelf geomorphology*.

INTRODUCTION

The Malfatano Bay (Fig. 1) is home to one of the most important maritime structure of the Punic-Roman times in the Mediterranean; in the absence of systematic excavations, the site is currently identified with the Ptolemaic *Βιθια λιμην* (MASTINO *et alii*, 2005). His two opposing monumental s have been preserved between - 7 and - 2 meters due to rising sea levels. recent studies led to identification of the paleo-sea level putting in relation the the eustatic component with the glacio-hydro isostatic deformations (ORRU & LOFTY 2003; ANTONIOLI et al, 2007; AURIEMMA & SOLINAS, 2009).

This paper, through stratigraphic, palaeontological and geochronological data, aims to increase the knowledge of the evolution of the Malfatano Bay in relation to the sea level rise during the last 3 ky.

Based on data derived from geophysical surveys , paleoshore lines have been redrawn and put in relation to data derived from drilling carried out in the inner part of the creek. Finally, we evaluated the relationships between changes in paleogeography and human settlements from the Bronze Age. The breakwaters have been surveyed in every their details using D-GPS techniques correlated to the geodesic 0. The litho- technic parameters of the blocs of the breakwaters were misured in order to evaluate the characteristic of the waves that demolished the structures (PIGNATELLI *et alii*, 2009 PISCITELLI *et alii*, 2009). Through this data the shape of the breakwaters has been reconsidered and, consequently, the paleo sea level has been reevaluated.

In order to assess the position of the past sea level, some topographic parameters of the quarry of Piscinnì Bay have been surveyed (total volume, mining walls, quarry, etc.).

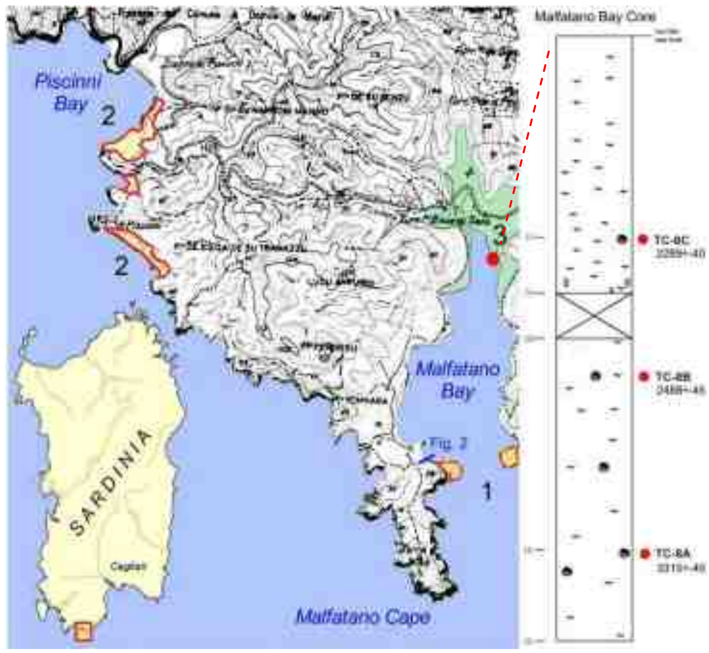

Fig. 1 – Studied area: 1) submerged breakwater; 2) punic-roman quarries; 3) coring location and and stratigraphic position of fossils analyzed

GEOLOGICAL SETTING

The coastal area stretching between Malfatano bay and Piscinnì Bay is characterised by the outcrop of the metamorphic basement (Formazione di Bithia, Lower Cambiano). The tectonic features of the southern continental margin of the Sardinia are due to rotation of the Sardinia and Corse during the Oligocene–Miocene and to the contemporary opening of the Algero-Provenzale basin. N-S elongated faults condition the evolution of the subaereous valleys and of the paleo valleys and canyons below sea level.

The Malfatano Bay corresponds to a rias firstly engraved in the continental phase occurred during the Messinian; finally, it was deeply escavated during the last glacial maximum (LGM = MIS 2). Along the western cliff of the bay some stratigraphic sequence of coastal sediments ascribed to the Last Interglacial Time (LIT = MIS 5) are preserved up to +3 m a.m.s.l.

The related inner margin is covered by continental/slope deposits ascribed to the MIS 2 (Fig. 2).

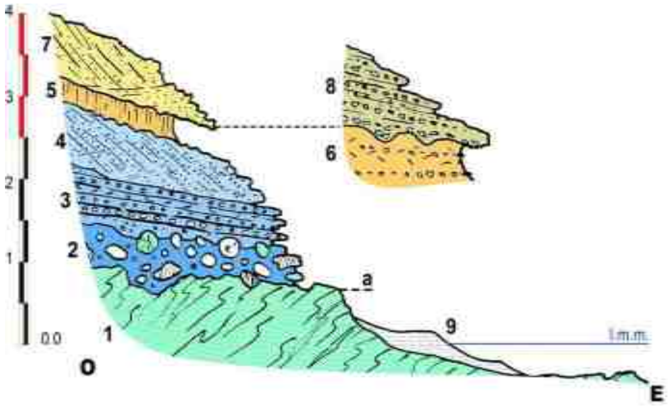

Fig. 2 – Stratigraphic section of West Malfatano: 1) metamorphic substrate; a) abrasion surface, 2) coastal polygenic conglomerate (MIS5), 3) laminated micro-conglomerate with *Spondilus gaederopus, Cardium tuberculatum, Venus verrucosa, Patella ferrugginea* (MIS5); 4) sandy beach with foresets (MIS5), 5) paleosoil (MIS5) 6) colluvium (MIS5); 7) aeolianite with cross lamination (MIS 4-2), 8) slope deposit with crioclasts (MIS2). 9) present beach

All together, these evidence seem indicate a substantial tectonic stability during the last 125 kys (FERRANTI *et alii*, 2006).

GEOARCHEOLOGY

The long and narrow inlet of Malfatano Bay represents a very important opportunity for landing. The inland area is the switch between the agricultural resources of the plain behind KRLY / Karales and the mineral resources of the *Territorium Sulcitanum*; it was densely inhabited during the Nuraghic age , as evidenced by the various prehistoric settlements built throughout the area near to the coast.

The breakwaters of Malfatano Bay are the only great specimen of maritime artifact recognized in Sardinia; They could be referred to the Phoenician settlement of Bithia (Fig. 3).

The two breakwaters occur based on the wall of the bay with cliff irregular rocks into metamorphic rock topped by irregularly shaped blocks of finishing, and their function was to disperse the energy of the wavefronts coming from SW.

They were built using the blocks of sandstone from the nearby quarry of Piscinnì Bay; these have a rectangular cross-section of cm. 50x70 approx. and next to two meters in length .

The materials found during underwater exploration indicate a long frequentation during the Roman period.

NEW DATA AND DISCUSSION

In the inner part of the creek a core up to -4 m from ground level was drilled (Fig. 1). Its top is located about 10 cm above the mean sea level, in a mudflat with *Salicornia* spp. which can be considered to be the upper limit the of the high tide. It returned a almost continuous sequence of dark gray massive silt without

Fig. 3. – Quarry of Punic - Roman age in the Piscinnì Bay; it was engraved in beach-dune sandstone.

lamination (Fig.1).

Along the carrot is a widespread presence of an oligospeciphic fauna with a prevalence of *Bittium* , *Rissoa* and *Cerithium* spp. There are frequent entire shells of *Cerastoderma* in living position. These presences could indicate an ''Euryhaline and Eurythermal in brackish water (LEE)'' environment; (PERES & PICARD, 1964). In particular the presence of this bivalve could be put in relation to a near sea level, in a water less than 2 m depth. In consideration of the general features of the inlet and of the area in which the core was made, considering also the present depth in which this mollusca lives in this inlet, we are led to think that it lived in a water column no more than 0,50 m depth.

They have been submitted to C14 age determinations in the CEDAD Laboratory of the Università del Salento (Lecce); analytical data are reported in Tab. 1.14C age have been calibrated using a DR = 71+/-50 in the Radiocarbon Calibration Program Calib Rev6.0.0 adopting Calibration data set Marine/INTCAL09. (REIMER *et alii*, 2009). Samples have been calibrated considering that the environment seems to be changed from fresh water to salt water; sample TC8A has been calibrated considering a 25% of marine carbon; sample TC8B has been treated considering a 50% of marine carbon; finally, the sample TC8C has been considered totally marine.

According to the recent evolution of the Ria of Malfatano in the early stages of the rise of Holocene sea level rise, much less when filled with sediment, and it was a river estuary with significant inputs of freshwater.

CONCLUSIONS

It was clarified the relationship between the latter stages of Holocene sea-lift and the dynamics of human settlements in the territory of Malfatano from the Nuragic age (Middle Bronze).

New detailed measurements make it possible a better

First outcomes of the coastal erosion and marine geology working group activity, Ordine Regionale dei Geologi della Calabria (O.G.R.C.)

F. PROCOPIO (*), D. CARRÀ (*), A. CEFALÌ (*), A. PISCIUNERI (*), A. A. STAMILE (*) & G. STRATI (*)

Key words: *marine geology, coastal erosion, working group, guidelines, seminar, Ibbeken.*

ABSTRACT

Calabrian Geologists Council in the four-years' program of activities (2009-2013) established the "Costal Erosion and Marine Geology Working Group" as a technical support team, dedicated to the professional upgrade and research, in order to promote collaboration among calabrian geologists and in order to encourage the professional progress of this category, serving all its members.

The working group was constituted on 16-04-2010 by publishing an announcement, continuously updated, on the website of the Calabria Geologists Professional Board (www.ordinegeologicalabria.it).

Current working group members: Dr. Domenico Carrà PhD, Dr. ANTONIO CEFALÌ, Dr. ANTONIO PISCIUNERI, Dr. ANGELO ALBERTO STAMILE, Dr. GIUSEPPINA STRATI, Dr. and Councillor FABIO PROCOPIO.

Just at the beginning of the activities, the analysis of the professional category needs, has pointed out the necessity to assemble the working group efforts to the followings targets:

Organization of technical/scientific meetings, valid for professional upgrade, in collaboration with universities and other research institutes;

updating, close examination and elaboration of working standards in accordance to the national and regional laws.

In order to the first point, the working group, has organized the seminar: "Twenty-year of the Volume Source and Sediment on Calabria Jonica Meridionale homage to HILLERT IBBEKEN " in Roccella Jonica on 20-21/04/2011 thanks to the collaboration of the Università della Calabria, Università di Parma, Comune di Roccella Jonica institutions and thanks to the patronage of the Società Geologica Italiana organization.

The seminar, has represented a Scientific award to the geologist HILLERT IBBEKEN, already professor to the Freies Universität of Berlino, who in 1991, at the end of a long research project, published the prestigious volume "Source and Sediment: a case Study of Provenance and Mass Balance at an Active Plate Margin." (Springer-Verlag Ed.). The event has also represented the occasion of comparison between the scientific world and the professional world, with communication and invitation to debate and to discuss some physical asset of the territory and the problems of hydro-geologic disarrangement which the whole Calabrian coast is subject and particularly the ionic coast. To the conference a geologic excursion has been combined along the ionic littoral, conducted by Prof. IBBEKEN, during which the geomorphological peculiarities of the places has been treated, with particular focus to the processes of coastal erosion.

In order to the second point the working group has pointed to make reference to the Autorità di Bacino della Regione Calabria guidelines "*Progettazione ed esecuzione degli interventi difesa del suolo - erosione delle coste.*" and to divide the activity of preparation of the working standards in more sections submitted to every single member. Once the standards will be completed and verified they will be published on the "*Geologi Calabria*", the "O.R.G.C. bulletin.

Palaeoenvironmental reconstruction of Holocene coastline of Procida Island, Bay of Naples

MARIA LUISA PUTIGNANO (*), PAOLO EMANUELE ORRÙ (**) & MARCELLO SCHIATTARELLA (*)

Key words: *Sea level, Phlegrean Islands, Holocene, beach rock*.

INTRODUCTION

The areas interconnecting land and sea through time are of critical scientific interest and the most valuable source of data for the reconstruction of the Holocene evolution. In territories of high instability, such as the bay of Naples, geo-archaeological research is an important starting point for paleo-environmental studies, thanks to their multidisciplinary approach to the complex investigations of such areas.

A number of paleo-environmental studies on the islands of Procida and Vivara have provided the reference framework of a complex evolution during the Holocene, which is marked by step-ups of the sea level (PUTIGNANO *et alii*, 2009; PUTIGNANO & SCHIATTARELLA, 2010). In this context, the study was focussed on two phases of specific paleo-environmental interest, well supported by a wealth of geomorphologic, geologic and archeological data. The geo-archeological data, the ones of a "long sea-level stand" at -5/-6 m and at -13/-14 m, are complexly characterized by geological markers, both depositional (beach rock) and erosional (notches, platforms of marine abrasion), as well as archaeological markers (landing bench or pier, bollards etc) which allows a more precise use of such markers in a broader geomorphological context to a better understanding of the paleo-environment.

GEOMORPHOLOGICAL AND GEOLOGICAL FRAMEWORK

The Campi Flegrei area and the adjacent islands (Procida, Viviara and Ischia) are localized along the Tyrrhenian margin between 40^0 and 41^0 N. During Quaternary, the Tyrrhenian margin of Campania was dissected by NW-SE and NE-SW trending normal faults, which defined zones of major subsidence, as witnessed by the large depression of the Piana Campana bounded to the northwest by the morphotructural high of the Monte Massiccio and by Monti Lattari to the southeast (Fig. 1).

Fig. 1 – Location map of the study area. 1) quaternary epiclastic deposits with volcanic deposit intercalations; 2) quaternary volcanic products; 3) sicilid units (Upper cretaceous – Miocene); 4) syn and post orogenic deposits (Miocene – Pliocene); 5) carbonatic units of the Appenine chain and silicoclastic deposits related (Trias lower - middle – Miocene); 7) Canyon axis.

The islands of Procida e Vivara, together with the island of Ischia, represent morphostructural highs of volcanic origin uplifted on the continental platform (Fig.1). They form a SW-NE trending alignment that separates two typologically different sectors of the continental platform: the area facing the lower part of the northern Lazio - Campania coast, which is characterized by active depositional processes, from the area to the south of the Golfo di Napoli, which is marked by the interaction between depositional and erosional processes (DE ALTERIIS & TOSCANO, 2003).

The volcanic islands of Vivara and Procida have been formed by several eruptions that established a polycrateric field. The oldest products are tuffs, dated at about 70 ka (DE ASTIS *et alii*, 2004). The Solchiaro volcano represents the last volcanic event at 19 ka (ALESSIO *et alii*, 1976). The other products, which are

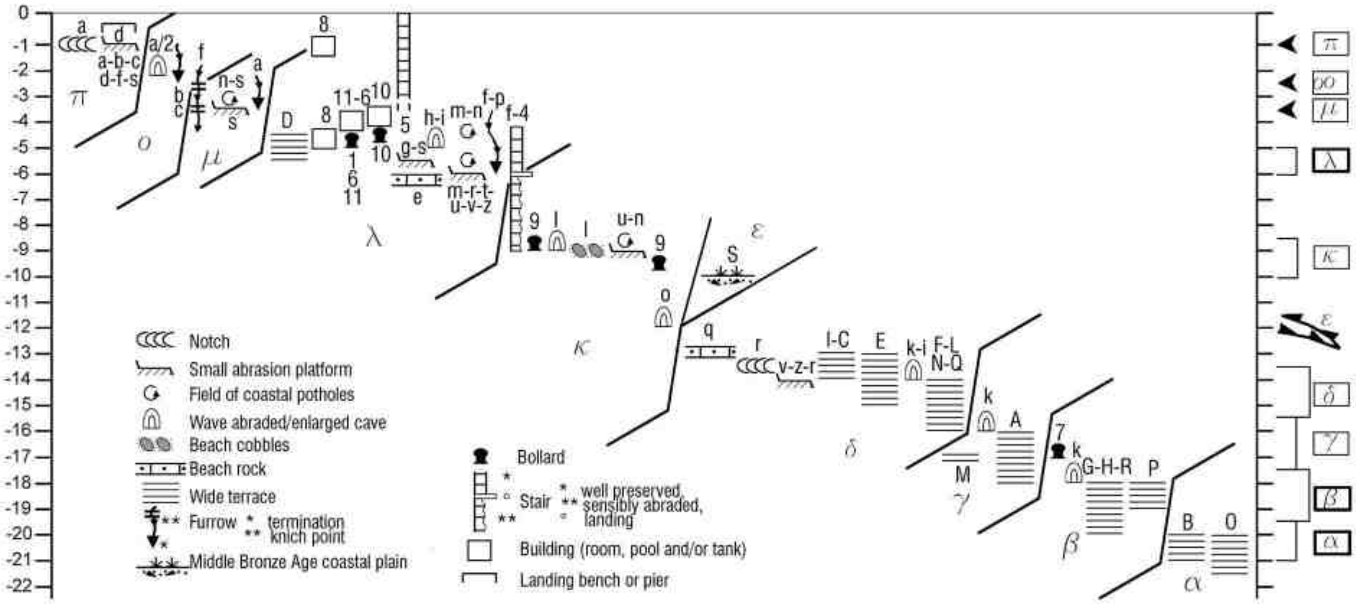

Fig. 2 – Bathymetric distribution of sea-level indicator marking -or helping to constraint- ancient positions of the sea level. Small letters and numbers close to the symbols indicate sites of occurrence (see Fig. 2 for location). Greek letters indicate the different orders of palaeo sea-levels. At the right margin of the diagram, relatively long sea-level stands are shown by thick rectangles, while short-lived ones are shown by thin rectangles (da PUTIGNANO *et alii*, 2009).

related to the eruptions of the neighbouring volcanos of the Ischia Island, the Canale di Ischia and the continental portion of the Campi Flegrei (DI GIROLAMO *et alii*, 1984), form a draping on the cooling units locally deposited.

The eruptive events triggered volcano-tectonic collapses in the area, which was also dissected by various sets of faults and fractures that are the cause of the disintegration of the original structures. The inception of such phenomena coincided with the initial build-up of the first volcanic structures (AIELLO *et alii*, 2007), resulting in the transition to the marine environment of several land sectors. The detailed surveys of such areas are reported and integrated in the regional geological maps and the related explanatory notes (FEDELE *et alii*, 2012).

GEOMORPHOLOGICAL AND ARCHAEOLOGICAL DATA

The reconstruction of the most recent morphological evolution of the submerged areas surrounding the Vivara and Procida islands (PUTIGNANO *et alii*, 2009; PUTIGNANO & SCHIATTARELLA 2010) has also allowed a detailed reconstruction of the last 4,000 years of history, starting since the well documented portions of the Bronze Age (MARAZZI, 1994). A synthetic chart of the data related to the paleo levels (PUTIGNANO *et alii*, 2009) is reported in Figure 2. In the chart, the results of the study of the geo-archeological markers of a ”long sea level stand” at -5/-6 m and -13/-14 m are described in detail. The novel data are also related to depositional geological elements, such as beach rocks discovered within these sea level stands. These deposits present stratigraphic and sedimentologic characteristics that are very distinctive from a geomorphological viewpoint: thus, they concur to provide a better correlation with all the other markers of the paleo levels of both erosional and archeological type.

Volcaniclastic Deposition and migration of basin depocentres after the eruption of the Neapolitan Yellow Tuff: the Pozzuoli Bay (Naples, Italy)

SACCHI M. (°), PEPE F. (*), CORRADINO M. (*), DUARTE H. (^)

Key words: *Pozzuoli Bay, Density flow, Depocentre migration, Resurgence, Vertical movements.*

The Campi Flegrei is an active caldera located on the coastal zone of SW Italy (Fig. 1), close to the town of Naples Bay, that has been characterized by explosive activity and unrest throughout the Late Quaternary. This area represents a very active segment of the Eastern Tyrrhenian margin and may be regarded as an ideal laboratory to understand the mechanisms of caldera dynamics and the interplay between volcanism, tectonics and sedimentary processes along a continental back-arc margin. Recent research at Campi Flegrei has shown that a significant part of the offshore volcaniclastic products and structures, the late-stage geodynamic evolution of the inner caldera resurgence and the stratal geometry of the caldera fill are still poorly known. Particularly, high-resolution seismic data highlight the presence of an intra-caldera resurgent dome in the inner sector of the Pozzuoli bay that underwent significant uplift/subsidence after the eruption of the NYT (SACCHI *et alii*, this volume).

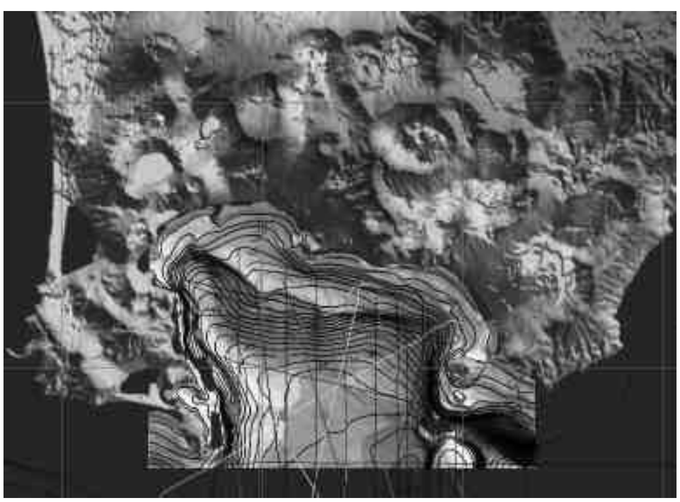

Fig. 1 – Map of the Campi Flegrei active volcanic area and location of seismic profiles and gravity core data

In this study we integrate geophysical data of different resolution/penetration obtained from high-resolution reflection seismic profiles (Chirp and Sparker sources) partly calibrated by gravity core in order to provide a 3D depositional model of density flows and migration of basin depocentres for the Pozzuoli Bay after the eruption of the NYT.

The new data document the occurrence of two distinct layers of resediments, mostly represented by density flow deposits, separated by an interval of hemipelagic sediments. The two density flow units display a remarkable difference in their thickness and internal geometry. Across the bay, the lower unit is ca 5m thick in the western sector and reaches its maximum of ca 10 m in the central sector while it is absent towards the east. The upper unit, on the contrary, displays the minimum thickness of 10m close to the central sector of the bay and increases up to ca 16 and 12m in the western and eastern sector of the bay, respectively. The variation in thickness of the density flow deposits appears to be related with the amount of sediments available. The upper density flow deposits is also internally more chaotic respect to the lower one, suggesting higher energy and/or turbulence (Fig. 2).

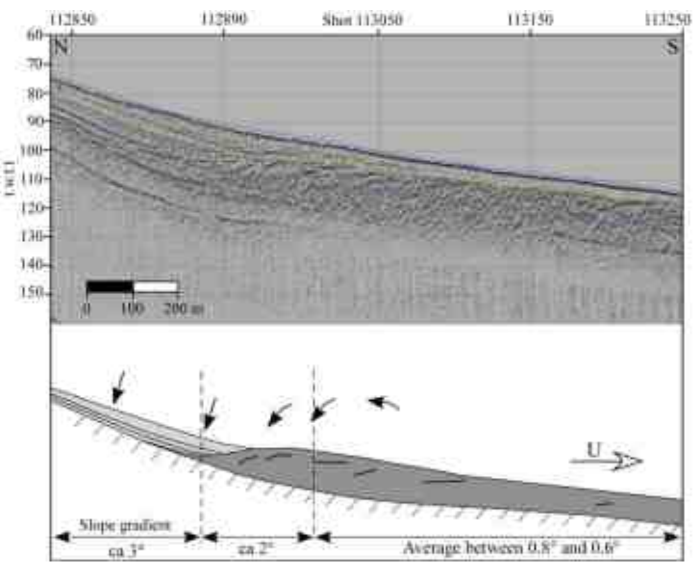

Fig. 2 – Particular of the upper density flow deposits. Dark grey shading indicate the tail and part of the body. Light gray shading indicate sediments deposited by settling of a suspended material. U, vector velocity.

* Dipartimento di Scienze della Terra e del Mare, Università di Palermo, Italy.
^ GeoSurvey Consulting, Portugal.

Sections and isopach maps clearly illustrate that the basin depocentre topography is not fixed at one position but migrates southwards in time (Fig. 3).

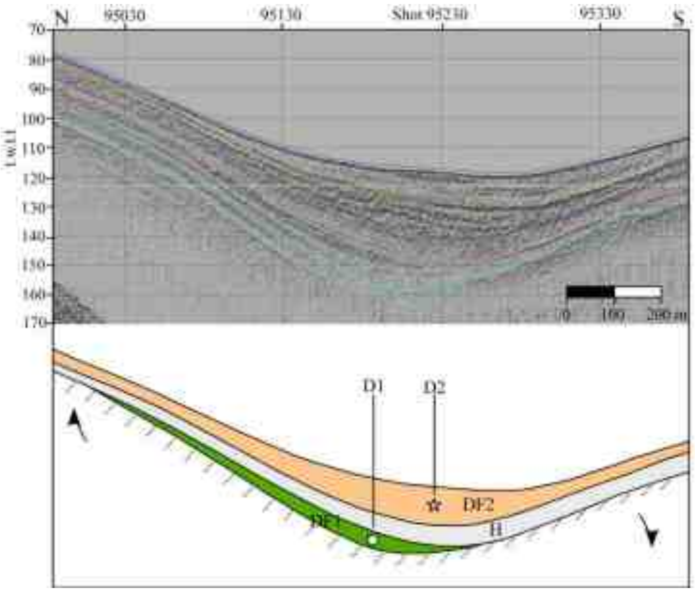

Fig. 3 – Particular of the density flow deposits showing the migration of the depocentre. D1 (circle) and D2 (star), basin depocentres; DF1, lower density flow; D2, upper density flow; H, hemipelagic deposits.

Based on the above observations, we suggest that the uplift of the resurgent dome and subsidence of the southern sector, occurred after the eruption of the Neapolitan Yellow Tuff, acted as a major control in the increase of the sea-floor gradient in the Pozzuoli bay. This may have triggered in turn, the deposition of gravity flow deposits along with a progressive migration of basin depocentres through time.

The submerged structure and stratal architecture of the Neapolitan Yellow Tuff (NYT) caldera, offshore the Campi Flegrei, (Eastern Tyrrhenian Margin): new insights from high resolution seismics and gravity core data

Sacchi M. (°), Pepe F. (*), Molisso F. (°), Insinga D. D. (°)

Key words: *Pozzuoli Bay, Prograding Wedge, Vertical movements.*

The Campi Flegrei is an active volcanic area defined by a quasi-circular depression that covers some 200 km^2 of the coastal zone of SW Italy, a large part of which develops off the Naples (Pozzuoli) Bay (Fig. 1). The area has been active at least since 60 ka BP (Pappalardo et al., 1999), and is structurally dominated by a caldera, 6 km in diameter, associated with the eruption of the Neapolitan Yellow Tuff (NYT), a 40 km^3 Dense Rock Equivalent (DRE) ignimbrite (Scarpati et al., 1993) dated at ca 15 ka BP (Deino et al., 2004), that covered the district now occupied by the city of Naples, the Campi Flegrei and a large area of the continental shelf off the Pozzuoli Bay.

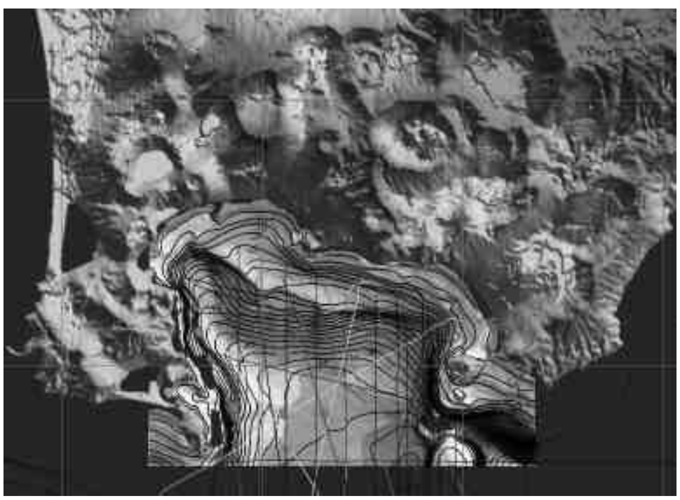

Fig. 1 – Map of the Campi Flegrei active volcanic area and location of seismic profiles and gravity core data

The volcanological evolution of the NYT caldera as been long described on the basis of outcrop and subsurface studies onland (Rosi & Sbrana, 1987; Orsi et al., 1996, 2004 and references therein; Di Vito et al., 1999; Perrotta et al., 2006; Fedele et al., 2011), but its offshore morphology, detailed structure and recent stratigraphic setting are still poorly understood.

In this study we integrate geological and geophysical data of different resolution/penetration obtained from high-resolution reflection seismic profiles (Sparker and Chirp source) with gravity core and swath bathymetry to better constrain the shallow structure, stratigraphic architecture and latest Quaternary to Holocene evolution of the submerged sector of the NYT caldera off the Pozzuoli Bay.

Our data clearly image, for the first time, the offshore geometry of the NYT caldera ring-fault zone, as well as the style and timing of volcano-tectonic deformation associated with the late stage evolution of the NYT inner caldera resurgence. Our interpretation suggests that since 15 ka the offshore sector of NYT inner caldera underwent significant deformation and uplift (with minor subsidence episodes) that occurred at almost the same rate as the post-glacial sea-level rise. Particularly, the inner Pozzuoli Bay started to deform soon after 15 ka BP, when sea-level rise was initially faster than uplift. This caused a general increase of the accommodation space that was progressively filled up by volcaniclastic sediments. Since ca. 8 ka BP, along with the mid Holocene decrease in the rate of the sea-level rise, the early NYT resurgent structure was then uplifted up to the sea-level or even to partial subaerial exposure. From ca. 8 to 5 ka BP two distinct layers of volcaniclastic resediments, mostly represented by gravity flow deposits, formed throughout the Bay. A significant post-Roman (post 2 ka BP) subsidence phase of ca 10 m is then recorded offshore Pozzuoli by the drowning of the infralittoral prograding wedge below the present-day fair-weather wave base.

Sea level fluctuation in the Mediterranean after the March 11th, 2011 Japan tsunami from Italian tidal records

ANTONIO VECCHIO (1), MARCO ANZIDEI (1,2), VINCENZO CARBONE (1,3), VINCENZO CAPPARELLI (1,4), IGNAZIO GUERRA (1) & GIOVANNI ARENA (5)

ABSTRACT

The sea level perturbations generated by the large M 9.0, Tohoku-Oki earthquake of March, 11th, 2011, in the Mediterranean sea, have been investigated by tide gauge data. The tidal records, acquired by 26 stations located along the coast of Italy, managed by ISPRA (Institute for Environmental Protection and Research), have been analyzed through the Empirical Mode Decomposition. After an inverse barometric correction was applied and considered the effects of wind velocity and direction at the tidal stations, we found that the abrupt changes in amplitude and frequency of the tide, which lasted for several hours, were caused by the arrival of the perturbations at the recording stations, approximately 40-50 hours after the main shock and about 13 hours after its arrival at Gibraltar, namely about 45 hours after the origin time of the earthquake. In particular, this tsunami caused two main effects in the Mediterranean: the generation of frequency fluctuations, that destabilized the diurnal and semidiurnal constituents and a temporary variation of the sea level with a maximum amplitude of ~10 cm, demonstrating that this particular tsunami was a truly global event.

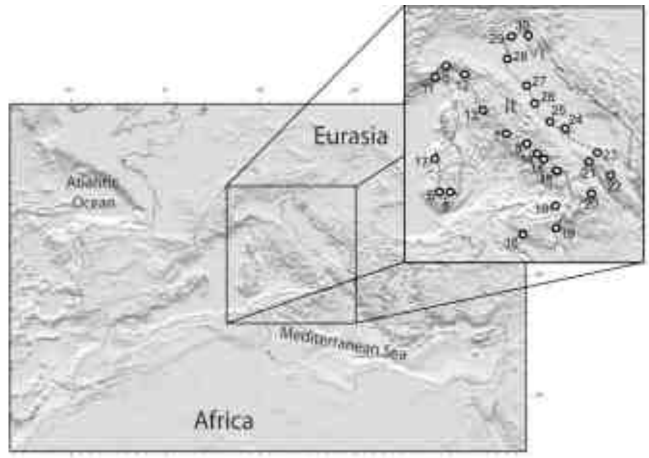

Fig. 1 - Map of the Italian tidal network with stations used in this study: 5. Cagliari ,6. Carloforte, 7. Civitavecchia, 8. Gaeta, 9. Genova, 10. Ginostra, 11. Imperia, 12. La Spezia, 13. Ancona, 28. Ravenna, 29. Venezia, 30. Trieste.

DATA SET, DATA ANALYSIS AND RESULTS

In order to investigate the effect of the tsunami on the tides in the Mediterranean sea we focus on the sea level recordings in the time span 9-15 March 2011, in proximity of the Tohoku-Oki earthquake. In particular we analyzed 26 records from the Italian tidal network managed by ISPRA (Institute for Environmental Protection and Research), retrieved on the internet at www.mareografico.it. This network is characterized by an instrumental and spatial homogeneous coverage and stations are collecting data almost with the same sampling rate (10 minutes). Moreover, for each station, the atmospheric pressure, wind velocity and direction are provided. During the time window analyzed the weather situation around the Italian seas was favorable. Additionally, we restricted our analysis to those tidal stations located in sheltered positions were wind effects on the sea level recordings, both for intensity and direction, based on the length of the fetch and the mean sea depths for the location were negligible in our analysis (GILL, 1982; see also the Fetch- and Depth-Limited Wave Calculations facilities at http://woodshole.er.usgs.gov/staffpages/csherwood/sedx_equations/RunSPMWave.html). The sea level data were first reduced for atmospheric pressure variations applying an inverse barometric correction to the data (e.g. WUNSCH & STAMMER, 1997). The time series of the raw tidal data show a sudden change on the tidal oscillation between 40 and 50 hours after the earthquake origin time. The normal tidal oscillation is broken, more frequencies are appearing, and the time behavior becomes more complex and highly non stationary.

To characterize the observed changes in the raw data, we used the EMD technique, developed to process non stationary data (HUANG *et alii*, 1998) and successfully applied in several different contexts (JANOSI & R. MÜLLER, 2005; SALISBURY & M. WIMBUSH, 2002; ZHEN-SHAN & XIAN, 2007; VECCHIO, CAPPARELLI & CARBONE, 2010).

The analysis shows that stations simultaneously felt the effect of the main tidal components, and suffer from the change of oscillating regime at ~40 hours after the origin time of the Tohoku-Oki earthquake. The change of behavior after $t = 0$ is clearly underlined when we look at the instantaneous frequency $\omega(t)$ of the semidiurnal component.

This effect is related to a variation of the sea level that reaches a maximum amplitude of ~15 cm and the timing of the variation

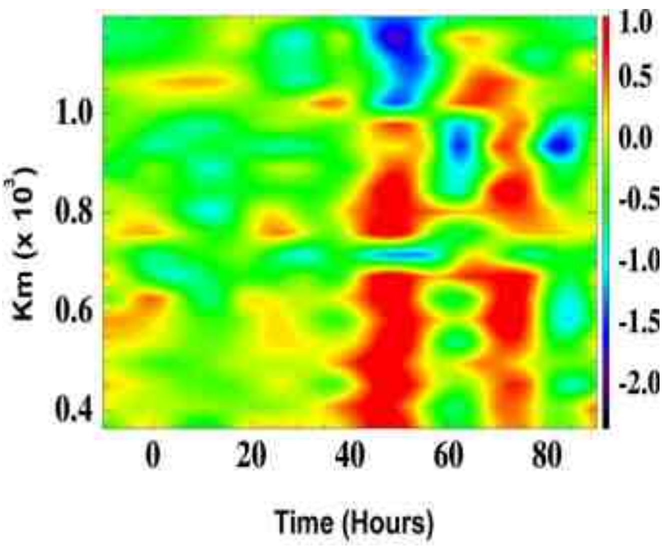

Fig. 2 - Contours of *LF(t)* for 20 stations in the space-time plane. The y-axis reports the distance in Km from Gibraltar.

occurred in a few hours of duration and depending on the geographic location. The time at which the high fluctuation regime is at its maximum absolute value changes, about linearly, with the distance from Gibraltair. This result is consistent with a traveling perturbation in the Mediterranean sea that we address to the sea level perturbation induced by the tsunami, in agreement with the prediction of its timing of propagations through the Oceans, up to the straits of Gibraltar (see http://nctr.pmel.noaa.gov/honshu20110311/honshu2011-globalmaxplot.png), for which the perturbation should arrive here ~38 hours after the earthquake. In particular, the perturbation is revealed at Carloforte, the westernmost station of the Italian tidal network, about 42 hours after the Tohoku-Oki seismic event, is in agreement with the theoretical models of tsunami propagation (http://nctr.pmel.noaa.gov/honshu20110311/honshu2011-globalmaxplot.png).

In particular two effects arise from our analysis: *i)* the presence of frequency fluctuations, that destabilized the main tidal components, and *ii)* the anomalous variation of the sea level. As a consequence of the former, the higher amplitude of the tidal components (semidiurnal and diurnal) become irregular and highly non stationary as also shown by the instantaneous frequency plots. These effects can be addressed to the morphology of the Mediterranean sea which is a closed basin and is connected with the Atlantic Ocean only by the narrow strait of Gibraltar (if we exclude the channel of Suez, that connect the eastern Mediterranean with the Red sea). The sea level fluctuations induced by the tsunami, propagating up to the European limits of the Atlantic ocean, forced the non-linear fluctuations in the proper tidal oscillations of the Mediterranean sea, in a similar way to those discussed by MAAS (1997). We relate the anomalous variations of the sea level, observed in the low frequencies EMD variations, to the direct transmission of the long period sea level fluctuations across the Strait of Gibraltar in consequence of the Tohoku-Oki earthquake. These tidal records and the EMD analysis demonstrate that this tsunami was a truly global event.

Quantitative assessment of soil erosion rates: results from direct monitoring and digital photogrammetric analysis on the Landola catchment in the Upper Orcia Valley (Tuscany, Italy)

P.P.C. AUCELLI (*), M. CONFORTI (**), M. DELLA SETA (°), M. DEL MONTE (°) L. D'UVA (°°),
C.M. ROSSKOPF (°°) & F. VERGARI (°)

Key words: *badlands, erosion rates, digital photogrammetry, quantitative geomorphology*

INTRODUCTION

Soil erosion is a serious threat in many parts of the world and particularly in the Mediterranean environment where many areas are widespread affected by accelerated erosion, largely promoted by the peculiar geological and climatic setting and by anthropic land use.

To evaluate the spatial-temporal development of denudation processes in central Italy, particularly badland erosion, direct measurements at erosion "hot spots" (DELLA SETA *et alii*, 2007) and a digital photogrammetric analysis (BETTS AND DEROSE, 1999; MARTINEZ-CASASNOVAS *et alii*, *2003*) at the hillslope and catchment scale have been performed in a test area representative of Upper Orcia River Valley badland landscape (Tuscany).

STUDY AREA

The test area is located on the Tyrrhenian side of Central Italy (Fig. 1) and coincides with the upper-middle sector of the Landola catchment, a small tributary basin on the left side of the Upper Orcia Valley.

In this area the calanchi landscape is well developed and widespread on Plio-Pleistocene marine deposits; these deposits have filled up a NW–SE elongated graben, then uplifted during the Quaternary up to several hundreds of meters above the present sea level (LIOTTA, 1996).

The Landola catchment covers ca. 4.4 km^2. Here, most of the slopes are rapidly evolving for denudation processes and, consequently, water courses show high suspended sediment loads. Water erosion is very pervasive and leads to typical rounded-edged *biancane* and sharp-edged *calanchi* badlands. Also gravitational processes contribute to slope denudation with landslides (present even on gentler slopes), soil creep and solifluction.

Badlands correspond to denudation "hot spots" within such catchments. Field monitoring at various test sites suggests that rill, inter-rill and gully erosion contribute the most to the overall denudation at the catchment scale, through extreme episodic events at the hillslope scale, triggered by prolonged rainfall events (DELLA SETA *et alii*, 2007, 2009).

MATERIALS AND METHODS

Field monitoring of denudation processes has been performed

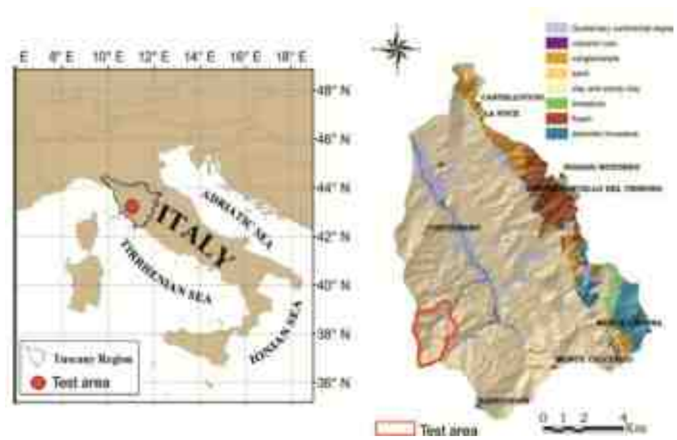

Fig. 1 – Location of the study area

at several sites in Southern Tuscany since the '90s, using iron pins placed at different depths, in order to cross the weathered horizon (DELLA SETA *et alii*, 2009)

In this work, together with direct erosion monitoring, we compare different methods to perform estimations of denudation rates.

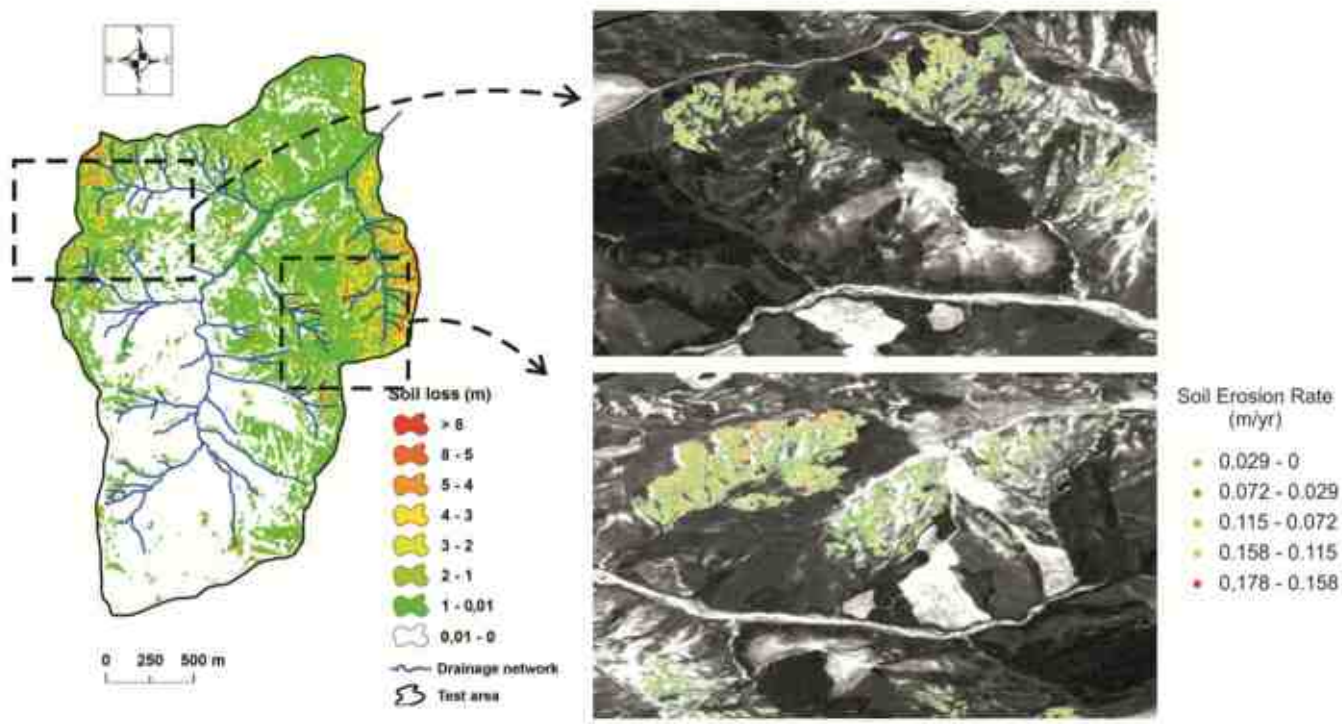

Fig. 2 – Left side - "Difference Map computed by subtraction of two digital elevation models in grid format (2003 – 1976). Right side – Focus on the average velocity of material removal at single *calanco scale.* In the background a 2003 orthophoto with 3D effect.

A multi-temporal digital photogrammetric analysis of landforms has been performed on four series of black and white aerial photographs dating to 1954, 1976, 1994 and 2003, respectively. The aerial photos have been scanned with a resolution of 1200 dpi. These photographs were elaborated by using a digital photogrammetric workstation and a specific software, Z-map™, which provided for the generation of digital stereo models, image exploration and interpretation tools and supported the generation of dense surface models, digital elevation models and digital orthophotographs.

In order to increase the relative stability of the non-metric image blocks (both in terms of internal and external orientation), 30 tie points for stereo pairs were computed through semi-automatic operations, which significantly improved aerial triangulation results

For the absolute orientation, a differential global position system (DGPS) survey was carried out and about 70 ground control points (GCPs) were located within and around the test area.

For the 1954 photographs, the application of the previously described procedure was not possible, as the necessary camera calibration certification was not available. So we used the Computer Vision technique with the free software PMVS (Patch-Based Multi-View Stereo Software) that resolves, with only one prospect matrix, internal and exterior orientation (ACKERMANN *et alii*, 2011).

Digital Elevation Models (DEMs) have been derived from each set of photos on a stereopair-by-stereopair basis and then mosaicked to produce a high-resolution DEM for each photo. The DEM resolution was 2 m. The quantitative evaluation of the rate of sediment loss was computed by overlaying these DEMs. This operation produced a new grid with the altitude difference for each cell of the grid. Negative values in the difference grid were interpreted as erosion areas, positive values as filling or accumulation areas (MARTINEZ-CASASNOVAS, 2003).

DEM comparisons were performed considering only values included within the 95% confidence level, thus leaving out errors and inaccuracies associated with peaks of terrain models.

In addition, photo interpretation carried out for each set of aerial photos, allowed to map land use and the effects of the main denudation processes that affected the landscape in 1954, 1976, 1994, 2003, respectively. Data analysis was performed within a Geographic Information System.

RESULTS AND DISCUSSION

The multi-temporal digital photogrammetric analysis allowed to reconstruct the changes which have occurred during the considered time window (1954-2003).

A volumetric evaluation of morpho-topographical changes was achieved with the "Difference Maps" obtained by comparing the three DEMs, and showing the areas affected by erosion or accumulation, respectively (Fig. 2). This kind of analysis, at catchment scale, enabled us to assess that: (i) the areas mainly affected by erosion are located within the upper portions of hillslopes, close to the top of *calanchi* badlands and along the highest part of the slopes' main ridges; (ii) the average erosion rate calculated for the period 1976-2003 is 1.2 cm/yr; (iii) erosion rates were higher during period 1976-1994 (on average 2.61 cm/yr) than during period 1994-2003 (1.1 cm/yr), most likely because of the increase of vegetation cover and important interventions along the slopes that allowed to mitigate erosion processes in the second period (AUCELLI et *alii*, 2010).

Moreover, focusing only on areas affected by erosion (negative values in the "Difference Map"), at the scale of a single *calanco*, we have calculated that the material was removed from slopes with an average velocity of 5.5 cm/yr (Fig. 2); this value is higher than the average computed for the entire basin, because it is normalized on a smaller area; however, it is in agreement with that of ca. 6.5 cm/year obtained in other test areas located in Tuscany region, investigated by using photogrammetric analysis and pins (CICCACCI *et alii*, 2008; DELLA SETA *et alii*, 2009).

In addition to the DEM reconstruction, an accurate stereoscopic analysis was performed on high-resolution (1 m) aerial photos and orthophotos, in order to map the active *calanchi* and to evaluate the evolution and trend of the denudation processes. Comparing the surface and the perimeter of some *calanchi*, we assessed that they varied with a mean rate of about 6.5 cm/yr which results from two opposite trends: first, from 1976 to 1994, to reduce the surface (on average 2.6 cm/yr) then, from 1994 to 2003, to increase it (average rate of 17.8 cm/yr). In particular, a maximum headwater retreat of up to 10-15 cm/yr is recorded.

CONCLUSION

While field studies of soil erosion are expensive, time-consuming and data need to be collected over many years, the application of digital photogrammetric methodologies has revealed to represent a powerful and low cost tool to evaluate the rate and spatial-temporal development of denudation processes, as confirmed by the comparison with point monitoring in the field and indirect estimations using geomorphic parameters.

Nevertheless, the quality of aerial images and errors caused by the data interpolation in the DEM-constructing phase may negatively affect photogrammetric analysis. Moreover, the obtained DEMs should be cleaned considering the possible different height of vegetation cover in various periods, in order to compute a more accurate assessment of erosion rates. Thus, rates computed from photogrammetric analysis should be used only in analysis covering very large time intervals (at least some decades).

Photogrammetric digital methodologies can be very useful for sustainable land management, planning of erosion control measures and calibration of regional erosion prediction models in Italy, as well as in other Mediterranean environments. The proposed method can be considered very useful to better locate denudation landforms and associated processes and to assess related erosion rates.

Key words: *Soil erosion. soil reflectance spectroscopy, PLS regression, spatial distribution, Calabria.*

INTRODUCTION

Soil erosion is one of the most serious types of land degradation and it has severe economic and environmental impacts in the Mediterranean belt, as well as in large areas of the Italian territory. Water erosion and mass wasting are the major causes of soil degradation in large areas of the Calabria region, which may determine soil truncation or complete removal, loss of biodiversity and quality of ecosystem functions, decrease in productivity and may lead to desertification. The occurrence, depth and quality of surface horizons can be considered as indicators of the preservation/degradation state of soils in the field. Therefore, many soil properties can be directly linked to the soil erosion status, such as organic matter, calcium carbonate, texture, aggregation structure, infiltration capacity, etc. In particular, soil organic matter (SOM) content and its possible depletion can be assumed as a reliable tools for a quantitative assessment of soil degradation. It was shown that, in many cases, soils with <2% SOM content are highly erodible and thus much prone to degradation (FULLEN & CATT, 2004). Also, SOM has been identified as one of the major sinks in the global carbon cycle that may influence global warming (LAL, 2004).

Conventional methods for mapping and monitoring SOM content are, time consuming, and expensive, as a great number of samples are required (DEMATTÈ *et alii*, 2006). An alternative approach to determine these properties is based on the use of the proximal spectral reflectance in the visible-near infrared-short wave infrared (VIS-NIR-SWIR) region. (LEONE & SOMMER, 2000), that has the advantage to be rapid, non-destructive and inexpensive (DEMATTÈ *et alii*, 2006).

The purpose of this study was to delineate eroded zones in a representative sample area of southern Italy, using SOM as a key indicators. To do that, was to test the use of laboratory VIS-NIR-SWIR spectroscopy as fast and accurate technique to develop an empirical model for predicting SOM. A calibration model between SOM and soil spectral reflectance measurements was developed using a PLSR statistical method. (VISCARRA ROSSELL *et alii*, 2006). Finally, a geostatistical approach was employed to map spatial pattern of SOM, obtained from the laboratory measurements and the ones predicted from the soil spectral reflectance data, that consequently provide a characterize spatial variability of the soil erosion severity.

DATA AND METHODS

The study site is the Turbolo watershed, located in the northern Calabria (South Italy) between 39°32'25''N and 39°29'51''N latitude, 16°12'57''E and 16°05'21''E longitude (Fig. 1). It was selected as a sample area because its pedo-environmental variability can be assumed as representative of widespread sites of the Calabria region. This watershed is about 30 km^2, with altitude ranging from 75 to 1015 m a.s.l. The climate is sub-humid, with average annual precipitation of 1200 mm, distributed on 105 rainy days, and average temperature of 16°C. The western part of the Turbolo watershed is characterized by steep slopes shaped on Palaeozoic metamorphic rocks (mainly gneiss and schists) whereas its eastern and wider, hilly reaches consist of gentle slopes and terraces cut on sedimentary terrains, of Neogene-Quaternary ages, in particular clays and sands and gravels.

The pedological data, according to the soil map of Calabria (ARSSA, 2003), indicates the occurrence of soil types from highly mature (Alfisols) to poorly developed soils (Inceptisols and Entisols) (USDA, 2010), which frequently appear truncated or strongly degraded by water erosion processes and landslides (CONFORTI *et alii*, 2011; BUTTAFUOCO *et alii*, 2012).

For this study, 215 topsoil samples (depth of about 20 cm), representative of different soil types and various soil erosion conditions were collected (Fig. 1). The geographic positions of the sampling points were determined using a GPS. The soil samples were air-dried and sieved at 2 mm and each sample was split into two sub-samples: one was analyzed for SOM content using routine chemical methods, while spectral measurements were conducted on the other.

The VIS-NIR-SWIR reflectance measurements of the soil samples were carried out in the laboratory with an ASD

FieldSpec Pro spectroradiometer. Spectral measurements were taken at 1.5 nm steps between 350 and 1000 nm and 2 nm steps between 1000 and 2500 nm. A reflectance standard of known reflectivity (Spectralon©) was used. The optical head of the spectroradiometer was mounted on a tripod in nadir position with a distance of 10 cm from the sample. Two 100 W halogen lamps, positioned in the same plane, with a zenith angle of 30° were used for illumination. To reduce instrumental noise, four measurements for each sample were averaged. Reflectance

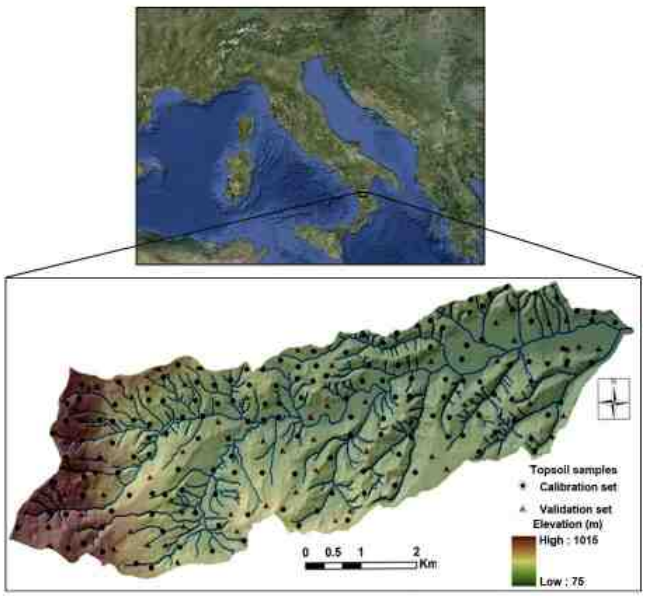

Fig. 1 – Location of the study area and sample locations

spectra were then re-sampled at 10 nm interval obtaining 216 spectral reflectance bands for each soil sample. The topsoil data set was randomly divided into two groups (Fig. 1): one group (calibration set, 161 samples), was used to obtain the prediction model and the second subset (validation set, 54 samples) was used to test the model accuracy.

A partial least squares regression (PLSR) algorithm with leave-one-out cross-validation was used for SOM content predictions. The coefficient of determination (R^2), the root mean square error (RMSE) and the residual predictive deviation (RPD) were used to evaluate the performance of prediction model (VISCARRA ROSSELL *et alii*, 2006 and references therein). The analysis was performed using the PArLeS software developed by VISCARRA ROSSEL (2008). In order, the spatial prediction of SOM content was investigated using a ordinary multi-Gaussian kriging (WEBSTER & OLIVER, 2007) and SOM maps were created for measured and predicted datasets.

RESULTS AND CONCLUSIONS

The SOM content of the topsoil ranged from 0.3% to 12.1% with an average of 3.0% and a standard deviation of 2.0%. Lower SOM contents indicate that soils are poorly developed and/or have undergone a strong erosion. Still, low content of SOM (<2%), was recorded in cropland area, often characterized by intense water erosion, mainly sheet and rill erosion and secondary gulling (CONFORTI *et alii*, 2011) and tillage erosion due to stronger mechanization.

The results of reflectance measurements, in the VIS-NIR-SWIR spectral domain, of 215 topsoil samples indicate that the SOM considerably influence the reflectance curve of topsoils. Changes in soil surface conditions modify the shape of the soil reflectance spectra. In fact, it was observed that eroded soils showed higher values of reflectance intensity in the entire spectrum domain, as a response to topsoil removal and subsequent loss of SOM.

The results of the prediction model, obtained from the relationship between the laboratory soil spectra and SOM content of the calibration set, by using PLSR analysis, were summarized in Fig. 2. A very good calibration (R^2 = 0.87) was obtained with 10 prediction factors selected for the model, because it exhibits the lowest RMSE (0.72%) of cross-validation. The very high accuracy of the models are also indicated by the RPD value (Fig. 2). The RPD is considered good when it is greater than 2.0 (VISCARRA ROSSELL *et alii*, 2006). The validation results of the prediction model obtained using the independent data set

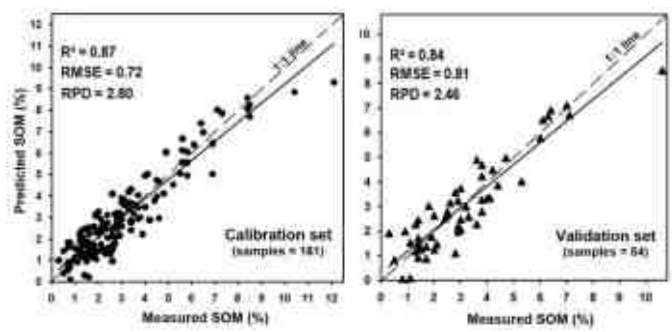

Fig. 2 – Scatterplots of predicted vs. measured SOM content for calibration and validation sets. NF: number of factors; R^2: coefficient of determination; RMSE: root mean square error; RPD: residual predictive deviation.

(validation set), are satisfactory (Fig. 2). As may be observed, the points are dispersed on both sides of the first bisector with only a high values of SOM underestimated. The results show a R^2 = 0.84, RMSE= 0.81% and RPD = 2.46, and moreover were in good agreement with the cross-validation results.

Regarding geostatistical analysis, SOM values for both measured data and predicted data were transformed to normal distribution using a Gaussian anamorphosis. For each dataset (measured and predicted data), a variogram map (not shown) was calculated and they did not show any significant difference as a function of direction. The experimental variogram for the Gaussian measured SOM content was modelled by a nested variogram that combines three basic structures including a nugget effect, a short range exponential model with a range of 598 m and a long range spherical model with a range of 2755 m. The nugget effect implies a positive intercept of the variogram. It arises from errors of measurement and spatial variation within the shortest sampling interval (WEBSTER & OLIVER, 2007). The experimental variogram for the Gaussian predicted SOM content was modelled by a nested variogram that combines the same basic structures including a nugget effect, a short range exponential model with a range of 713 m and a long range spherical model with a range of 2755 m.

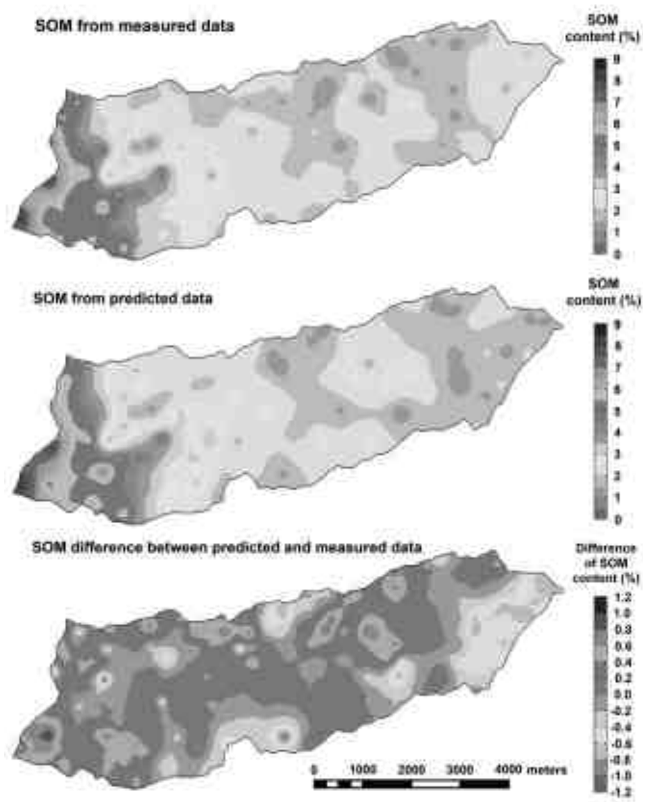

Fig. 3 – Maps of measured data and predicted data of SOM content. A map of differences between measured and predicted data is also reported.

These models were used with multi-Gaussian ordinary kriging to interpolate the Gaussian values of SOM content for measured and predicted set. Therefore, to evaluate the effectiveness of multi-Gaussian ordinary kriging interpolations, the estimated values of the SOM of the two maps were compared (Fig. 3).

The interpolate maps showed similar spatial distribution and value ranges of the SOM content (Fig. 3), the mean value of the spatial distribution of SOM for measured data was of 2.66 %, whereas for the prediction data was of 2.70 %. In both the maps, the high contents of SOM were observed along the slopes in the western part of the study area, which are dominated by woodland, whereas low values of SOM were mapped in areas characterized by a extensive agriculture, such as deep ploughing, that in many places has caused soil tillage erosion, and also intense water erosion.

The comparison between the two maps showed the quantitative differences in SOM content between predicted and measured data (Fig. 3). Therefore, even though 44 % of the pixels were overestimated and about 29% of the pixels were underestimated, the mean difference between observed and estimated values was 0.0039 % whereas the max difference was 1.2 %. Finally, these results showed that the spectral reflectance measurements and geostatistics analysis can replace conventional methods for evaluating and mapping SOM content in soils that represent very important indicators of the soil erosion status.

INTRODUCTION

Badland landscapes are very widespread throughout a number of Italian regions. They consist of landforms carved into clayey deposits and are known as *calanchi* and *biancane.*

Extensive literature on Mediterranean badlands areas has pointed out how, together with geological and climatic factors as well as human impact, more local conditions, such as parent material properties, play a relevant role in explaining the rapid erosion intensities, as well as the development of different slope landforms in these sites (BATTAGLIA *et alii*, 2002; FAULKNER *et alii*, 2000; GERITS *et alii*, 1997; TORRI *et alii*, 1994, PICCARRETA *et alii*, 2006; SUMMA *et alii*, 2007; PULICE *et alii*, 2012; VERGARI *et alii*, 2012).

Mineralogical and physico-chemical composition of samples from badlands sites of Central and Southern Italy (Fig. 1) have been investigated in order to better understand the variability of mean erosion rates measured in different eroded landforms developed in the two study areas as well as to compare the results with respect to the triggering and development of different badlands forming processes in the two areas.

Central Italy site is located in the Upper Orcia Valley (Tuscany), where Plio-Pleistocene marine deposits, filling NW–SE elongated sedimentary basins have been uplifted during the Quaternary, due to volcanic activity, up to several hundreds of meters above present sea level (Fig.1).

Southern Italy site is situated in the Crotone area, (Calabria), at the Plio-Pleistocene clays of the Crotone Basin. (Fig.1)

Tab.1 summarizes the mean climatic features of the study areas.

composition, performed using an Rigaku X-ray diffractometer, are discussed, in order to unravel the role of main topographic and geological erosion factors.

RESULTS

Upper Orcia Valley samples

The performed analyses showed that (Tab. 2, VERGARI *et alii*, 2012):

a) most of the samples fall in mud grain class, where the proportions of clay and silt are approximately the same. Parent material of *biancane* samples are characterized by a finer grain size and a more dispersive clay fraction than calanchi samples, according to previous literature (VITTORINI, 1977; ALEXANDER, 1982; BATTAGLIA *et alii*, 2002);

b) mineralogy appear quite uniform: the main non-clay minerals are quartz, calcite and feldspars, while among clay minerals prevail chlorite, kaolinite, poorly crystallized illite and mixed layer minerals, which smectite component is responsible for the expandable character of the studied sediments;

c) considering the soluble salts analysis, Na^+ is the most abundant, while SO_4^{2-} is the prevalent anion.

All the samples from calanchi sites show salt content considerably lower than the one in biancane parent materials.

Calabria site samples (Tab.3, PULICE *et alii*, 2009)

As shown in Tab. 3, the Crotone sample analysis showed that:

a) the particle size analysis evidences that the analyzed samples can be classed as clayey silts (Shepard, 1954);

b) the major mineral phases present, in order of abundance, are: clay minerals, quartz, calcite, K-feldspar and plagioclase. Among clay minerals illite and mixed layers illite-smectite prevails on kaolinite and chlorite.

c) the analysis of soluble salts has shown that, irrespective of the morphology of the badlands, Na^+ is always the most abundant cation, despite the relative abundance of $CaCO_3$ total (on average 19%), consistent with the nature of the clay marl.

DISCUSSION AND CONCLUSION

Topographical and geological features of Upper Orcia Valley denudation-hot spots have a more significant influence than physico-chemical properties of parent material in explaining the initiation and development of different badland landforms (calanchi and biancane) (Fig. 2). Physico-chemical clay properties have been proved to be directly related to different erosion intensity measured at calanchi and biancane sites. Vegetation cover seems to stabilize upper layers of soil profile, although not permanently: agricultural manipulation and cropland abandonment increase the proneness to gully formation and related accelerated erosion.

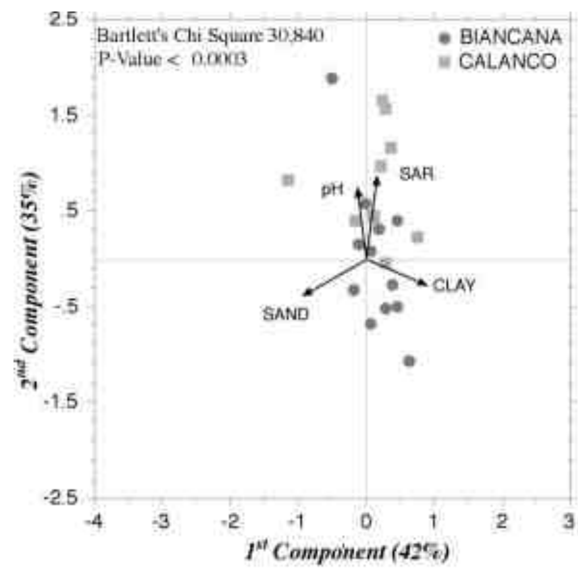

Fig. 3 – Orthogonal plot of the PCA using as variables in the input matrix the distributions physico-chemical parameter

In the Crotone basin, using a multivariate statistic approach – which adopts the Principal Component Analysis (PCA) method to extract factors – it has been possible to hypothesize the main processes responsible for the dynamic evolution of the study area. Fig. 3 shows the comparison between the samples taken

TABLE 3

Mg^{2+} (meq/l)	11,10	0,71	33,78

*SAR=[Na]/([Ca+Mg]/2)^{0,5}

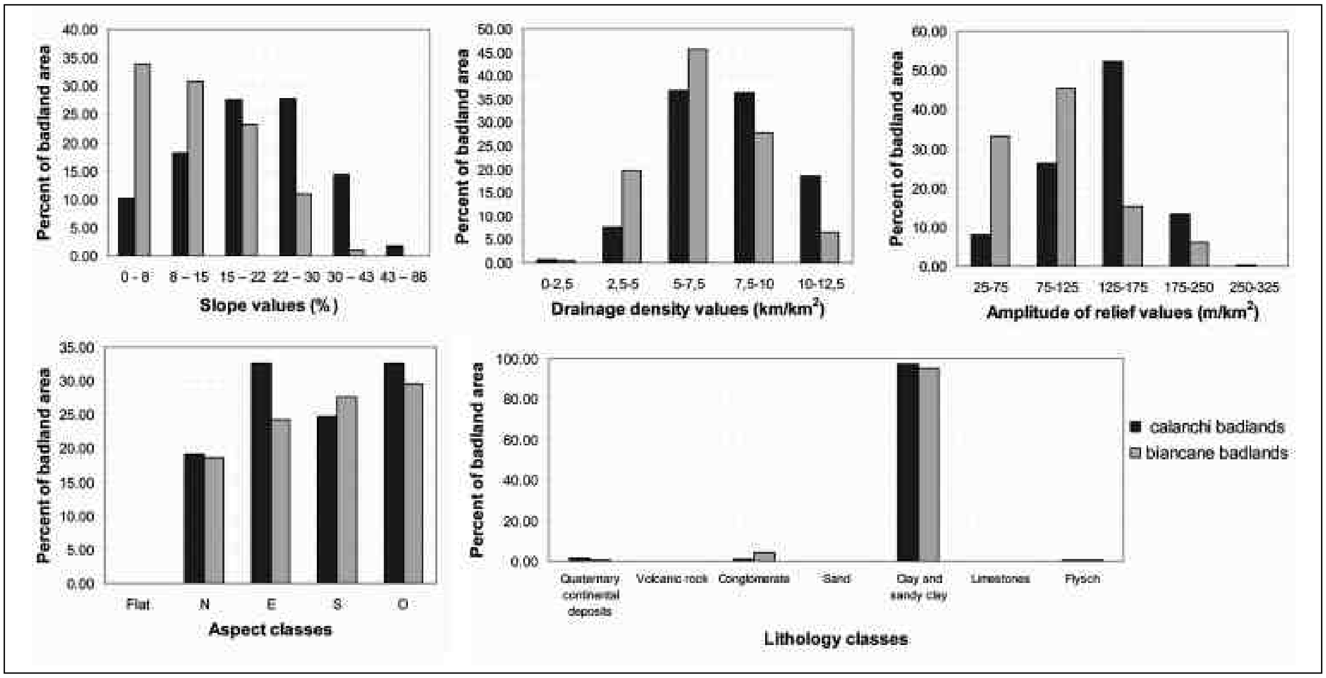

Fig. 2 – Distribution of Upper Orcia Valley calanchi and biancane badlands areas in the classes of the main conditioning factors (Vergari et al., 2012).

from the *calanchi* and those of two *biancane* based geochemical data. The PCA (77% of total variance explained) - carried out using as input variables in the matrix pH, SAR, clay (% wt), and sand (% wt), - shows that the distribution of these parameters is statistically independent of the badland forms on which they were taken (biancane and calanchi A and B). Therefore, in the Crotone catchment, the intensity of precipitations coupled with topography, which in turn control overland flow and water infiltration, has to be considered the main control factor in the dynamic evolution of *calanchi*.

Comparison of the two calanchi basins - placed in different areas in terms of location (Central and Southern Italy), climate and local geology - evidenced that local topography, i.e. strong slope gradients, coulped to a precise local climate context, i.e marked semiarid conditions during the summer period followed by heavy rainfall in autumn, plays a primary role in the dynamic evolution of badlands if compared with the control exherted by physico-chemical and mineralogical features of badlands.

Process-Based Assessment of Erosion Dynamics in the Upper Orcia Valley (Southern Tuscany, Italy): A New Semi-Quantitative Integrated Approach

MICHAEL MAERKER (*), MARTA DELLA SETA (**), FRANCESCA VERGARI (**), MAURIZIO DELMONTE (**)

Key words: *soil erosion, terrain analysis, Erosion Response Units, Turbidity Units, GIS.*

INTRODUCTION

Accelerated water erosion is one of the most serious environmental problems to be faced in the Mediterranean region, due to the strong impact it has on several human activities and to fast modifications produced in natural environments (ANANDA & HERATH, 2003). Therefore the problem of evaluating the intensity of erosion processes is of significant scientific and social importance.

This work illustrates part of the results derived from the activities of the EROMED Italian National Project, which was aimed at the development of an integrated model for water erosion prediction in the Mediterranean environment. We propose, in particular, a new semi-quantitative integrated approach for process-based assessment of erosion dynamics for one of the project sample areas, the Upper Orcia Valley (Southern Tuscany, Italy).

We combined the Erosion Response Unit (ERU) approach (SIDORCHUK *et alii* 2003, FLÜGEL et *alii*, 2003) and the *Tu* approach for the quantitative geomorphic estimation of erosion rates (CICCACCI *et alii*, 1986, DELLA SETA *et alii*, 2009) to get information: i) about the principal erosion processes within specific spatial units (ERU); ii) about the intensity of erosion in the same units.

STUDY AREA: UPPER ORCIA VALLEY

The Upper Orcia Valley is located on the Tyrrhenian side of Central Italy, where Plio-Pleistocene marine deposits, filling a NW–SE elongated graben, have been uplifted during the Quaternary up to several hundreds of meters above the present sea level (LIOTTA, 1996). These deposits consist of lithological units particularly prone to denudation, which is favoured by the climate, showing marked semiarid conditions during the summer period, followed by heavy rainfall in autumn. For process-based assessment of erosion dynamics we focused on a sample subcatchment, which is representative of the geomorphic processes acting in the Upper Orcia Valley (Fig. 1).

Fig 1 - Upper Orcia Valley and Miglia subcatchment.

The majority of slopes are rapidly evolving for denudation processes and rivers show high suspended sediment load. In fact, water erosion is pervasive and leads to typical roundededged biancane and sharp-edged calanchi badlands (Fig. 2).
Gravitational processes contribute as well to slope denudation with landslides (even on gentler slopes), soil creep and solifluction. Badlands correspond to denudation "hot spots" within catchments and field monitoring at these sites suggests that rill, inter-rill and gully erosion contribute the most to the

We are grateful to the MIUR PRIN 2007 Project: "Messa a punto di un modello integrato per la valutazione dell'erosione idrica del suolo in ambiente mediterraneo" (No 200787NYYR_001. Coordinator: G.Rodolfi & M. Maerker).

overall denudation at the catchment scale, through extreme episodic events at the hillslope scale, triggered by rainfall events several days long (DELLA SETA *et alii*, 2007, 2009).

Fig 2 - Lithological sketch of Miglia subcatchment and badland landforms (biancane and calanchi).

METHODS

GRID ANALYSIS OF TU

In order to estimate the spatial distribution of the erosion rate (in terms of mean annual suspended sediment yield, *Tu*), we performed for the first time a grid analysis of the *Tu* parameter calculated using the empirical equations (1) and (2) by CICCACCI *et alii* (1986):

$\log Tu = 0.35312\ D + 1.43225$ if $D<6$ (1)

$\log Tu = 2.93936\ \log D + 1.13430$ if $D\geq6$ (2)

where D is the drainage density. These equations are based on statistical correlations among quantitative geomorphic parameters (drainage density in this case) and the measured suspended sediment yield at the outlet of a statistical number of geomorphologically similar catchments. Previous works outlined that *Tu* values predicted for catchments using these empirical equations exponentially increase with the areal ratio of badlands to the whole catchment (DELLA SETA *et alii*, 2009). This correlation indicates the sensitivity of the *Tu* parameter to the contribution from denudation "hot spots".

Applying the empirical equations within unit areas and taking into account the bulk density of the outcropping lithologies, we obtained a grid of estimated erosion rates in cm/a.

CLASSIFICATION AND REGRESSION TREE (CART) ANALYSIS

Erosion Response Units (ERU) are distributed threedimensionalterrain units, which are heterogeneously structured and have homogeneous erosion process dynamics characterized by a slight variance within the unit, if compared with neighboring ones (FLÜGEL *et alii*, 2003, SIDORCHUK *et alii*, 2003). Their erosion response is controlled by their physiographic properties and by the management of their natural and human environment. We obtained them using a Classification And Regression Tree (CART) approach (TREENET software by Salford Systems) aimed at finding the relationships between combinations of driving factors (*predictor variables*) and the distribution of specific surveyed erosion processes (*target variable*) (Fig. 3).

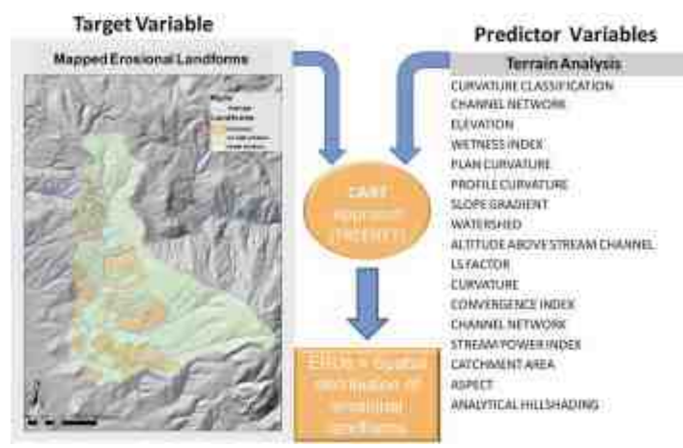

Fig 3 - Methodological sequence for the delineation of ERUs using CART approach.

We regionalized the spatial distribution of erosion processes using a map of erosion landforms that was sampled at the points of the grid of estimated *Tu* values. The model was firstly applied to predict the spatial distribution of classified erosion processes. Two classes were derived which are "badland erosion" and "no fast erosion".

The erosion rate was then regionalized separately with the same approach, using the sample points of estimated *Tu* values.

These point values correspond to the centroids of the unit areas in which the empirical equations were applied. Thus, we derived the average value of topographic indices in a buffer area around each point. Finally we obtained the spatial distribution of the average erosion rate.

RESULTS AND DISCUSSION

ESTIMATED TU *GRID*

Figure 4a shows the obtained *Tu* grid and the spline interpolation from this grid (Fig. 4b), evidences that the spatial distribution of predicted erosion rates is in agreement with field measured rates at monitoring station on denudation hot spots, equipped with erosion pins that recorded an average erosion rate of 3.2 cm/a.

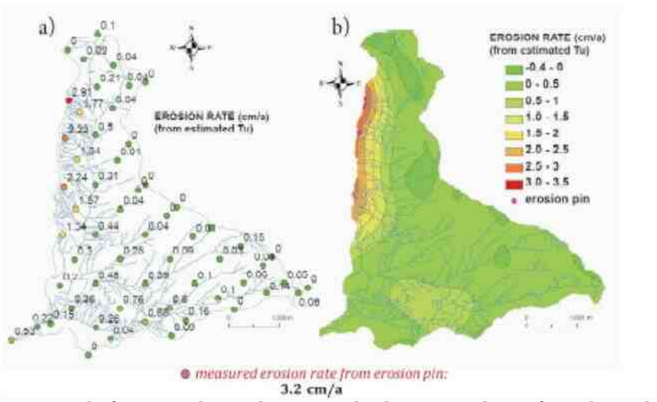

Fig. 4 - Grid of estimated Tu values (a) and spline interpolation from the grid points, showing the spatial distribution of predicted erosion rate (b). Predicted values are in agreement with the measured ones.

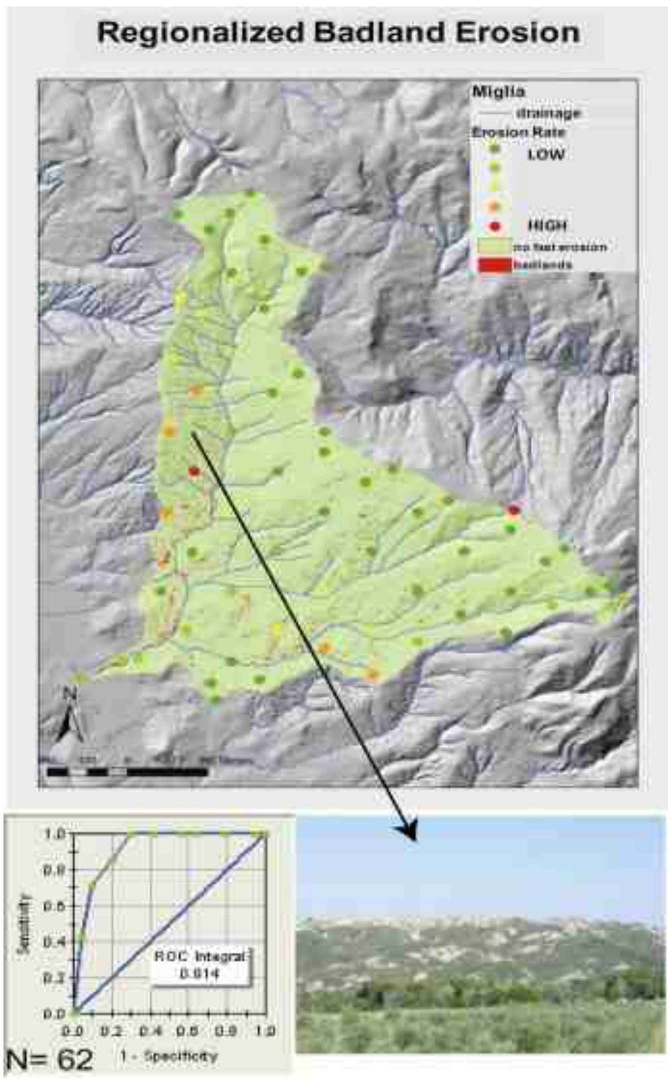

Fig. 5 - Model for spatial distribution of "badland erosion" ERUs (in red) and "no fast erosion" ERUs (in green) and results of validation.

ERU AND REGIONALIZATION OF EROSION PROCESSES

Figure 5 shows the spatial distribution of "badland erosion" ERUs (in red) and "no fast erosion" ERUs (in green). In agreement with field observations, badlands are mainly distributed along the hydrographical right side of the subcatchment.

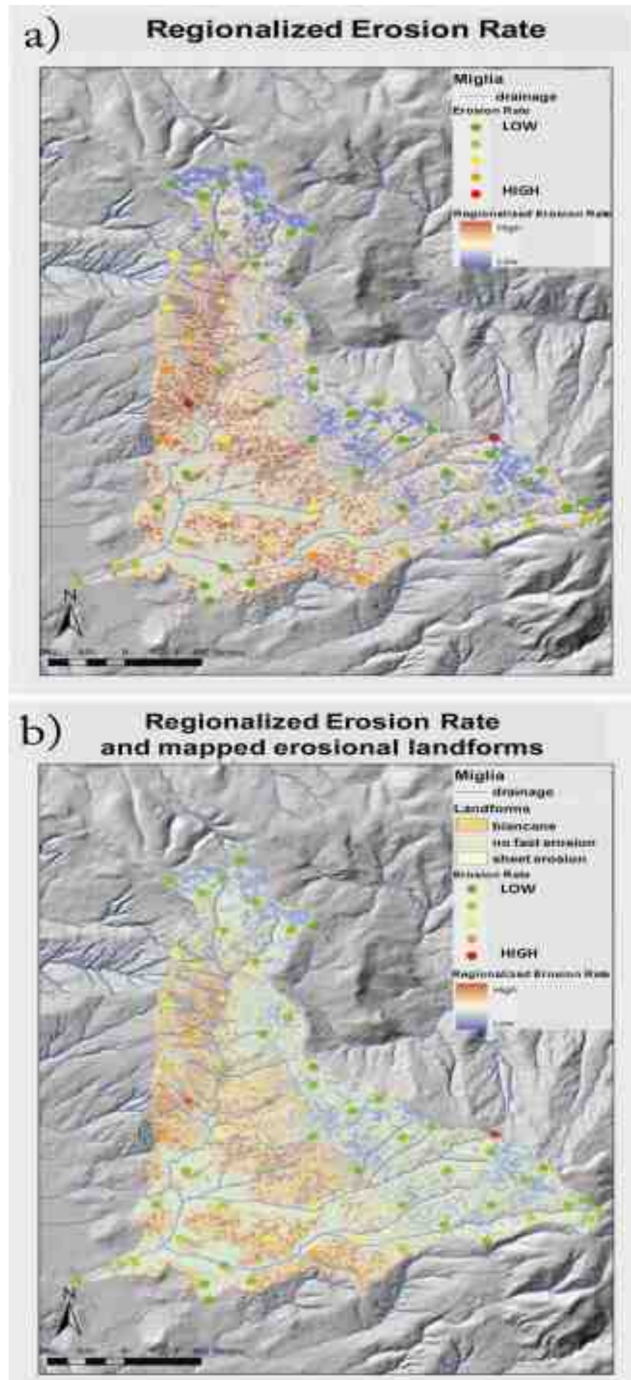

Fig 6 - Regionalized erosion rates predicted values (a) and comparison with the surveyed erosion landforms.

Moreover, the modelled distribution of badland areas fits well with the estimated *Tu* values (cm/a). Model validation provided good results (Receiver Operator Curve integral of 0.914).

REGIONALIZATION OF EROSION RATES

Figure 6a illustrates a characteristic distribution of the regionalized erosion rate, well fitting the original *Tu* data.

A NW-SE boundary divides higher values on the hydrographical right side from generally lower values on the left one. The model shows as well a concentration of high values towards the catchment head.

Moreover, the distribution of mapped badlands generally fits well the spatial pattern of erosion rates (Fig. 6b). Internal cross validation performed using train and test data evidenced good model performance and satisfactory prediction power.

CONCLUSIONS

The semi-quantitative integrated approach for process-based assessment of erosion dynamics provided satisfactory results, which can be summarized as follows:

i) grid analysis of estimated *Tu* provided good estimation of the average erosion rate per spatial unit;

ii) CART analysis delivered satisfactory information on the spatial distribution of erosion processes and estimated erosion rates (*Tu*);

iii) the highest values of the regionalized *Tu* fit well with the regionalized badland areas.

These preliminary results encouraged us for future outlook. In particular, we have plans for:

i) using the ERU approach to regionalize the principal hillslope processes for the whole Upper Orcia Valley;

ii) applying physically-based models within the ERUs in order to quantify the intensity of the different hillslope processes;

iii) validating the results of the physically-based models with the predicted *Tu*.

The case study of "San Michele Cave" of Saracena (northern Calabria, Italy): late Pleistocene to mid-Holocene paleoenvironmental reconstruction and human impact through a pedological and geoarchaeological approach

TERESA PELLE (*), FABIO SCARCIGLIA (*), ELENA NATALI (**), VINCENZO TINÉ (**)

Key words: *georchaeology; Holocene climate changes; human impact; soil and sedimentary processes*

INTRODUCTION

Recently the interest in Holocene paleoclimatic and paleoenvironmental variability is growing, because of the time proximity and continuity with modern climate changes, which may be helpful to predict forthcoming scenarios. In particular, the Holocene is characterized by relevant human impact and for this reason it is important to distinguish the role of natural forcing on the environment from that caused by anthropogenic activities. In this work we applied a multidisciplinary approach, integrating archaeological, geomorphological, pedological, geochemical and micromorphological analyses, to reconstruct late Pleistocene to mid-Holocene paleoenvironmental changes recorded in the pedosedimentary infilling of the San Michele Cave (north Calabria, southern Italy). We focus on the natural context and possible effects of late prehistoric human settlements on it.

SAN MICHELE CAVE

The San Michele Cave is located close to Saracena village (Fig. 1) and represents an open hypogeal karst landform shaped in the dolostone-limestone bedrock of the Pollino Massif. It is characterized by a single large room, with a high roof and two, front and back openings. Since the Paleolithic (of undetermined age) to the early Bronze Age it was repeatedly settled and abandoned by men, as evidenced by ceramic artifacts, pole pits, hearth remains and charcoals, human and animal bone fragments that were found in the stratigraphic succession (NATALI & TINÉ, in prep.). It was dated on the basis of such archaeological findings and radiocarbon ages of charcoals sampled at different stratigraphic heights, which range from 6808±60 a BP (early Neolithic) to 4521±35 a BP (Eneolithic). The stratigraphic succession is about 6 m deep. It is characterized by some brown to pale brown buried soils, alternated with unweathered to moderately weathered deposits and variably-cemented layers rich in secondary carbonate. These deposits are mainly thin-layered, (sandy-)loam in texture, with occasional very coarse debris related to rock-fall processes from the roof. Rare to occasional and in places not clearly identified clay coatings were observed in thin sections (obtained from undisturbed soil samples) under a polarizing microscope in early and recent Neolithic layers, as well as in the deepest soil horizons of not well-determined age, which predate the early Neolithic layers and postdate those of the Paleolithic. The whole pedosedimentary record indicates various stages of geomorphic stability leading to pedogenesis, represented by dominant humus accumulation, carbonate leaching and reprecipitation, and poor clay illuviation, alternated with morphodynamic processes recorded by sedimentary phases, occurred during late Pleistocene to mid-Holocene times.

Important reworking processes from outside and/or inside the cave are evidenced by siliciclastic sediments, pedorelicts and/or papules, observed at the microscale in thin sections. Siliciclastic sediments increase from bottom to top along the cave succession (in particular since early to late Neolithic). This can be related to the progressive enlargement of the cave back opening during the time, as a consequence of chemical and physical weathering, at least in part possibly related to advancement of karst processes. In such a seismic and tectonically active area, it is not to be ruled out also the role of possible earthquakes during the Holocene, although no clear documentation is available.

However, some paleoclimatic/environmental interpretation can also be proposed to explain above variation of siliciclastic content along the succession. In fact, the increase of non-carbonate sediments could have been caused by an increase of soil erosion from outside the cave, presumably promoted by high rainfall rates and an overall high moisture availability that characterized the early to middle Holocene (*cf.* JALUT *et alii*, 2009). This interpretation is also consistent with a major soil development during this period (during stages lower geomorphic dynamics) and the occurrence of illuvial clay coatings, which are well-documented in other sites of the mid-latitudes (CATT, 1989), especially in the Mediterranean area (CREMASCHI & TROMBINO, 1998) and southern Italy, during the warm and humid (and probably seasonally contrasted) Neolithic climatic *optimum* (*e.g.* SCARCIGLIA *et alii*, 2009; BERNASCONI *et alii*, 2010; PELLE *et alii*, 2012). Moreover, high moisture conditions could have promoted severe carbonate leaching, water dripping and consequent concretioning on progressively aggrading cave floor.

On the other hand, also one or more drought phases in the late Holocene, already known in the literature (*e.g.* DI RITA & MAGRI, 2009; JALUT *et alii*, 2009) could have been responsible for such an increase in siliciclastic sediments content. In fact, drier climatic conditions could have caused the degradation of arboreal vegetation cover on the landscape coupled with the establishment of herbaceous species (*cf.* ROBERTS *et alii*., 2011), thus leading to a severe land degradation and soil erosion. In addition, aridity phases could have promoted the formation of the major carbonate-concretioned layers.

The most likely hypothesis is that the complex and variegated pedosedimentary infilling of the cave could have been emplaced by alternation of both humid and dry phases during the Holocene, as already documented in other close sites (*e.g.* DI DONATO *et alii*., 2008; SCARCIGLIA *et alii*., 2009).

Such a complexity was presumably enhanced by human activities both in the cave (in particular possible agro-pastoral practices) and in its surrounding external environment, where anthropogenic degradation of the soil and vegetation cover probably occurred. Deforestation could have been carried out to exploit wood resources for settlements, buildings and hearths and/or for creation of arable land (even using fires).

Above chronological constraints permitted us to estimate approximate rates of sedimentary aggradation and soil formation in the range of some hundreds to thousands of years. In addition, we estimated some geochemical weathering indices (among which those based on pedogenic iron) to evaluate the degree of pedogenetic maturity. We realized that the buried soils developed during the Neolithic display a lower degree of weathering than those predating the Neolithic (presumably formed during the late Pleistocene and/or the early Holocene). This behavior is consistent with a shorter time of soil evolution experienced by the former soils, despite their development under the best suited *climatic optimum* conditions. Conversely, the higher degree of weathering of the older, pre-Neolithic soils is coherent with a longer time of exposure to pedogenetic processes prior to their burial, notwithstanding they mainly formed during less favorable climatic conditions possibly during the early Holocene and/or the Last Glacial to the Lateglacial.

CONCLUSIONS

This paper showed the great potential of combining archaeological, geomorphological, pedological, geochemical and micromorphological analyses to reconstruct and compare local environmental responses of pedogenetic and sedimentary processes in the San Michele Cave in Calabria (southern Italy), in response to the natural landscape evolution and late Pleistocene-Holocene climatic changes, and the overprinting effects of man's practices.

Major changes from geomorphic stability to instability are recorded in the main pedostratigraphic features, where soil formation with humification, secondary $CaCO_3$ accumulation and clay illuviation alternate with sedimentary inputs from outside the cave at centennial to millennial scales.

Integrated study of a soil catena in the Turbolo watershed (Calabria, southern Italy): soil processes, hydrology and geomorphic dynamics

FABIO SCARCIGLIA (*), MASSIMO CONFORTI (*, **), GABRIELE BUTTAFUOCO (**), GAETANO ROBUSTELLI (*), PIETRO P.C. AUCELLI (°), FABIO MORRONE (*), FELICE CASUSCELLI (*) & GIUSEPPE PALUMBO (#)

Key words: *erosion, Mediterranean environment, pedogenetic processes, soil catena, soil hydrology*.

INTRODUCTION

Erosion susceptibility varies along slopes as a function of lithology, relief features, hydrological processes, vegetation cover and land use changes, which lead to spatial variability of erosion processes and intensity. The "soil catena" concept (*e.g.* MILNE, 1936) represents a basic and powerful tool for analysing the results of variations in soil profiles (soil depth, assemblage, juxtaposition, thickness and boundaries of different genetic horizons) on a landscape at the hillslope scale (soil toposequence). This concept takes into account the recurrent patterns and changes of soil profiles on a topographic transect and permits to interpret them in terms of interplay between soil-forming and geomorphic processes, based on flow connectivity of materials and processes from hillslope summit to its base. It has been progressively refined and applied to different purposes across the last decades (*e.g.* SOMMER & SCHLICHTING, 1997; BRUNNER *et alii*, 2004; PING *et alii*, 2005; HATTAR *et alii*, 2010), also including evaluation of soil degradation (YANDA, 2000). Tillage effects on soil redistribution play a key role in reshaping and changing sloping agricultural landscapes, influencing soil quality and productivity and causing soil loss rates in places strongly exceeding tolerance levels (*cfr.* DE ALBA *et alii*, 2004 and references therein). The main objective of this study was a multidisciplinary characterisation of a soil catena in the Turbolo watershed (northwest Calabria, southern Italy).

STUDY AREA, RESULTS AND DISCUSSION

A soil catena located along a north-facing slope in the Turbolo watershed was studied with an integrated geomorphological, pedological and hydrological approach. We focused on understanding the interplay among soil-forming processes, geomorphic dynamics, physico-chemical and hydraulic soil properties. The geological and environmental context of the soil toposequence can be assumed as representative of more widespread sites in the same region, as well as of several zones in the Mediterranean area, on the basis of its variegate but common lithological, topographic, pedological and climatic features, on the whole prone to high soil erosion susceptibility (CONFORTI *et alii*, 2011).

The Turbolo stream is a left tributary of the Crati river, and develops longitudinally from west to east up to about 13 km in length. It originates from the eastern flank of the Coastal Range and ranges from more than 1000 m to 75 m a.s.l. Its watershed covers an area of about 30 km^2 and is developed through Palaeozoic metamorphic rocks in the western sector, where high relief and steep slopes dominate, whereas the eastern hilly reaches are characterised by gentler slopes and terraces cut on sedimentary terrains of Neogene-Quaternary ages (LANZAFAME & ZUFFA, 1976).

The soil catena studied consists of six soil profiles in the eastern sector of the catchment, where Pleistocene silty clays of marine origin outcrop. They developed on a slope comprised between 85 and 140 m a.s.l in elevation and 5 to 20° inclined.

The soil profiles were described in the field and sampled for specific laboratory analyses. Chemical and physical analyses were carried out on bulk samples (air-dried, sieved at 2 mm mesh size) from each pedologic horizon. In particular, particle size distribution, organic matter (OM) content, total carbonate, pH(H_2O), electrical conductivity, cation exchange capacity (CSC) and exchangeable bases were determined (MIPAF, 2000). Also undisturbed soil samples were taken from surface horizons and 30 μm thick thin sections were prepared and described under a polarizing optical microscope according to the guidelines of FITZPATRICK (1984), with special emphasis on soil microstructure and pore distribution. Intra-aggregate microporosity of topsoil samples was investigated using mercury intrusion porosimetry. Moreover, hydraulic properties of soil surface were determined using a tension disc infiltrometer (PERROUX & WHITE, 1988). It allowed in situ measurement of the unsaturated soil hydraulic properties (hydraulic conductivity, macroscopic capillary length λ_c and mean pore size $\lambda_m(h_0)$) at water pressure heads close to saturation (WHITE & SULLY, 1987; JARVIS & MESSING, 1995).

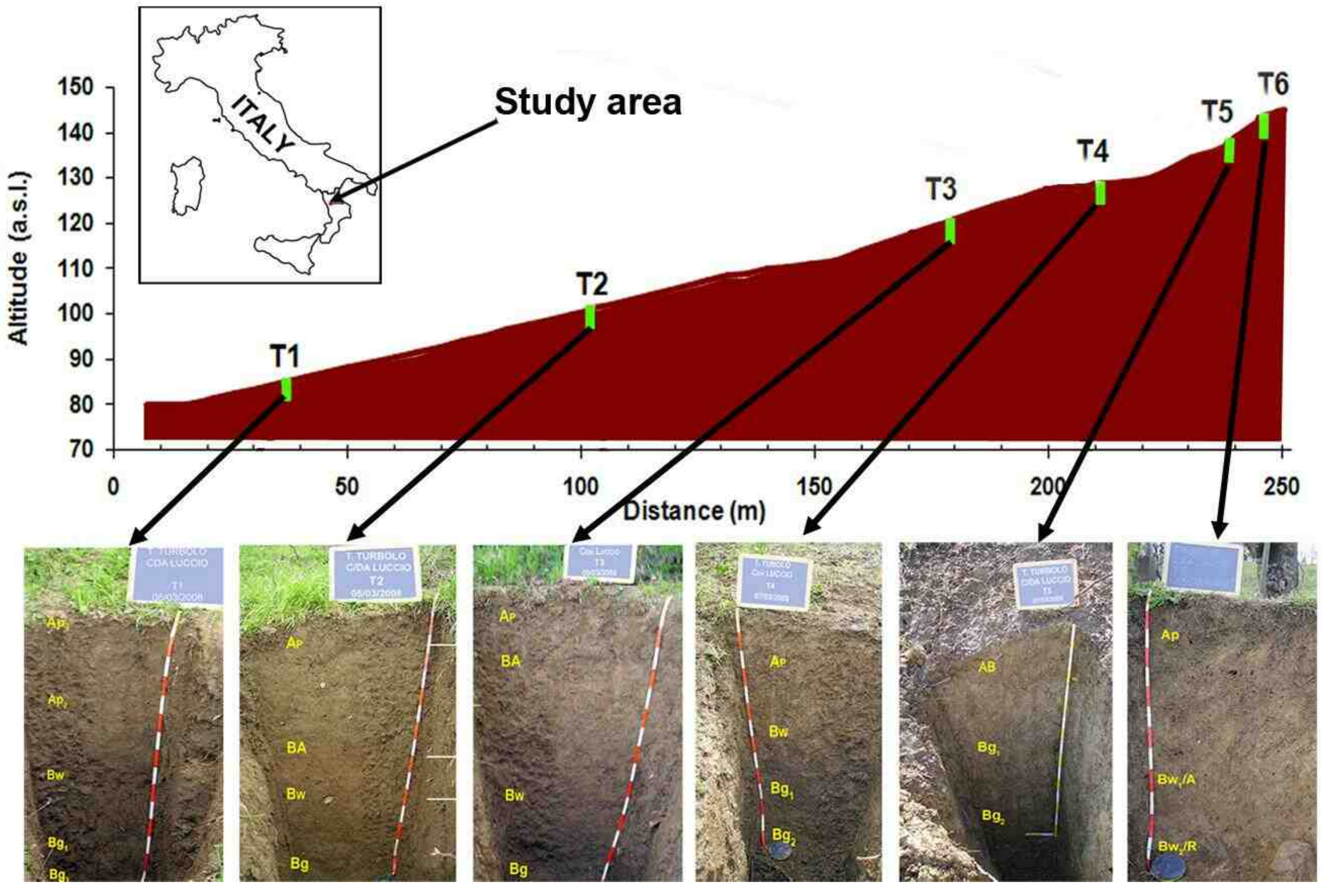

Fig. 1 – Location of study area and soil profiles along the toposequence.

The slope where the soil catena is located is affected by sheet wash and rill erosion, with poor gully incision in places. The present land use is characterised by uncultivated land with sparse olive trees, which followed the recent abandon of agricultural crops in the last decade. The main morphodynamic processes are presumably promoted by such land use change, coupled with the slight local relief of the footslope (about 3 m) above the Turbolo valley-floor, whose main channel occurs less than 100 m far.

The selected soil profiles represent loam to (sandy-)clay-loam Inceptisols characterised by surface accumulation of organic matter (always > 2% except in one profile), neutral to strongly alkaline reaction, granular to (sub)angular blocky (to prismatic) structure, some vertic properties, poor $CaCO_3$ dynamics, and pseudogley features in deep horizons indicating transient *aquic* moisture regime (seasonally saturated) and fluctuating water-table. The soils consist of variable combinations of most or few of these genetic horizons: Ap1-Ap2-BA-Bw-Bg1-Bg2. The variable juxtaposition of such horizons, along with wavy to irregular, sharp to abrupt lower boundaries and variable thickness of surface Ap horizons (completely lacking in one upslope soil profile of the catena and doubled in the lowermost one), clearly testify for the influence of past agricultural activities, soil erosion and colluviation. On the whole, reworked soil accumulation prevails at the footslope, whereas erosion is severer upslope. This is also evidenced by the overall decrease of organic matter upslope and corresponding increase of carbonate reaction and total $CaCO_3$ content (with a correlation coefficient R^2 of 0.77 between OM and $CaCO_3$), which clearly indicate soil rejuvenation. Evidence of surface erosion is supported by the occurrence of some small carbonate concretions in surface or subsurface horizons in the soil profiles located in the intermediate-upper slope. However, also effects of past tillage cannot be ruled out.

The micromorphological analysis of thin sections confirmed the presence of secondary carbonate accumulations, hydromorphic features (Fe-Mn segregations and iron-depleted zones), anisotropic clay domains (observed between crossed polars) representing stress features due to vertic dynamics, and highlighted occasional degenerated clay coatings emplaced by relict illuviation processes. Moreover, topsoils exhibit variably aerated, highly porous structures with frequent evidence of bioturbation and likely anthropogenic disturbance. Some centimetre-thick surface crusts occur, especially in one soil profile along the lower-intermediate slope segment, where subhorizontal, upward-concave, laminar aggregates separated by submillimetric to 1-2 mm thick cracks, were identified.

Mercury intrusion porosimetry performed on topsoil samples revealed slight changes in percentages of intra-aggregate microporosity, but very variable pore size distribution and extremely different permeability. A good correlation was observed between bulk density and porosity (R^2 = 0.89), whereas the correlation is very poor between porosity and permeability (R^2 = 0.16), suggesting the effects of quite varying pore size distribution.

In general terms, hydraulic conductivity values showed considerable variations along the soil catena at different pressure heads h_0. Larger differences occurred at pressure heads h_0 between -9 and -15 cm. Lower values of hydraulic conductivity were determined for the two soil profiles located upslope, which are also affected by severe erosion, as highlighted before. The other hydraulic properties (□$_c$, □$_m$) showed considerable variations, too. The mean characteristic pore sizes □$_m$ showed that at the same imposed water pressure head h_0, the pores hydraulically functioning were larger in soil profile 2 than in other profiles.

These results indicate that the water flow into the soil is characterised by capillarity, which is consistent with a finer texture measured in the corresponding topsoils. This behaviour enhances water runoff rather than infiltration, in turn promoting soil erosion, as also confirmed by field features and trends of above chemical properties (OM and total carbonate content).

Infiltrometer-based hydraulic conductivity and Hg-porosimeter permeability exhibit some relevant differences. The partial apparent discrepancy between these hydrological parameters obtained from these two methods is very likely caused by the well-known soil spatial variability. In particular, the former analyses were performed on single aggregates sampled from topsoils and thus take into account only (or mainly) intra-pedal porosity, whereas do not include the inter-pedal one. In addition, the latter method considers both types of porosity and is mainly influenced by upper soil horizons.

CONCLUSIONS

The integrated geomorphological, pedological and hydrological study of a soil catena in the Turbolo stream watershed (NW Calabria, southern Italy) permitted to highlight the main relief response to geomorphic dynamics. In particular, erosive processes and soil colluviation affect upper and lower slope segments, respectively. They were probably at least partly enhanced by past agricultural activities and their recent abandon. Some interesting relationships among particle size distribution, hydraulic conductivity, estimated microporosity, pore size and their effects on water infiltration or runoff and soil erosion were also evidenced.

Weathering of crystalline bedrock in Sila Massif and Catena Costiera (Calabria, southern Italy)

ANNA CHIARA TANGARI (*), SERGIO ANDÒ (**), LUCA CARACCIOLO (°), EDUARDO GARZANTI (**), EMILIA LE PERA (°) & FABIO SCARCIGLIA (°)

Key words*: clay minerals, heavy minerals, soil development, X-ray diffraction, weathering*

Granitoid and gneissic substrata that widely outcrop in Calabria (southern Italy) have been studied during the last decades in terms of detailed analysis of weathering features and landforms, reaction path modeling, controlling factors and related processes, spatial distribution and relationships with rock/soil susceptivity to degradation, slope instability and erosion (*e.g.* LE PERA *et alii*, 2001; SCARCIGLIA *et alii*, 2007; APOLLARO *et alii*, 2009; BORRELLI *et alii* 2012, and references therein). On the other hand, very poor knowledge exists on weathering profiles developed on gabbroic substrata. This work proposes a comparison of weathering and soil features and processes on gneiss and gabbro in this region, using and integrated approach of pedology coupled with bulk petrography of heavy mineral analyses.

In this paper we report preliminary results concerning the study of weathering and soil profiles (bedrock, grus, soil) developed on gneissic and igneous rocks in the Sila and Catena Costiera massifs in Calabria (fig. 1). These mountainous relieves belong to the northeastern sector of the Calabrian Arc, a section of the Alpine orogenic belt of western Europe, where allochtonous crystalline rocks are now exposed in the highest tectonic unit of the Apennine mountain chain (AMODIO-MORELLI *et alii*, 1976). The Sila massif consists of different Hercynian metamorphic and plutonic terrains, which represent the crystalline basement. The Hercynian rocks consist of gneiss, amphibolite, schist, and phyllite, all of which have been affected by various Alpine metamorphic events and intruded by late Hercynian plutons (the Sila Batholith; MESSINA *et alii*, 1991).The basement is widely exposed in the Sila Massif, but appears strongly thinned in the Catena Costiera area (LIBERI *et alii*, 2011).

Specifically, we sampled three representative soil profiles on crystalline bedrock: two of them, indicated as SC and GP2, developed on gneiss, in Sila (Serra Crista d'Acri site) and Catena Costiera (Guardia Piemontese site), respectively, and the third, GP1, developed on gabbro in Catena Costiera (Guardia Piemontese site). These soils profiles were described in the field and sampled for both chemical-physical and mineralogical analyses. Field study was focused on the main morphological features, such as: type of genetic horizons and their thickness, horizon boundary characteristics (pattern and distinctness), aggregation structures, texture, colour, consistence and pedogenetic features (coatings, concretions, nodules, etc.).

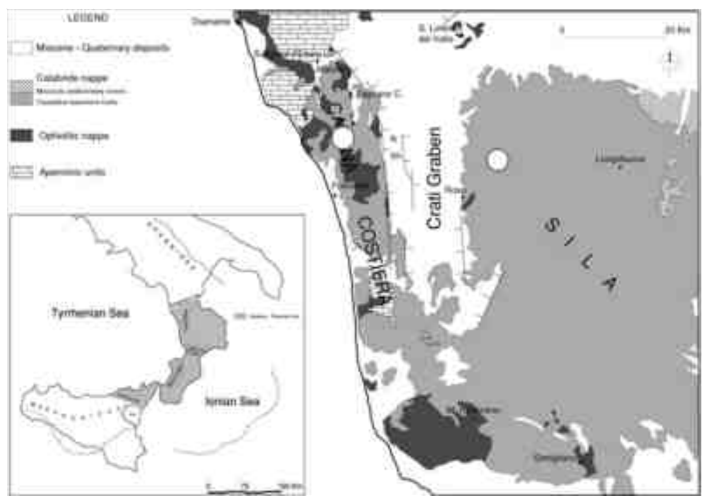

Fig. 1 – Location and geological map of Catena Costiera and Sila Massif (LIBERI *et alii*, 2009), with location of the study sites.

Laboratory methods concerned routine physical and chemical analyses for each soil horizon (particle size distribution, pH(H_2O), organic matter content, cation exchange capacity (CEC), electric conductivity), clay mineralogy analysis using X-ray diffraction (XRD) on oriented specimens of the clay fraction (< 2 μm), and mineralogy of heavy minerals (density > 2,90 g/cm^3). Heavy minerals were studied to better understand the weathering processes at source rock, to study the stability of different heavy minerals with respect to weathering and possibly establish hypothetical trends of alteration for each type of unstable groups (e.g., pyroxene and amphibole groups) (MORTON *et alii*,1999; VELBEL, 2007; ANDÒ, in press).

Field observations outlined the difference between the topsoil

horizons A and transitional AB, and the deepest horizons (Bt and Btg1-Btg2) in the soil profile SC developed on gneiss. These differences are evidenced both in the wavy, slightly sloping boundary of surface to deeper horizons and in varying aggregation structures. In fact, in the former horizons, the aggregates are crumb to granular, while in the deeper horizon they are angular blocky.

Other characteristics showing diversity are the consistence and the main pedogenetic features. The former changes from very weak in the superficial horizons (A, AB) to moderate (Btg1), up to strong in the deepest horizon (Btg2). Conversely, illuvial pedogenetic features, such as clay coatings, tend to increase with depth. In fact, they are more abundant in the deeper horizons than the surface. Some differences in the diagnostic features between superficial and deep horizons are also observed in the other soil profiles, GP1 and GP2, respectively developed on gabbro and gneiss. In particular, in profile GP1 surface soil horizons are more clearly separated from subsoil ones through an abrupt lower boundary. In the soil profile GP2, this diversity is not very marked, but we observed a structuring of the deeper horizons greater than the shallower horizons. The difference between the deeper and shallower portions in the three soil profiles, are also highlighted by laboratory analyses. In fact, the particle size distribution analysis showed, as well as coarse texture, the presence of abrupt grain size distribution changes in all the three soil profiles.

The heavy minerals assemblage was separated from the 32 to 500 µm range. The heavy mineral analysis was performed to describe surface textures observed on detrital grains and evaluate the stages of progressive weathering (unweathered, corroded, etched, deeply etched, skeletal) for diverse detrital minerals in crystalline parent rocks (gneiss and gabbro) in a Mediterranean climate. The main objective of this analysis was to derive heavy mineral suites that might reveal the along profile (grus + soil) pattern of chemical weathering through selective dissolution. The heavy minerals in the weathering profile developed on gabbro (GP1) consist of Ca-Amph+Piroxene, whereas Garnet+Sillimanite occur within the other two profiles developed on gneiss.

In general, the amount of detrital heavy minerals in GP1 profile (developed on gabbro) decrease from grus to soil, particularly the amount of pyroxene and apatite grains. In the SC profile (developed on gneiss) pumpellyite grains occur but these are lacking in the GP2 profile (also developed on gneiss).

Optical analysis of the amphibole and pyroxene grains from GP1 profile showed that highly corroded grains tend to increase from bottom to top of the soil profile, dued to dissolution or transformation of these less stable minerals enhanced by the topsoil organic acids. Heavy mineral grains concentration and diversity in SC and GP2 profiles increase from bottom to top, suggesting a more recent addition of parent material to the soil profile with consequent rejuvenation of soil-forming processes.

XRD analysis of the clay fraction showed the occurrence of vermiculite, kaolinite, illite and lower concentration of chlorite in each soil horizon. The only difference concerns the soil profile GP1, where also smectite occurs in addition to above clay minerals.

Smectite and kaolinite are typical weathering products of feldspars, whereas illite and vermiculite often derive from micas (both biotite and muscovite). Therefore, these clays are derived from the alteration of the main primary minerals present in the bedrock. Chlorite may represent the product of hydrothermal alteration formed both in gabbro and gneiss parent rocks.

On the one hand, the occurrence of kaolinite among the clay minerals indicates a rather high pedogenetic maturity, whereas the other phyllosilicates (chlorite, vermiculite and smectite) depict an early degree of advancement of pedogenesis. For this reason, the overall degree of alteration can be considered as moderate. This behavior could be explained by a rejuvenation of the weathering front due to erosion, which is indicative of a process under an overall weathering-limited regime.

Finally, the differences between the deeper horizons (pedogenetically more developed) and surface horizons (showing a younger pedogenetic degree) lead to assume the presence of a discontinuity between topsoil and subsoil horizons, even though such discontinuities are not always clearly identified in the field. These conclusions are confirmed in the three soil profiles by the discontinuous distribution of the heavy minerals fraction, the presence or absence of specific heavy minerals from the deep to the superficial horizons and from particle size distribution analysis. These features could be explained by a rejuvenation caused by erosion. Probably, pristine horizons were truncated by erosion and buried by further sedimentation, leading to the formation of younger soil horizons at surface. Therefore, both pedological and petrographic data outline a younger degree of evolution of pedogenesis than expected, which characterizes all the three profiles, even if in a different way and extent.

INTRODUCTION

It is well known that the assessing of the solid contribution provided by streams to a coastal setting plays a key role for the coastal equilibrium. The main source of sediments for coastal areas is the catchment area, by which is subtracted the excess material in the process of soil degradation and weathering of rocks. This material is then carried along the hydrographic network in the form of suspended- and bed-load, depending on the grain-size and energy of the water current.

In non-altered ecosystems, erosion is a natural phenomenon, but an acceleration of this process, due to anthropogenic disturbances, may lead to a gradual degradation of soil fertility and therefore their potential productivity. This process is influenced by many factors such as climate, soil type, morphology, hydrology, vegetation, crops, as well as processing systems and cultivation conducted in the examination area. Several attempts to evaluate and estimate the erosion phenomenon, resulting in the solid contribution supplied by the river to the coast, were conducted through the use of different mathematical models characterized by different degrees of complexity.

The USLE (Universal Soil Loss Equation) model, proposed by WISCHEMEIER & SMITH (1978), represents a good compromise between applicability (availability of necessary input data: climatic, topographic, soil and crop) and reliability (estimated soil loss) for the evaluation of the annual surface erosion of a single agricultural parcel.

With the aim to acquire additional elements for a better understanding of hydrological processes and coastal erosion, it is here presented the attempt to estimate the potential erosion of the Volturno River basin (southern Italy) through the application of the USLE model.

THE VOLTURNO RIVER CATCHMENT

The Volturno River is the largest river in Southern Italy, extending for 175 km and with a drainage basin of 5653 km^2; it occupies a considerable portion of Campania and Molise regional territory. Its headwaters are located in the Meta-Mainarde massif, at an elevation of about 560 m. The basin has a perimeter of 564,4 km and a drainage network developed for 12,960 Km.

The catchment area includes lithological units of different paleogeographic domains that have had different geodynamic evolution. The contribution of different sediment sources created a very complex stratigraphic setting with facies heteropy even over a short distances, characterized by lithotypes with different lithology, grain size and, therefore, different degrees of permeability.

THE EROSION MODEL: USLE

The basic equation of the USLE model (1) is:

$$E = R \times K \times LS \times C \times P \qquad (1)$$

where:
E = estimated annual soil loss (t ha/year);
R = annual rainfall erosivity factor (MJ mm/h ha year);
K = soil erodibility factor (t ha h/ha MJ mm);
LS = topographic factor, express by the product of the slope length factor (L) and slope-steepness factor (S) (adimensional);
C = cover and management factor (adimensional);
P = antierosive and conservation practices factor (adimensional).

The USLE erosion model has been developed, in the present study, into a GIS environment with the aim to obtain an estimate of soil loss expressed as t ha/year. For each parameter required by the USLE equation, it has been necessary to realize specific layers for the GIS project. Inside the latter, data are analysed through a series of operations based on the topological organization of cartographic data.

DISCUSSION AND CONCLUSION

Through the topological overlay of cartographic documents, only in vector format, a partitioning of the investigated areas was determined; in this way each partition is characterized by attributes, represented by the scores provided by the method in evaluating each factor, that contributes to assess the potential erosion. The above operations have also enabled an integrated assessment of the mutual influences and interactions that exist between the different factors affecting the erosional processes, such as rainfall, soil type, topographical features, coverage and

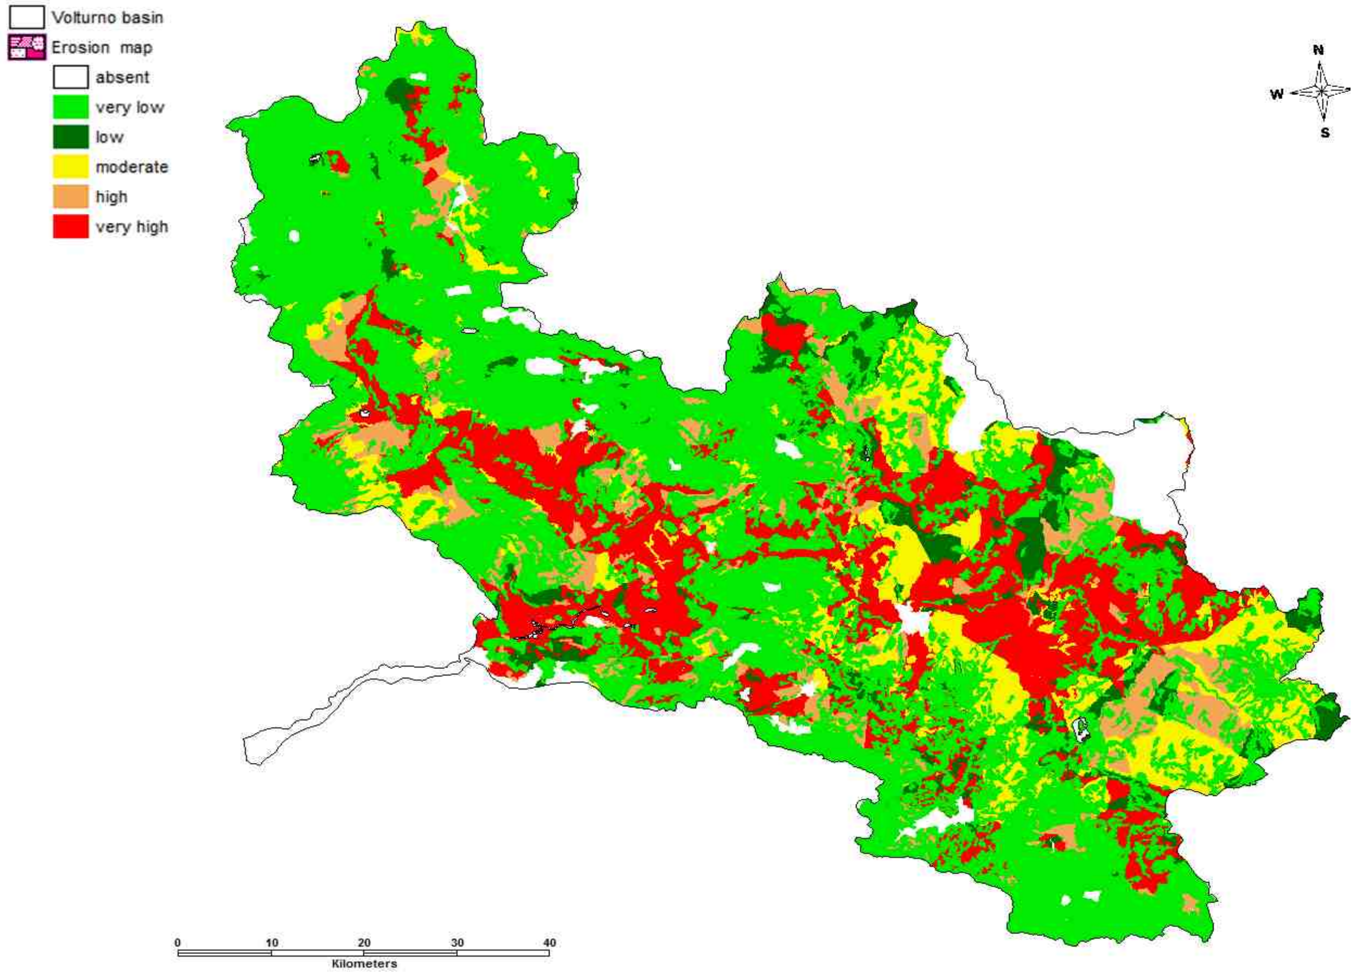

Fig. 1 - Erosion map for the Volturno river basin.

antierosive management practices exercised.

The erosion map highlights the most vulnerable areas interested by soil erosion and also gives an estimate of the maximum soil erosion. The latter is equal to 335,960 t/ha per year; taking into account that the basin area is 565,342 ha, it is possible to define the average soil eroded for the entire basin as about 7,408,479.94 t/year. From the above map it comes that the 55.6 % of the catchment is affected by very low erosion, 6 % by low erosion, 9.8 % by moderate erosion, 8.3 % by high erosion, 20.1 % by very high erosion.

Although the USLE provides useful indications for mitigating intervention planning on erosion processes, the amount of soil loss calculated in this way represents the "gross erosion", while the quantity of sediment deposited in stream is the "net erosion", which generally represents a small percentage of the former (ONORI et al., 2006). The relationship between "net erosion" and "gross erosion" is defined Sediment Delivery Ratio (SDR) that is influenced by a several number of factors (e.g. erosion type, catchment characteristics and sediment entrainment; BAGARELLO & FERRO, 2006).

Based on the calibration carried out on southern Italy catchments (cf. DUCCI et al., 2007, and reference therein), the SDR for the Volturno basin has been thus estimated:

$$SDRw = 5.37 \times 5{,}653.42(-0{,}69) = 0.014$$

This value indicates that only 1.4% of the eroded soil would arrive at the catchment outlet and it accounts for 103,718.719 t/year. This means that much of the eroded material does not reach the sea, although this result is influenced by the inability of the model to adequately simulate the gully erosion, sheet erosion and rill erosion in the catchment. Nevertheless, these limits are common to several erosion models; the simulation of these phenomena needs specific models for each erosion phenomenon.

Quaternary morpho-evolution, tectonic and environmental changes in the Boiano intermontane basin (central-southern Italy)

VINCENZO AMATO (*), PIETRO PATRIZIO CIRO AUCELLI (**), ELDA RUSSO ERMOLLI (***), CARMEN MARIA ROSSKOPF (*), MASSIMO CESARANO (*), GERARDO PAPPONE (**)

Key words: *Chrono-statigraphy Middle Pleistocene, Palaeosurfaces, Palaeoenvironments, Ar/Ar datings, Molise*

The Molise Apennine, located in the northern sector of the southern Apennine arc, is characterized by the presence of several Quaternary intra-montane basins of tectonic origin (Isernia, Carpino-le Piane, Sessano, Boiano, Sepino) (Fig. 1). Their evolution has been strongly influenced by the development of fault systems related to the post-collisional extensional tectonics that have affected these sectors of the chain since the Late Pliocene–Early Pleistocene, and since Middle Pleistocene, was controlled by extensional fault systems with a general NW–SE trend (AMATO *et alii*, 2011). The Boiano and Sepino basins, located within a narrow NW–SE deformation belt, are filled with huge Quaternary successions of marshy to lacustrine, volcanoclastic and alluvial deposits (AMATO *et alii*, 2010). Middle Pleistocene-Holocene chrono-stratigraphical and environmental data were available for the Boiano infilling successions (ISPRA, in press).

In order to better understand the chrono-stratigraphical features of the Boiano basin deeper infilling and its environmental and tectonic evolution, an integrated geomorphological, stratigraphical, geochronological, tephrostratigraphical, pollen and structural approach was carried out.

CHRONO-STRATIGRAPHY AND TECTONIC

Two new deep boreholes, appositely drilled in the centre of Boiano town at 480 m a.s.l. (S1 and S2 in Fig. 1), were carried out. The choice of the location of the cores was estabilished by a preliminary stratigraphical study of c. 50 boreholes, found at local and regional administration offices and by a detailed geomorphological study of the 1:5.000 Regional Topography Cartography. The thickness evaluation allow to identify sectors where the infilling is very huge (> 200 m), as between S. Massimo and Boiano, as in the Campochiaro alluvial fan and into the Sepino basin (Fig. 1). The latter are separated by sectors where the infilling is only few tens meters (generally < 25 m), as between the Castelpetroso pass and San Massimo village, as between Boiano and S.Polo village, and near the Vinchiaturo pass.

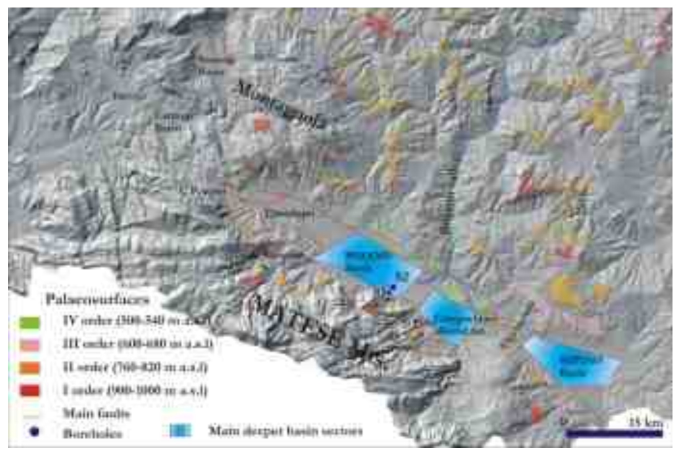

Fig. 1 – The Molise Apennine with the main intramontane basins,. In evidence the main faults , the palaeosurfaces, the sector of the basin more depressed and the location of the cores of the Boiano-Sepino basins

These thickness variations as the result of two distinct developmental stages of tectonic origin. The first stage, referring to the early Pleistocene, was characterized by the formation of NNW-SSE left transcurrent deformation zone, which ran along the basin. Within the deformation zone a partitioning with the formation of small subsidence areas was generated, elongated in the apennine direction, and separated by less subsidence areas. Unfortunately, none of the logs inside the basin reach the deposits related to Early Pleistocene. Tentatively, this stage of development may be related to the well-known lacustrine deposits outcropping in the S. Massimo area (DI BUCCI *et alii*, 2005). The second stage started from Middle Pleistocene with the onset of the NE-SW oriented extensional regime. The previously depressed areas continued to be subsident and to accomodate thick successions of lacustrine and fluvial-marshy sediments. The Middle Pliestocene syntectonic deposition within the basin is well documented by the presence of faults that displace some volcanoclastic layers dated in this work.

The drilled successions in the one of these deeper sectors

(Boiano town, Fig. 1) considerably contributed to improve the chrono-stratigraphical, palaeo-environmental and tectonic knowledge since Middle Pleistocene. The chronological framework was more clearly constrained through the $^{40}Ar/^{39}Ar$ datings of three tephra layers sampled in the S1 succession. On the basis of lithofacies, unconformities, presence of tephra layers and paleosols, the core successions were subdivided into lithostratigraphical units. The sedimentary units, the tephra layers and the main lithological unconformity was correlated in order to evaluate the presence between the two cores of sedimentary discrepancies, stratigraphical gaps and altimetrical discrepancies of the known layers. The integrated facies analyses, the chrono-stratigraphical and environmental features of the two cores were reported in ISPRA, *in press* and in AMATO *et alii*, 2010, while in this work are reported only the main data useful to the understanding the Middle Pleistocene-Holocene evolution of the basin. The main result are shown in Tab. 1, while the proposed correlations are shown in Fig. 2.

Starting from the Ar/Ar chronological framework the units 1 and 2 can be referred to the Middle Pleistocene, while the Unit 3 to the Late Pleistocene-Holocene. In particular the units 1was deposited between 500 and 400 ky BP, while unit 2 was deposited until c. 300 ky BP (Fig. 3). In this way the great part of the investigated succession was deposited during Middle Pleistocene, from OIS 13 (c. 500 ky BP) to OIS 9 (c. 300 ky BP), testifying an high sedimentation rate for this interval caused by a strong subsidence of the basin (Fig. 3). The latter

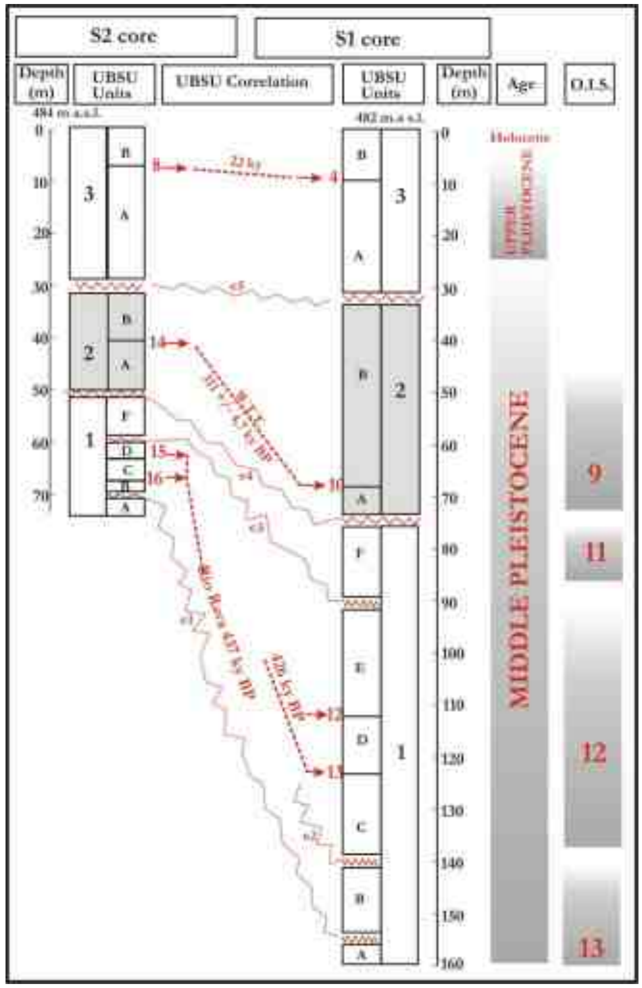

Fig. 2 – Chrono-stratigraphical correlation between the units and sub-units of the S1 and S2 cores. The erosional surfaces are signed with red symbol e while the tephra layers are signed with a number. The red dashed lines show the proposed correlations.

don't was homogeneous between the two cores: in fact the two Middle Pleistocene tephra layers (MOL13 and 10) were recognized at very high different depth, testifying a presence of fault between the two cores (Fig. 1), active during this period..

PALAEOSURFACES

Along the border of the Boiano and Sepino basins and into the Biferno valley four main orders of palaeosurfaces were recognizable, in addition to those hanging over of hundreds meters on the local base level of the plain, and located over 1000 m a.s.l. in the Matese and Montagnola mountains (Fig. 1). The palaeosurfaces are the relicts of paleolandscapes, mostly of erosional origin, which represent the remnants of gently-rolling ancient landscapes now hanging at different altitudes above the local base-levels of erosion. Their genesis can be related to prolonged periods of relative tectonic stability alternating with periods of uplift, or to the interplay between steady tectonic

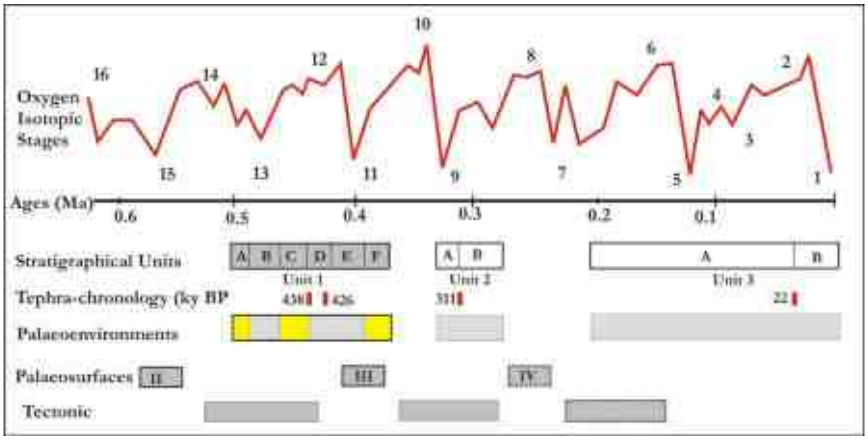

Fig. 3 – Boiano basin infilling chronology in relation to the identified palaeosurfaces, tectonic, environments (in yellow the lacustrine-palustrine intervals, in grey the fluvial-marshy intervals), and Oxigen Isotopic Stages

uplift and climatic fluctuations. The four orders of paleosurfaces are: I (900—1.000 m a.s.l), II (760—820 m a.s.l.), III (600—680 m a.s.l.), IV (540-500 m a.s.l.) (Fig. 1). The most ancient order (I) is cut into the bedrock and are mainly located on the flanks of the Matese and Montagnola massifs. The II order, at S. Massimo cut into Quaternary deposits, are recognizable along all the border of the Boiano and Sepino basins, hanging over the base level of c. 320 m. Their gradient is mainly oriented ward the plains, and their age is clearly estabilished by Ar/Ar datings of the S. Massimo fluvio-lacustrine deposits (DI BUCCI *et alii*, 2005). So this order is later than 0,6 Ma BP. The III order, cut both into quaternary deposits both into pre-quaternary bedrock, are located in all the borders of Boiano and Sepino basins and along the valley flanks of the Biferno river. Their gradient is oriented ward the basins and only partially ward the Biferno valley, testifying a connection between the two basins, which hosted lacustrine environments. In addition, the III order could be correlated with the SBP palaeosurface of the very close Sessano basin (AUCELLI *et alii*, 2011), that was dated at 0,3 Ma BP. The IV order are located along the borders and into the basins and along the Biferno valley, testifying the Biferno river capture of the Boiano basin. Near Vinchiaturo village, this order represents the watershed between Boiano and Sepino basins, testifying a separation between the two basins since this phase.

CONCLUSION

The integrated chrono-stratigrafical data of the Boiano basin infilling and the palaeosurfaces remnants hanging over the basin and the Biferno valley allow to understand the main morpho-evolution changes of the Middle Pleistocene, related to the main tectonic phases and climatic fluctuation (Fig. 3):

- the investigated infilling cover an interval spanning between the OIS 13and today (500 ky BP-today)
- from 500 ky BP and 300 ky BP the sedimentation was mainly lacustrine-palustrine and secondly fluvial-marshy with high sedimentation rate caused by strong subsidence and by volcanoclastic sedimentary inputs. The remnants of the palaeolandscapes of this phase are now hanging over the border of the plain at c. 600-680 m a.s.l. (c. 120-200 m over the base level of the basin) (III order of palaeosurfaces). The II order (760-820 m a.s.l) was just hanging over the basin because dated at c. 0.6 Ma by DI BUCCI *et alii*, 2005. In this phase most probably the Boiano and Sepino basin were connected.
- from 300 ky BP and a 250 BP, the sedimentation of the basin was mainly fluvial marshy and secondly palustrine. The remnants of the palaeosurfaces (IV order, 540-500 m a.s.l.) of this phase are now hanging over the basin of c. 60-20 m testifying a decrease of the subsidence rate. Only in the sector of the Boiano town and in the other more depressed sectors of the basin the subsidence was active: in fact a differential subsidence is recorded between the two Boiano cores, caused by the presence of a fault. In this phase the Boiano and Sepino basins were separated.
- in the last 250 ky BP the sedimentation was mainly fluvial-marshy, with many stratigraphical gaps testifying a similar to the present environments, a decrease of the subsidence and changes induced by climatic changes.

INTRODUCTION

The Quaternary basins of the axial zone of central Apennines represent a key areas for a better understanding of the morphotectonic evolution of this sector of the chain, during the Pleistocene times. In the axial zone of the Umbria-Marche Apennines are preserved several fault-bounded intramontane basins, formed at the end of Lower Pleistocene. These basins was raised by Pleistocene tectonic uplift and subsequently some of them were partially incised by fluvial network.

In order to improve the knowledge on the evolution, and the extinction of these basins, morphotectonic features, such as relicts of ancient and more recent planation surfaces and drainage network arrangements, have been correlated to the distribution of the master faults which controlled the development of the intramontane basins of Umbria-Marche sector. Gravimetric measures produced in the basins have allow us to reconstruct the arrangement in the depth of the sedimentary top of bedrock, and to evaluate the thickness of the Quaternary clastic infill of basins.

GEOLOGICAL FRAMEWORK

The Colfiorito, Norcia, Castelluccio and Leonessa basins are located in the central Apennines (Fig. 1), constituted by a Neogene fold and thrust NE-vergent belt (DEIANA & PIALLI, 1994). These intramontane depressions are filled by Pleistocene to Holocene fluvial-lacustrine coarse grained deposits, whereas the bedrock units are represented by limestone and pelagic marls of Jurassic to Miocene age (The Umbria-Marche succession; CENTAMORE & DEIANA, 1986). Several historical and instrumental highly destructive earthquakes have occurred in this area: January 14, 1703 (X MCS, M=6.6); September 19, 1979 (Ms = 5.9, focal depth of 6-8 km); September 26, 1997 (Mw = 6.0, focal depth of 6-8 km). Fault data and earthquake focal mechanisms show a predominant NE-SW extension, but strike-slip and even reverse mechanisms have also been determined (TONDI & CELLO, 2003).

The Colfiorito basin is made up of several small depressions filled by fluvial-lacustrine continental sediments dating back to the late Lower Pleistocene (FICCARELLI & SILVESTRINI, 1991). These small depressions are bounded by normal to oblique-transtensional faults displaying a general NW-SE trend. Their recent activity is clearly shown by the occurrence of minor faults, within continental Upper Pleistocene deposits, showing centimetric to decimetric oblique- to dip-slip normal motion.

The Norcia basin is affected by two major NNW-SSE trending faults turning north-south at both ends. Evidence of recent activity along these faults is due to the existence of fault scarps in the Pleistocene-Holocene fluvio-lacustrine sediments infilling the basin. The surface of the Norcia basin is flat, slightly inclined to the NW, with only an almost isolated basement hill in the middle.

The Castelluccio depression (Fig. 2) is a hanging basin located eastwards of the Norcia area. Along the western slope of the Vettore Mountain a well preserved fault scarp is exposed in bedrock, for a length of about 7 km. The fault branches into two splays: the eastern one strikes N150°, whereas the western fault branch maintains a roughly constant north-south trend. Kinematic indicators (striae) from shear surfaces exposed along fault scarps in bedrock record left-lateral strike-slip motion along the north-south oriented splay and a transtensional behaviour, with a sinistral component of slip, of the N150° trending one.

The Leonessa basin is a WNW-ESE elongated tectonic depression infilled with Pleistocene-Holocene continental deposits and bounded by a NE dipping, N130° striking fault. The fault is exposed in bedrock for a length of about 20 km and shows a dextral transtensional behaviour with a strong dip-slip component of motion (TONDI & CELLO, 2003).

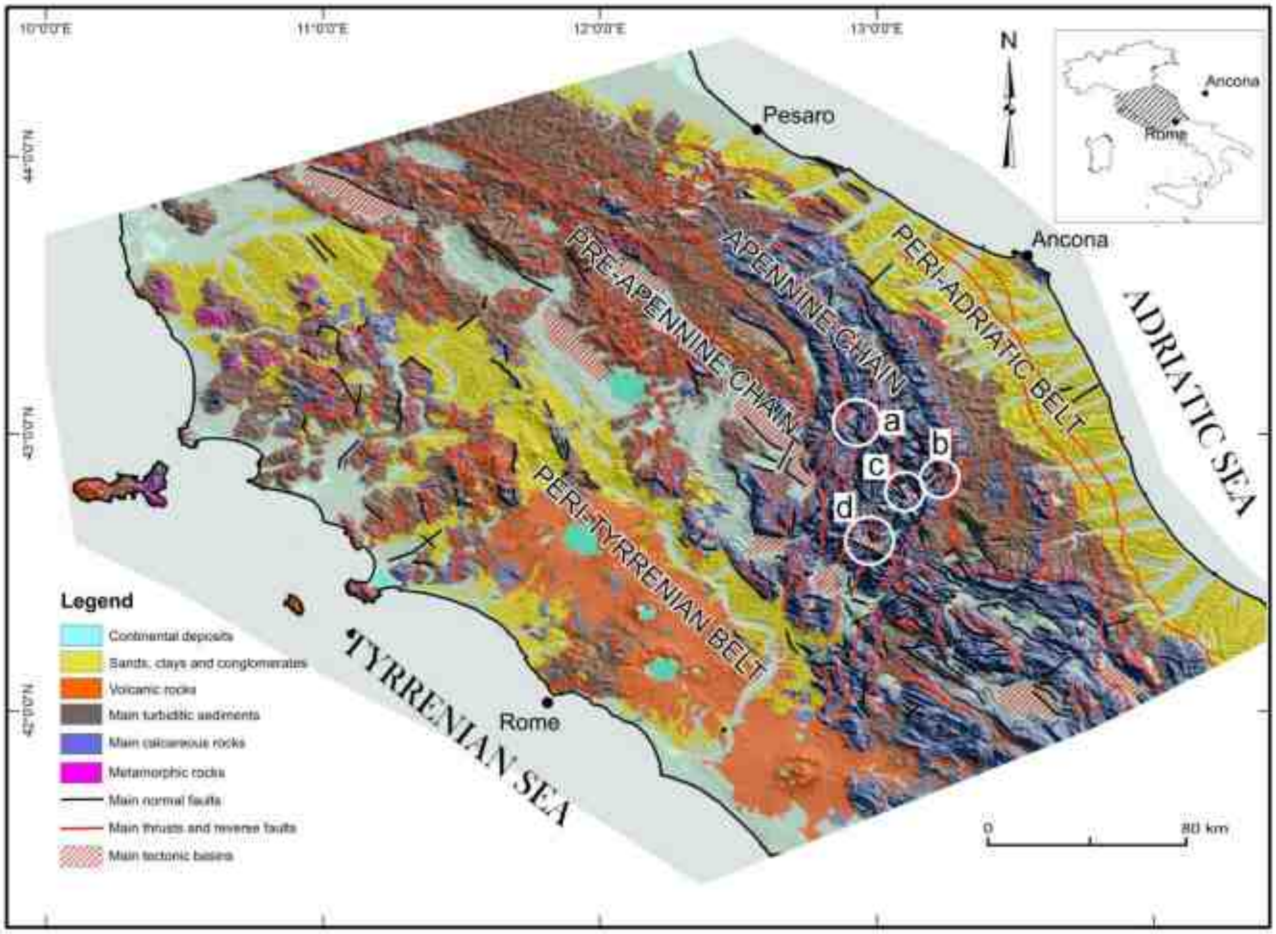

Fig. 1 – Geological sketch map of the Umbria-Marche Apennines. White circles show the studied intramontane basins: a) Colfiorito, b) Castelluccio, c) Norcia, d) Leonessa.

GEOMORPHOLOGICAL SETTING

The most ancient landform distributed in the summit of relief of the entire central Apennines chain is the Palaeosurface Auctt. (COLTORTI *et alii*, 1996; COLTORTI & PIERUCCINI, 2000). This latter represents an ancient erosional landscape modelled in a continental environment, after the emergence of the central Apennines chain occurred in the Early-Middle Pliocene. It is actually fragmented and displaced by erosional processes and tectonics and only some remnants crop out in the axial zone of the chain. The Palaeosurface *Auctt.* was prevalently sculptured in a carbonate bedrock producing a low-angle landscape. The morphoclimatic regimes which sculptured this ancient landscape have been in the first instance a warm-arid climate and successively a cold-arid one, consequently the palaeosurface could be considered as a polygenic landform. The first and slow uplift occurred in the chain produced a vertical incision by fluvial networks and then large fluvial valleys were produced in the palaeosurface landscape. In the Early-Middle Pleistocene a rapid uplift, which is related a strong extensional tectonics, dismembered the ancient landscape of the palaeosurface together with gravitational and tectono-gravitational phenomena (ARINGOLI *et alii*, 2010). Several tectonically-controlled basins - such as the Colfiorito, Norcia, Castelluccio and Leonessa basins - were produced in the hanging wall of master faults of the chain.

Fig. 2 – Panoramic view of the Castelluccio intramontane basin.

DISCUSSION AND CONLCUSION

In order to determine the distribution of the sedimentary infill, a gravity survey has been developed in the region (Fig. 3), including several profiles orthogonal to the depression edges and additional scattered data that improve the map coverage. Measurements have been done in the depressions and also in the basement in order to determine the regional anomalies. A

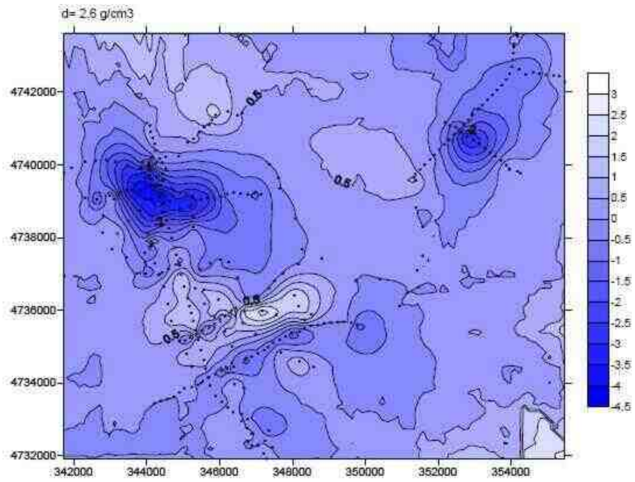

Fig.3 – Residual anomalies map of the both Norcia and Castelluccio basins.

Scintrex CG-5 gravitometer with an accuracy of 0.001mGal, a barometric altimeter of 0.5 m of precision, and a Garmin e-trex GPS have been used during the acquisition of the 294 measurements. A density of 2.60 g/cm^3 (mean density of the basement limestone) has been considered for calculating the Bouguer Anomalies. Terrain corrections have been determined using the SRTM90-m. The Foligno absolute gravity base station has been taking into account during this survey. The Bouguer Anomaly is negative in all the area, with a regional trend that decreases northeastwards, indicating an increase of crustal thickness towards the Apennine edge, in agreement with the regional Bouguer map available from whole Italy.

The sedimentary infill of the four studied basins show different relationships with the active normal-transtensional faults that surround them. In the Colfiorito basin, the depocenter is located in downthrown-block fault and appear not be direct related to the main fault bordering the basin to NE. In the Norcia basin, a roughly triangular depocenter is located to the northwestern part (Fig. 3), where probably are situated the most intense tectonic activity. It is surrounded by sharps west and northeastern scarps, corresponding to faults, the second clearly formed on recent sediments. Surprisingly, the southern half of the Norcia Basin, in spite of its flat character, seems to have a very thin practically absent sedimentary infill. It may represent an old flat surface of erosion, perhaps downthrown during recent fault activity. The Castelluccio depression has a slightly asymmetrical sedimentary infill (Fig. 3), controlled by faults located to the northwestern and northeastern borders. In the Leonessa basin, the depocenter is parallel to the main faults bordering the basin to SW but displaced in respect to the same fault.

These different relationship between the sedimentary infill and the active normal-transtensional faults that bound the basins could have different reasons. For examples, at the initial stage, these basins could have had an endorheic behavior (i.e. Castelluccio basin); moreover, basins are easily captured by the fluvial network, as it possible to observe in the Leonessa basin.

A correlation between the morphotectonic features, such as palaeosurfaces displaced by faulting activity and relict of fluvial palaeovalley and the master faults which bound the basins and their continental infills, allow us to establish step by step the activity of the master faults for each basin. Faulted slopes, faulted fan and fluvial deposits pertaining to the Pleistocene infill of basins, hanged fluvial valleys, and wide fault scarps represent the more recent evidence of the faults activity in the basins. The reconstruction of the clastic basin infill by means of gravimetric data allowed us to know the subsurface distribution of the bedrock and then to recognize the palaeo-morphology arrangement of the basins. It will be possible on the other hand to connect the buried morphology of the basins with the surroundings landforms and processes such as palaeo-hydrographic network and huge landslides.

Tectonic history and subsidence of the Betic intramontane basin: a key to record timing and exhumation rates in the Alboran domain

J.M. AZAÑON (1,2), J. RODRÍGUEZ-FERNÁNDEZ (2), F.J. ROLDÁN-GARCÍA (3), A. AZOR (1), M. DELLA SETA (4)

Intramontane basins in the Betics represent past and present-day depressed areas surrounded by mountains. These basins are mainly located in the central and eastern parts of the chain. South of these basins, the biggest one is the Alboran basin in the westernmost Mediterranean, which is bound westward by the Gibraltar arc (an oroclinal bend), and opens eastward to the Algero-Balearic basin. The Betic intramontane basins provide a record of late orogenic extensional tectonics, after a poorly known early collisional stage (Eocene). This record includes information on ages of basin initiation, as well as tectonic controls on depositional systems and basin architecture. Biostratigraphic age controls on strata and their relationships to the main faults systems allow us to infer that these basins initially developed on the hanging walls of the major extensional detachments that were active in Late Serravallian-Early Tortonian times (13–7 Ma). The exhumation history of the various surrounding basement units can also be obtained from the sedimentary record, through provenance studies, and these can be combined with thermochronometric data on the basement. The present-day altitudes of well-dated near-shore sedimentary rocks can provide some constraints on uplift rates in the sierras surrounding the basins. The aim of this contribution is to summarize the main features of the Betic intramontane basins in terms of sedimentary record and structural style, in order to infer the timing of the main late orogenic tectonics events in the basins and exhumed basements. These interpretations will then be integrated into current models of tectonic evolution for the Betics as a whole.

The evolution of Tammaro River Basin (Southern Apennines, Italy): tectonics and morphometric analysis

ELENA CARTOJAN (*), BRUNO MASSA (*) & ALESSIO VALENTE (*)

Key words: *morphometric parameters, Tammaro River, tectonics.*

INTRODUCTION

The Tammaro basin is about 670 km2-wide, it is located in Southern Apennines between Molise and Campania regions. Its main springs are sited in Matese Mounts, a carbonate massif. The Tammaro R. hydrgraphic network features an asymmetrical distribution of elevations and gradients, with a mean flow of 7.84 m3/s.

Carbonate units derived from the Apennine platform constitute the geological substrate of the basin. External units of southern Apennine chain also crop out in the study area; They are mainly made up of Late Miocene-Pliocene basin deposits consisting of sandstones and clays interbedded with marls and limestones, of Sannio and Fortore tectonic units (CASNEDI *et alii*, 1982). Finally, Quaternary deposits, consisting of landslide piles, scree-taluses, alluvial and fluvial deposits, widely crop out (BERGOMI *et alii*, 1975). Pre-Quaternary fault systems affect the describe dgeological units, they are mainly NW-SE and NE-SW and strongly imprint hidrographic network development (PESCATORE *et alii*, 2008). Youngest tectonic features are represented by E-W and N-S faults (PESCATORE *et alii*, 1996), very difficult to recognize in the field depending on the presence of many poorly conservative lithotypes (APAT, 2007).

METHODS

Tammaro Basin and its hydrographic network were investigated through methods useful to the reconstruction of the evolutionary model, taking into account the tectonic signature (morphometric features). Data processing was carried out using the GIS tools and applications.

The morphometric analysis of drainage basin is based on elevation-relief ratio (CICCACCI *et alii*, 1988; CENTAMORE *et alii*, 1996), slope, relief energy and morphometric features (AF: Asymmetry Factor; HI: Hypsometric Index) investigation (STRAHLER, 1952; PIKE & WILSON, 1971; HACK, 1973; KELLER & PINTER, 1996). The quantitative analysis of drainage system performs a parameterisation of hydrographic network anomalies (AVENA *et alii*, 1967), an estimate of the erosion rates through the suspended sediment yield (Tu) index (CICCACCI *et alii*, 1986, 1988, 1992; LUPIA PALMIERI *et alii*, 1995, 1998, 2001), a longitudinal profiles analysis (WHIPPLE & TUCKER, 1999; SCHUMM, 2000; BURBANK & ANDERSON, 2001; WOBUS *et alii*, 2006), an estimate of the Stream Length gradient (SL) index (HACK, 1973; KELLER & PINTER, 1996); furthermore, it considers the statistical azimuthal distribution of river channels (BENEDUCE *et alii*, 2004; RIBOLLINI & SPAGNOLO, 2008).

RESULTS

Geomorphic indexes show a low organisation for drainage network in the sub-basins located on the left side: the highest number of anomalous basins are here set. Up to 57.7% of bibliographical derived fault segments, fall in the most anomalous sub-basins; it suggests that a low basin organization strongly depend on substratum lithology and tectonics, mostly for widest and high hierarchical-order basins.

Data analysis shows a strong relationship between erosion rates and elevation-relief ratio. Areal erosional processes predominate in upper part of Tammaro hydrographic basin as confirmed by several Hypsometric Integral (HI) values lower than 0.45. Conversely, high HI values for sub-basins at the Tammaro-Calore confluence attest a predomination of linear erosion processes with an high convex longitudinal profile at the mouth. A quite equilibrate relationship between areal and erosional processes was discovered for all others sub-basins.

Recognition of several knickpoints and SL (Stream Length gradient) index variations along longitudinal profile are clues of a fluvial landscape very far from an equilibrium. Major sub-basins experience a typical regressive erosional trend, induced by a lowering of the relative base level. On the contrary, minor sub-basins tend to evolve, initially, trough regressive erosional processes; afterwards the erosional processes is locked by the different migration rate of knickpoints between main and tributaries channels; this evolutionary hypothesis could be useful for the explanation of southern sub-basin evolution, they show clues of reactivation of erosional processes but with a very

(*) Dipartimento di Scienze per la Biologia la Geologia e l'Ambiente, Università degli Studi del Sannio, Via dei Mulini 59/A, 82100 Benevento. E-mail: elena.cartojan@unisannio.it, massa@unisannio.it, valente@unisannio.it.

This research was financially supported by FRA – Università degli Studi del Sannio, Resp. Alessio Valente.

low erosion rate.

Statistical analysis of fluvial channels azimuthal distribution outlined a NW-SE and NE-SW main trends, this is in accordance to key regional tectonic lineaments. In this view, high-order fluvial channels are mainly subsequent. E-W and N-S trends are preferential for low-order channels (1st and 2nd): this is a clue of more recent activity of hosting structures.

DISCUSSION

An approach based on tectonic and morphometric analyses allowed a complete reconstruction of the Tammaro Basin evolution: firstly extremely influenced by natural factor as lithology and tectonics, then strongly conditioned by anthropic activities, these last responsible for slope instability and modification of erosional processes. The effect of a large dam at Campolattaro is also discussed in terms of increment of incision and linear erosional processes.

Reconstruction of the geomorphological evolutionary trend of the Tammaro River represents a key subject in order to correctly exploit a so endangered fluvial environment.

A multidisciplinary approach to the study of the Montereale intermountain basin (Central Apennines)

CHIARINI E. (*), LA POSTA E. (*), D'AMBROGI C. (*), EULILLI V. (*), FERRI F. (*), MARINO M. (*) & PUZZILLI L.M. (*)

Key words: *Upper Aterno River valley, 3D reconstruction, multidisciplinary study, geophysics, tectonic activity.*

This study focuses on the Montereale intermountain basin as a part of the researches related to the Sheet 348 "Antrodoco" of the Geological Map of Italy (1:50,000 scale).

This area can be considered an interesting case-study for the comprehension of the Quaternary history of the Apenninic intermountain basin since it is located in a highly seismic zone hit by strong historical earthquakes (e.g.: 1703 events), along the transition between the Gran Sasso and the Laga structural-paleogeographic domains.

We present the first results of our studies based on original data (pre-Quaternary units, structural data, Quaternary deposits, geomorphology, geophysic data) collected for the realization of the Sheet "Antrodoco", and existing data (boreholes, time-structure map) partly revised after the field work.

Intensive and detailed geological mapping, interdisciplinary studies and use of innovative data processing techniques provide a valuable and up-to-date geological knowledge base and an opportunity of interaction, check and integration of results obtained with different methodological approaches.

The Montereale depression is set in northern Abruzzo along the apenninic divide, in the highly seismic axial zone of the chain (ROVIDA *et alii*, 2011). Indeed it was hit by strong historical earthquakes, among them the January 14 and February 2, 1703 events, both with a 6.7 estimated Mw (GUIDOBONI *et alii*, 2007).

The origin of the basin is highly controversial for the general paucity of information on the structural setting. Besides the basin is not downcut and is extensively covered by Holocene floodplain deposits.

The quadrangular shape of the basin records the presence of NW-SE and NE-SW trending normal fault systems.

The recent literature highlights two main NW-SE trending normal faults: the Capitignano fault, along the northeastern margin, and the S. Giovanni fault, running at the base of the Mt. Mozzano southwestern slope (GALADINI *et alii*, 2000) (fig. 1).

The role and the activity of these faults are debated: i) they are thought to be part of a system (GALADINI & MESSINA, 2004) showing evidences of Holocene activity (i.e. M. Pettino and M. Marine faults; BLUMETTI, 1995; GALADINI *et alii*, 2000); ii) the Capitignano fault has been interpreted as the main fault controlling the evolution of the basin (BAGNAIA *et alii*, 1996).

On the other hand DEMANGEOT (1965) argued that the Montereale basin could be of erosional origin; according to his hypotesis the morphologic evidence of the Capitignano fault is not linked to recent activity but constitutes an example of fault plane exumation.

From a geological point of view the Montereale basin is located along the western part of the Gran Sasso thrust, marking the transition from the Meso-Cenozoic pre-orogenic carbonate successions, to the Laga fm (Messinian).

A basin-to-slope carbonate succession (Jurassic p.p. – Upper Miocene p.p.) composes the Mt. Mozzano structure at the southern margin of the plain (fig.1); the top of this succession locally crops out in the middle of the plain (Collicchio hill, fig. 1) and along its northern margin.

The Laga fm composes the north-western and north-eastern margins; moreover it emerges (Collicchio and Pago hills, fig. 1) from the alluvial deposits suggesting a complex morphology of the substratum of the Quaternary infilling of the plain.

Structural analysis reveals: i) the Gran Sasso thrust is exposed only in the south-eastern corner of the area, and is buried, to NW, by the Quaternary filling of the plain; ii) a NW-SE trending normal fault along the south-western slope of Mt. Mozzano (S. Giovanni fault) separates the Oligocene Scaglia cinerea from the Lower Cretaceous Marne a fucoidi; iii) a NE-SW to E-W high angle fault system produces the displacement of different lithofacies of the Laga fm (Sivignano – Capitignano area) and affects the termination of the Mt. Mozzano structure; iv) minor evidences of a NW-SE extensional fracture system occur in the Capitignano area, related to the Capitignano fault.

The Bouguer and residual gravity maps of the basin show two main negative anomalies with NW-SE orientation. A composite gravity low is present in the central-northwestern (Colle Calvo-Piedicolle) area and a second more intense anomaly is positioned in the extreme southeastern (Capitignano) part of the basin.

(*) ISPRA – Servizio Geologico d'Italia
Via Vitaliano Brancati, 60 – Roma
edi.chiarini@isprambiente.it

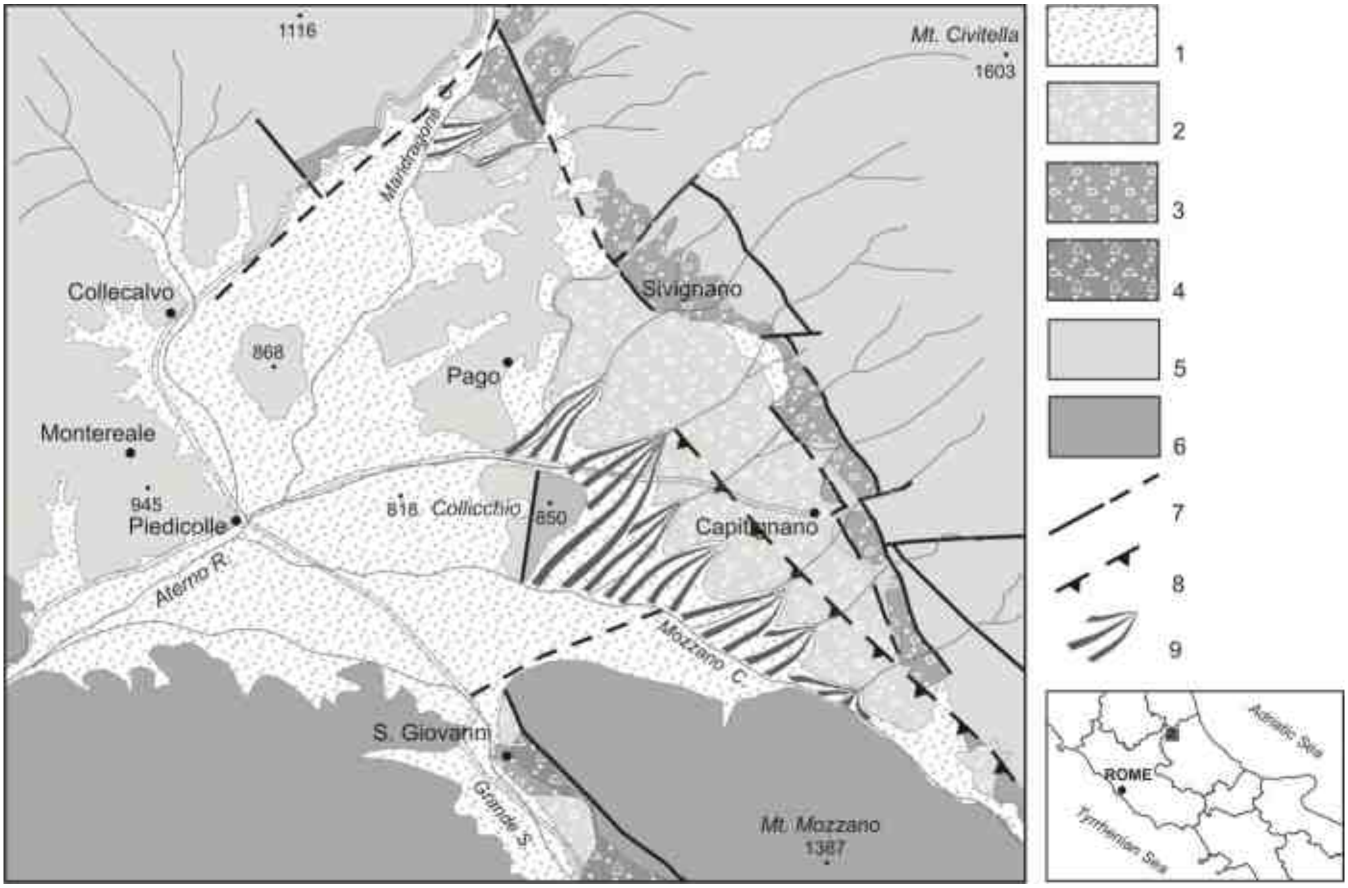

Fig. 1 – Geological map of the Montereale basin. Legend: 1. Eluvio-colluvial, slope debris, alluvial fan and alluvial plain deposits (*Holocene)*; 2. Alluvial fan deposits (*Upper Pleistocene p.p.)*; 3. Alluvial fan and slope debris deposits (*Middle? Pleistocene)*; 4. Calcareous breccias of alluvial-gravitational origin *(Early ? – Middle? Pleistocene*); 5. Laga fm *(Messinian)*; 6. Slope-to-basin carbonate succession (*Jurassic p.p.-Upper Miocene p.p.*); 7. Fault; 8. Thrust; 9. Alluvial fan.

These gravity lows highlight the presence of two distinct depocenters of the Quaternary deposits and this interpretation is also supported by fundamental frequencies microtremor data analyses. Both negative anomalies have a higher gradient on the NE side which suggests the presence of sharp density discontinuities. Moreover the produced maps show that the Capitignano negative anomaly has limited extension to the NW and ends S of Sivignano, its NE steep flank correlates well with the Capitignano fault.

The study of the Quaternary infilling has been integrated with geomorphological analysis and a drilling survey in key areas of the basin. The Quaternary succession, mainly alluvial plain and alluvial fan deposits, is characterized by several erosional unconformities. The most relevant ones are marked by well-developed paleosols referable to the Middle Pleistocene. Four main stratigraphic units are distinguished (1-4, fig. 1). During the surveying along the S. Giovanni fault the displacement of Upper Pleistocene slope deposits (Fig. 1) has been observed.

The north-eastern mountain front, set in the arenaceous-pelitic lithotypes of the Laga fm, shows typical features of a tectonically active slope: i) triangular facets related to different evolutional stages; ii) a piedmont belt of coalescent alluvial fans; iii) a remarkably straight piedmont junction.

Alluvial fans are related to a complex succession of climate-driven depositional events mostly occurred during glacial periods, alternated with phases of stream channel downcutting related to interglacial conditions. At least three generations of alluvial fans can be recognized: the oldest one mainly crops out on the Capitignano fault footwall; the most extensive, referable to the Upper Pleistocene, and the less developed one, Holocene in age, lie in the hanging-wall. Alluvial fan position relative to the mountain front could be related to the activity of the fault.

The Capitignano fault, along the piedmont junction, is made of two sub-parallel elements. The north-eastern one cuts the Laga fm. The southern segment is inferred based on the presence of geomorphological evidences (e.g. gravity controlled scarps and drainage network anomalies).

Problems related to the deep structural setting and the thickness of the Quaternary infilling are faced with a multidisciplinary approach allowing the development of a 3D geological model based on:
- original surface data on pre-Quaternary and Quaternary deposits;
- original data on Quaternary filling coming from analysis of

borehole stratigraphies;
- the analysis of available time-structure map (BIGI *et al*., 2011) and borehole stratigraphies (ENEL, 1969);
- a 2.75D density model, based on gravity data extracted from the geophysical database of ISPRA, mainly collected from original surveys and covering the complete study area;
- original geoelectric data resulting from 3 multi-electrode profiles of the length of approximately 1 Km each suitably located within the plane to characterize the depositional geometries and define the thickness of the alluvial cover;
- original microtremor and MASW prospecting to define the local seismic bedrock and for dynamic site characterization.

Geospatial reconstruction of the paleo Farfa River catchment and relict landscape in the Tyrrhenian drainage system (Central Italy)

G. FUBELLI (*), M. DELLA SETA (**) & G. AMATO (*)

Key words: *GIS analysis, Paleoshoreline, Paleosurface, Uplift.*

Air-photo interpretation and GIS analysis can be a valuable key to reconstruct past landscapes and landscape-forming processes, where the investigated area is too wide to be studied with conventional methods. In this perspective we applied a simple GIS based method to model the Farfa River paleo drainage basin.

The present Farfa River, a left tributary of the Tiber River, has presently a 132 km^2 wide drainage basin. It flows from the Sabini Mts. (Central Apennines) crossing the "Transitional Sabina Sequence" (Lias to Miocene in age) made of limestone, marls, calcarenites and syn-orogenic deposits (PAROTTO & PRATURLON, 1975).

In the upper basin sector, the river cuts fluvial conglomerates and sands Gelasian in age. Downstream, on the left side of the Tiber Valley, the facies of the incised sediments shows deltaic to frankly marine characters, that indicate the presence of the Gelasian paleo shoreline (AMBROSETTI *et alii*, 1978; COSENTINO & FUBELLI, 2008). This is also testified by the finding of lithodomus holes in the calcareous bedrock, at an elevation of 260-290 m above the present sea level. The shape of the Gelasian alluvial plain and delta has been outlined and redrawn by means of GIS techniques. We sampled the remnants of the Gelasian plain surface, as well as the base limit of the Gelasian deposits, from a 20 m resolution DTM. Then, using geospatial analysis tools we reconstructed the top and base surfaces of this sedimentary body (Fig. 1). The raster difference between the top and base surfaces allowed us

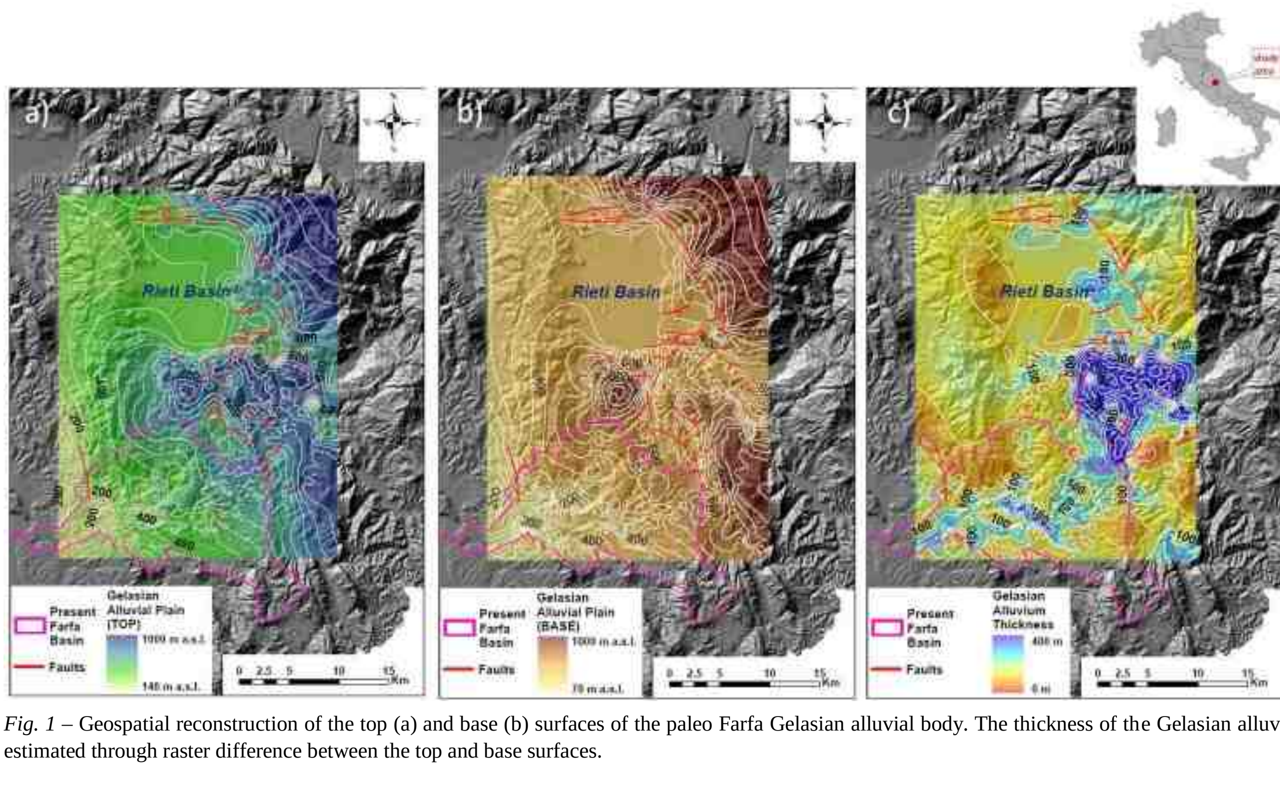

Fig. 1 – Geospatial reconstruction of the top (a) and base (b) surfaces of the paleo Farfa Gelasian alluvial body. The thickness of the Gelasian alluvium (c) was estimated through raster difference between the top and base surfaces.

estimating also the alluvial deposit thickness and confirming the occurrence of Quaternary faults in the study area. We extended our investigation upward the western sector of the central Apennines starting from the present-day divide between Tyrrhenian and Adriatic sea. The northern border of the investigated area corresponds to the Sibillini Mts., whose

(*) Department of Geology, University of Rome "Roma Tre", Italy.

(**) Department of Earth Sciences, University of Rome "La Sapienza", Italy.

western sector is characterized by a gentle landscape (known as *"Paleosuperficie Sommitale"*, RAFFY, 1979; DRAMIS, 1992; RASSE, 1995). This relict landscape lies at an elevation of about 1500 m a.s.l., and lowers down to 1000 m a.s.l. in the area between Norcia, Cascia, Leonessa and Rieti tectonic depressions. No continental deposits have been recognized on this relict suface, while a thick terraced fluvial deposit sequence has been recognized from the present-day divide between the Nera and Velino River basins. The contact zone between the gentle landscape and the alluvial fan passing to fluvial deposits is located, from west to east, in a 10 km wide area, from Ferentillo up to Rivodutri (Fig. 2).

The top of terrace elevation is around 900 m a.s.l. in the northern part of the Rieti basin, while between Rieti and the Farfa River it decreases from 800 m a.s.l down to the paleo shoreline before mentioned. We reconstructed the relict erosional landscape and compared it to the Gelasian alluvial plain surface, in order to locate the head of the paleo-Farfa River. This analysis allowed us reconstructing the ancient Farfa River drainage basin, whose surface area, more than 1000 km^2, was much wider than the present one.

Finally, from the shoreline elevation, an uplift rate of 0.12/0.14 mm/yr has been calculated in the western part of the Apennines. It is much difficult estimating the uplift rate in the inner sectors because of the trouble in obtaining the elevation of the Gelasian alluvial plain, which is also dissected by the Quaternary extensional tectonics.

The connected Auletta, Vallo di Diano, and Sanza basins, southern Apennines, Italy: opening kinematics and morphostructural evolution

SALVATORE IVO GIANO (*), DARIO GIOIA (°) & MARCELLO SCHIATTARELLA (*)

Key words: *morphotectonics, intermontane basins, Quaternary, southern Italy.*

INTRODUCTION

Several Pliocene to Quaternary tectonically-controlled continental basins are scattered along the axis of the southern Italian Apennines. They represent the result of the differential tectonic uplift which affected the axial zone of the orogenic belt. In particular, three different but morphologically connected intermontane basins have been here investigated from a morphotectonic point of view. Opening kinematics of such fault-bounded basins and their morphological features and evolution have been compared to define the behaviour of this particular interconnected negative morphostructure.

GEOLOGICAL AND GEOMORPHOLOGICAL FRAME

The southern Apennines are a north-east verging fold-and thrust belt derived from the deformation of the African palaeomargin, strongly dismembered by neotectonics and therefore articulated in longitudinal and transversal structural depressions (Fig. 1). Several Authors have delineated a complex Quaternary tectonic picture for the axial zone of the southern Apennines, which implies superimpositions of strike-slip and extensional movements along fault surfaces (ASCIONE *et alii*, 1992a, 1992b; HYPPOLITE *et alii*, 1994; SCHIATTARELLA, 1998; GIANO *et alii*, 2000; SCHIATTARELLA *et alii*, 2003, among others). On the other hand, a more simple Quaternary tectonic evolution, characterized by a continuous active SW–NE extension, was recently proposed on the basis of seismic data from Agri, Auletta and Vallo di Diano basins (BARCHI *et alii*, 2007; AMICUCCI *et alii*, 2008).

In the frame, the structural sketch of the same area is reported.

THE AULETTA BASIN

The Auletta basin is located between the carbonate massifs of the Alburni Mts to the south and Marzano Mts to the north, both characterized by high relief. A very thick middle Pliocene to middle Pleistocene sequence (at least 500 m in the depocentral area of the basin, AMICUCCI *et alii*, 2008), both of marine and continental origin, filled the basin and are shaped by erosional land surfaces and fluvial dissection. The ages of the morphological de-activation of such terraced surfaces have been roughly defined on the grounds of their morpho-stratigraphic relationships with Pliocene and Quaternary deposits, and better constrained by radiometric dating. N110-130° trending high-angle faults with polyphase kinematics, as well as NE-SW-striking faults, are widespread in the Mesozoic carbonate mountains and in the Quaternary basin itself. The SW margin of the tectonic depression is bordered by a N120-130° trending and NE-dipping master fault (Alburni Line) which has strongly controlled the stratigraphic and geomorphological evolution of the basin. The activity of the 20 km-long Alburni Line provoked the tilting of continental deposits and land-surfaces in the hanging-wall of the fault (AMICUCCI *et alii*, 2008; GIOIA & SCHIATTARELLA, 2010). Transtensional tectonics along NW–SE striking, listric faults of the Alburni margin system created the depression since Pliocene times, whereas extensional tectonics plays a key role in the middle to late Pleistocene morphotectonic evolution of the basin. The stratigraphic, structural, and geomorphological data recently presented (GIOIA *et alii*, 2011a, 2011b) suggest that the studied basin appears to have a more complex tectonic evolution than an extensional graben. As a matter of fact, the high-angle faults show a marked poly-modal distribution of the kinematic indicators. In particular, the NNW-SSE trending fault of the Alburni Mts exhibits a superimposition of two sets of striations, indicating a former left-lateral transtensional kinematics and a later dip-slip kinematics. Moreover, faults and fractures compatible with a NE-SW extension have been also detected in the lower-middle lacustrine deposits of the Vallo di Diano (DI LEO *et alii*, 2009).

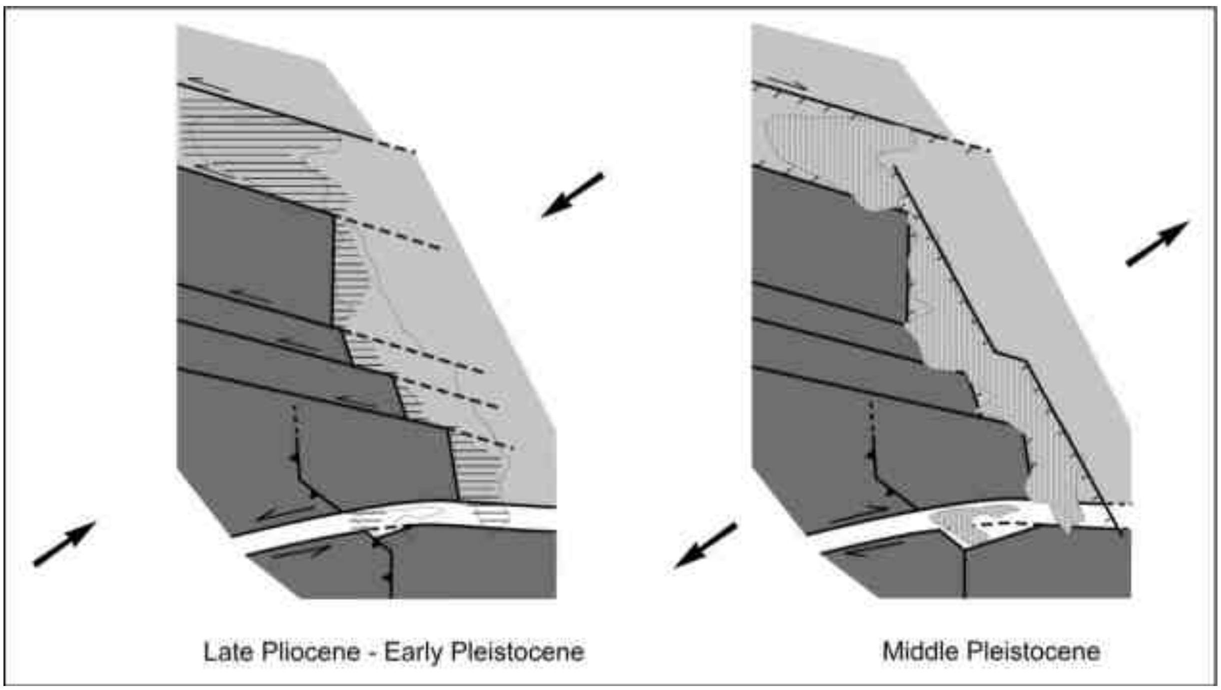

Fig. 2 – Two-step morpho-structural evolution of the connected basins of the Campania-Lucania Apennine axial zone. Different tones of grey indicate the Alburno-Cervati block (dark grey) and the Mt. Marzano - Maddalena Mts block (light grey). Convergent and divergent arrows are respectively related to contractional and extensional tectonics. Straight lines are faults with different kinematics (orthogonal traits indicate normal faults, oblique traits indicate transtensional faults, arrows indicate strike-slip faults, triangles indicate thrusts). Hatched areas of the scheme on the left represent the upper Pliocene – lower Pleistocene accommodation space for sedimentation, whereas the stippled area of the scheme on the right show the mid-Pleistocene to Present basin infill.

THE VALLO DI DIANO BASIN

The Vallo di Diano basin is a NW-SE-trending elongated basin, about 35 km-long and 7 km-large. A N140-150°-striking master fault bounds the eastern side of the basin whereas the western flank is affected by N120°-trending left-lateral strike-slip faults (ASCIONE *et alii*, 1992a). The sedimentary infill of the basin is constituted of fluvio-lacustrine deposits and coeval slope to alluvial fan deposits located along the flanks of the basin. Two different depositional episodes have been recognized in the lacustrine succession (SANTANGELO, 1991), responsible for the formation of an older cycle cropping out in the southern sector of the valley, lower-middle Pleistocene in age, and of a younger lacustrine depositional cycle, mid-Pleistocene to Holocene in age, filling the depocenter of the basin. A recent 40Ar/39Ar radiometric dating of sanidine crystals from tephra layers interbedded in the fluvio-lacustrine sequence, allowed to better constrain the age of the older deposits, set to 706.3±8.1 ka (DI LEO *et alii*, 2009). In addition, an age of 106.7±1.6 ka has been proposed by the same authors for a weathered horizon at the top of the Grotta S. Angelo succession, located on the eastern side of the valley in the central portion of the basin.

THE SANZA BASIN

The Sanza basin is hosted in a 10 km-long E-W-trending narrow trough. This morphostructural low is a lateral branch of the wider Vallo di Diano basin, characterized by a multi-stage morphoevolution. In such a basin, lacustrine red clays and fan conglomerates form the clastic infill. The fluvio-lacustrine succession age is univocally set to the middle-late Pleistocene by radiometric dating (DI LEO *et alii*, 2009). To the sedimentary-top, weathered horizons and palaeosols with interbedded tephra represent the younger deposits. Geomorphological, mineralogical, and geochemical studies on these red clays and associated palaeosols revealed that a climate change occurred during their formation. A transition from cold-temperate to warm/humid climate has been clearly recorded in the red clays and associated palaeosols during middle to late Pleistocene time-span.

The Pleistocene morpho-sequence of the Sanza trough has been outlined also comparing its stratigraphic succession with those from the adjacent Vallo di Diano basin. The study of land surfaces, organized in six altimetric classes, permitted us to reconstruct the Pleistocene geomorphological evolution of the area. Using the surface at the top of the Sanza deposits as a reference marker with regard to the other orders of terraced surfaces, it has been possible to include the genesis and evolution of the basin in a larger time-span and to relate its structural history with regional and local tectonic episodes. In particular, the E-W trending trough was generated in a tectonically-controlled narrow transversal strip due to the activity of a transfer zone of the chain. The changing tectonic regime was responsible for the endorheic conditions reached by the depression during mid-Pleistocene times. The Sanza basin can be assimilated to a morphostructural trough coinciding with a long-term transfer zone of the chain, in which a severe change in stress field, uplift rate, climate conditions, and relief production occurred during Pleistocene times.

CONCLUSIONS

Such a complicate morphostructural setting, related to three connected basins with quite different characters, may be interpreted as a function of the original orientation of the structural depressions, only partially coeval. In this sense, the Vallo di Diano basin should represent the structural low generated by pure extension during the Pleistocene, but probably already living as a Pliocene seaway, whereas both the Auletta and Sanza basins stand for two lateral branches with oblique kinematics, indeed inherited from a pre-existing (i.e. Pliocene in age) set (Fig. 2). In particular, the right-angle relation between the Vallo di Diano basin and the Sanza trough suggests to consider the latter as a basin developed within a regional-scale transfer-zone and characterized by reverse drainage.

Arrangement of terraced surfaces and middle Pleistocene to Holocene geomorphological evolution of the Ofanto Basin (southern Apennines)

ROBERTA LABELLA (*) & PAOLO GIANNANDREA (*)

Key words: *geomorphological evolution, Quaternary stratigraphy, terraced surfaces , Ofanto River valley.*

ABSTRACT

The Ofanto Basin is a morphostructural low located in an intermediate position between the axial zone and the front of the southern Apennines. The morphological evolution of this area is very interesting because of the peculiarities related to its E-W orientation, the anomalies of the drainage network and the distribution of terraced surfaces. This paper focuses on the distribution of low fluvial terraces, landslides terraces and strath terraces as a clue to interpret the sequence of events that have controlled the geomorphological evolution in the middle Pleistocene – Holocene time range.

INTRODUCTION

Low fluvial terraces distributed in the western sector of the Ofanto River high valley, between the settlements of Cairano and S. Andrea di Conza just to its confluence with the Fiumara di Atella, were attributed previously with three levels of terraces located in the middle Pleistocene – Holocene time range (Fig. 1). This interpretation, however, imply an inconsistency in the distribution of surfaces at issue, since the altitudes of the second order terraces are higher, on average, than those of the first order unlike that generally occurs in a normal sequence of terraced surfaces.

This paper proposes a different interpretation about the three orders of terraces obtained by separating lower terraces in the flood deposits, characterized by the presence of a thin gravel cap, from landslide terraces that have greater inclinations than the first and are placed at higher altitudes. Terraced surfaces analysis was also extended to strath terraces (*sensu* MERRITS *et alii*, 1994; BURBANK & ANDERSON, 2001) i.e. the terraced surfaces carved in the Mesozoic-Cenozoic bedrock.

The distribution of all terraced surfaces recognized may be useful as a clue of interpretation to reconstruct the sequence of events that have controlled the geomorphological evolution of the study area from the middle Pleistocene until today (MARTINO & SCHIATTARELLA, 2006). Data concerning elevation-genetic classification of terraced surfaces recognized both on the right and on the left bank were summarized and graphically represented by a schematic cross-section of the basin (Fig. 2 and Table 2).

The profile shape highlights the asymmetry of the basin whose flanks have a geometry substantially different: wider and less sloped (on average 2.3°) the left side, less wide and more sloped (on average 5.1°) the right one. The asymmetry index of the drainage basin (KELLER & PINTER, 1996), that in the study area corresponds to 43.8% (Table 1), confirms quantitatively the asymmetry of the basin due to the greater areal size of the left side. In addition to the areal size and inclination of the two sides, the asymmetry of the basin also extends to the distribution of terraced surfaces. Their arrangement is in fact significantly different on the two sides of the basin. On the right flank, moving from lower altitudes to higher ones, there are three orders of sub-horizontal low fluvial terraces located respectively to the following altitudes a.s.l.: 450-480 m (a), 500 m (b) e 530 m (c). They are carved in the Pliocene clay soils and present at the top a thin alluvial gravel cap of the maximum thickness of 1-2 m. Between altitudes of 775 and 825 m a.s.l., there are instead some landslide terraces (d) with an average slope of 5° towards north and with the apex joined towards south to the Mesozoic-Cenozoic bedrock. Landslide bodies are 5-6 m thick, have a lateral extension of several kilometers and are located on gray-blue clay of the Pliocene-Quaternary Ofanto Basin. At a higher altitude (between 850 and 1150 m a.s.l.), a terraced surface (*e* in Fig. 2) carved in the Mesozoic-Cenozoic bedrock, here represented by siliceous-calcareous rocks of the *Flysch Rosso* Fm (FYR in Fig. 2), has been surveyed. Terraced surfaces arrangement along the left side of the basin is less complex than along the right one: in this case, not low fluvial terraces and landslide terraces have been observed.

(*) Department of Geological Sciences - Università degli Studi della Basilicata.

There are instead various terraced surfaces gently sloping in the clay bedrock represented by the *Argille Variegate* Group (AV); these surfaces are located at three different levels (f, g end h in Fig. 2), corresponding to the following ranges of altitude: 600-620 m, 700-750 m and 830-850 m a.s.l. The identification and the classification of terraced surfaces on both sides of the basin represent the first phase of this work; the second phase, currently in progress, consists in the interpretation of control factors on the components of asymmetry previously described.

SUB-CATCHMENT AREA ON THE RIGHT SIDE		SUB-CATCHMENT AREA ON THE LEFT SIDE	
Arso	33 km^2	Orata	88 km^2
Ficocchia	22 km^2	Cortino	26 km^2
Tragino	14 km^2	Rifezze	26 km^2
Liento	40 km^2		
	A_{DX}=109 km^2		A_{SX}=140 km^2
	A_{TOT}=249 km^2		
	AI = (A_{DX}/AT) x 100 = (109/249) x 100 = 43.8%		

Table 1 – Asymmetry Index in the study area.

Undoubtedly the different lithological nature of the Mesozoic-Cenozoic bedrock, clay on the left side and siliceous-calcareous on the right one, has exerted a conditioning on the landscape in terms of differential erosion by determining the differential of steepness described on both sides of the basin as well as the absence of landslide debris bodies on the left side.

It is not excluded, however, that structural factors have contributed to control the morphological asymmetries observed in the Ofanto Basin. The map of morphostructural clues and terraced surfaces in the study area (scale 1:25.000) highlights, in fact, some structures that have clearly influenced the current landscape in the middle Pleistocene – Holocene time range.

INTRODUCTION

Since the second half of 1980's, the Earth Sciences Department of "La Sapienza" University of Rome and the Paleontological Museum "Ex Chiesa S. Tommaso" of Terni, in accordance with "Soprintendenza Archeologica per L'Umbria", carried on field researches focusing the palaeoenvironmental evolution of the South-western branch of the Tiberino Basin (southern Umbria, Italy). Field activities leaded to discover several fossil-bearing localities with vertebrate remains. All the fossil bones come from the sediments belonging to a fluvio-lacustrine sequence, the Santa Maria di Ciciliano Formation (SMCF). Up to now, only part of the fossils have been studied, being most of the huge palaeontological material collected so far still under restoration. Despite this fact, the study of the vertebrate fossil record from southern Umbria gave an important contribution for a more accurate definition of the local biostratigraphy and biochronology, suggesting different scenarios also for reconstructing the geological events occurred during the Late Pliocene (Piacenzian) and Early Pleistocene (Gelasian-Calabrian) in that area.

GEOLOGICAL AND STRATIGRAPHICAL SETTING

The Tiberino basin developed during the Plio-Pleistocene in an extensional tectonic regime linked to the opening of Tyrrhenian Sea Basin. It is the largest intramontane basin of Apennines, 150 km in length and up to 15 km wide, in which non marine sedimentation took place from Pliocene up to Holocene (BASILICI, 1997, and references therein). It consists of three NNW oriented branches, forming together an upside-down Y shaped basin. Recent studies gave an updated picture of stratigraphy and palaeontology of its south-western branch, where the sedimentary successions widely crop out. In particular, the southwestern branch of Tiberino basin corresponds to a well defined half-graben filled with alluvial-lacustrine sequences, and bounded westerly by the Amerini Mts.-Narni Ridge, and easterly by the Martani Mts. In the horsts the Mesozoic-Cenozoic Umbro-Marchean pelagic succession and Miocene syn-orogenic flysh crop out. The main structural element in the basin is represented by the east-bounding Martana Fault, a N-S trending, west-dipping normal fault, that abruptly separates the Pliocene-Quaternary basin infill from the Martani ridge. The fault likely exerted a strong control on local accomodation and sedimentation, at least up to Early Pleistocene time. The Basin infill stratigraphy was depicted with detail by AMBROSETTI *et alii* (1995), BASILICI (1995, 1997), ABBAZZI *et alii* (1997). Pliocene and Early Pleistocene deposits, which extensively crop out in the basin, are referred to four lithostratigraphic units. Their main features are summarised as follows (BASILICI, 1997): 1) FBF - Fosso Bianco Formation, composed of lacustrine clays, sands and gravels, approximately 250 m thick and east dipping (Late Pliocene-earliest Early Pleistocene, i.e. Piacenzian-Gelasian). It crops out in the central-western portion of the basin, being uplifted by local intrabasinal normal faults, and strongly backtilted (20°-30°) to the east. 2) PNF - Ponte Naja Formation, made of silty clays referable to an alluvial fan, with an estimated thickness of 140 m. It is localized close to Todi, in noth-westernmost part of the basin, is dated to the earliest Early Pleistocene, i.e. Gelasian, and shows a general progradation to the East. 3) SMCF - Santa Maria di Ciciliano Formation. This formation is composed of a complex alternation of silty clays, clays and tabular sands, referable to an articulated alluvial, meander-dominated environment, with floodplain, crevasse splay and channel belt facies. The estimated exposed thickness is approximately 150 m, and increases to the east toward the Martana Fault. Attitudes are in general sub-horizontal or gently dipping eastward (less than 10°); SMCF overlays with angular

unconformity the older formations. On the SMCF age, this formation has been long considered to be Early Pleistocene (Santernian) in age on the basis of fossil content and on the lateral continuity with the Santernian (1.8-1.5 Ma) portion of the nearby marine and transitional Chiani Tevere Formation. The latter fills the westerly contiguous Paglia-Tevere Graben, just to the west of the Amerini Mts-Narni ridge (GIROTTI & MANCINI, 2003; MANCINI *et alii*, 2004; 2007). Fossil vertebrate evidence suggests that SMCF could be partially referred also to late Gelasian. 4) AF - Acquasparta Formation is composed of fluvio-lacustrine calcareous silts alternating with travertines (c. 50 m thick), crops out only along the Martana Fault, and is referred to the Early Pleistocene. As a whole, the basin architecture of south-western Tiberino Basin shows an asymmetric wedge-shaped infill, with vertically stacked formations piled up close to the Martana Fault.

THE FOSSILIFEROUS LOCALITIES

Although southern Umbria was studied by geologists and palaeontologist since the end of 1800's the only remarkable discover of fossil mammal from the region was an almost complete skeleton of the Etruscan rhino *Stephanorhinus etruscus* (Falconer), studied by AMBROSETTI (1972) and in exhibition at the Paleontological Museum of "Sapienza" University in Roma. In the second half of 1980s field surveying allowed to find vertebrate remains from different localities in the nearness of Massa Martana (Terni), where quarry activity exposed sequences referable to SMCF. The fossil assemblages have been referred to late Villafranchian (?Olivola-Tasso Faunal Units – FUs, i.e. Santernian) (see GLIOZZI *et alii*, 1997). The faunal lists are the following (AMBROSETTI *et alii*,1995, SARDELLA *et alii*, 1995): Villa San Faustino - Elephantidae indet., *Stephanorhinus etruscus*, *Equus stenonis* Cocchi, *Sus strozzii* Meneghini, *A. nestii* (Major) (Fig. 3), Cervidae indet., *Leptobos* sp. (*vallisarni* vel *etruscus*), *Megantereon cultridens* (Cuvier, *partim*), *Castor* sp.; Colle Sant'Andrea - *Pachycrocuta* cf. *P. brevirostris* (Aymard) Cervidae indet., *Leptobos* cf. *L. vallisarni*, *Castor* sp.; Colle Violino - *Stephanorhinus etruscus*; Casale le Grotte - *Eucladoceros* sp.

In the 1990s, in the surroundings of Montecastrilli four new fossiliferous localities were discovered: Torre Picchio, Colle Sant'Umano, Colle Logato and Colle Poggette. Torre Picchio, up to now the richest locality as concerning the number of fossil remains discovered, was investigated with a multidisciplinary approach encompassing lithostratigraphy, malacology, vertebrate paleontology, micropaleontology and paleobotany (GIROTTI *et alii*, 2003). From Torre Picchio a great number of plants ("mummified" woods, fruits and seeds), freshwater molluscs, ostracods, vertebrate bones and some coprolites, belonging to megaherbivores and carnivores, have been collected. The following taxa have been found: Pisces indet., Anura indet., *Emys orbicularis* (Linnaeus), *Mauremys* sp., Testudinata indet. (?*Trionyx* sp.), Ciconiidae, Accipitridae, *Canis* sp., ?*Baranogale* sp., *Homotherium* sp., ?*Mammuthus meridionalis* (Nesti), *Equus* cf. *E. stenonis*, *Stephanorhinus* cf. *S. etruscus*, *Sus strozzii*, *Eucladoceros dicranios* (Nesti) vel *ctenoides* (Nesti), *Axis nestii*, Cervidae gen. et sp. indet., *Leptobos* cf. *L. etruscus* (Falconer), Bovidae gen. et sp. indet.(medium sized antelope), Bovidae gen. et sp. indet., *Castor* sp., *Mimomys medasensis* Michaux, *Prolagus* sp., *Oryctolagus* cf. *O. lacosti* (Pomel). The mammal assemblage was referred to middle-late Villafranchian (Costa S. Giacomo and Olivola FUs) (late Gelasian) (see GLIOZZI *et alii*, 1997). Moreover, PETRONIO *et alii* (2000-2002) pointed out that the site of Torre di Picchio can be correlated to the so called "fossiliferous level of Capitone", from which the Etruscan rhino skeleton was unearthed. At Colle Sant'Umano mammal remains have been found in a deposit cropping out nearby the railway station of Montecastrilli. The faunal list includes a large sized equid referable to *Equus* ex gr. *bressanus-suessenbornensis*, a large bovid, *Hippopotamus antiquus* and *Axis eurygonos* (Azzaroli). This faunal assemblage can be referred to Late Villafranchian (Farneta FU)-Early Galerian (Colle Curti FU) Large Mammal Ages, but is clearly late Early Pleistocene (Calabrian and not Gelasian) in age (PETRONIO *et alii*, 2000-2002). At Colle Poggette, fossil vertebrate remains (bones and coprolites) have been found in sands and gravels, being some of the bones in anatomical connection. The faunal list includes: *Emys* sp., *Mammuthus* sp., *Stephanorhinus etruscus*, *Equus stenonis*, *Axis* cf. *A. nestii*, *Ursus etruscus* Cuvier and coprolites referable to hyaenids and large herbivores (?equid). The faunal assemblages of Colle Poggette is older than that from Colle Sant'Umano, and can be generically referred to the late Villafranchian. Finally, faunal remains have been recently discovered from Colle Logato and they are still under preparation. A preliminary analysis suggests the occurrence of a very large equid, at least two different taxa of cervids, and a bovid (represented by an almost complete skeleton in anatomical connection). As listed above, Torre Picchio faunal assemblages is characterised by the occurrence of taxa of Pliocene-earliest Pleistocene affinities (the medium-size bovid, ?*Baranogale* sp. and, above all, *Mimomys medasensis*). The fossils coming from Colle Logato seem to strength this hypothesis. On the other hand, the faunal assemblage from Colle S. Umano, where a large sized stenonoid horse, advanced bovid and cervid, and hippo occur, is clearly Early Pleistocene in age.

REMARKS ON STRATIGRAPHY AND IMPLICATION ON SEDIMENTARY BASIN EVOLUTION

Up to now, the interpretation of the continental fossil record from the south-western branch of the Tiber River basin, with emphasis on vertebrates, may provide a more detailed framework and constraint for litho and chrono-stratigraphy of the Tiberino basin, than previously supposed. According to the large mammal biochronology data, the age of some deposits, already referred only to the late Early Pleistocene (Calabrian, and Santernian in particular), has to be considered slightly older and namely attributable to the earliest Pleistocene, Gelasian. On the other hand, the Colle Sant'Umano assemblage is a bit younger than Santernian, at the latest Early Pleistocene (1.4-1.1 Ma approximately). So, evidences from the mammal fossil record support the hypothesis of a wider chronological interval for the deposition of SMCF. The biochronological positions of Torre Picchio and Colle S. Umano are clearly different, almost 500 ka spaced. This cannot be the result of significant palaeoecologial differences between the two local faunas, since the two fossil-bearing sites are in close proximity each other (some 1 km far). The diachrony between the two so closely spaced assemblages may result from different conditions on local sedimentation. In fact, fluvial sediments of SMCF bearing the younger assemblage (Colle Sant'Umano) may have deposited laterally with respect to the Torre di Picchio sediments, and were not stacked vertically. This lateral position of younger fluvial sediments can be interpreted as a lateral shift of active channel-belts, and related lateral accretion of fluvial facies, as opposed to the dominant style of vertical stacking of sediments within the south western Tiberino Basin. The occurrence of such an inferred lateral migration of channel belt can thus be dated to latest Early Pleistocene (1.4-1.1 Ma) by mammal biochronology. Conversely, the phase of vertical accretion within SMCF is older than 1.4-1.1 (Farneta-Colle Curti FUs), since it encompasses the Piacentian-Santernian interval, when active fluvio-lacustrine sedimentation in the basin occurred under a relatively strong tectonic subsidence regime controlled by the Martana Fault activity. The subsequent lateral shift of fluvial system may have recorded a reduction of accommodation and subsidence in the basin, in the 1.4-1.1 Ma interval.

As a conclusion, mammal biochronology may be used to provide useful chronological constraints to define the intramontane basin infill evolution (see also MANCINI *et alii*, 2012), and to qualitatively estimate changing modes of sedimentation and accommodation within such kind of basins.
