Oceanic Anoxic Events: the record from Italy and beyond

HUGH C. JENKYNS

The description, in 1891, by Guido Bonarelli of 'uno strato di scisto nero bituminoso dello spessore di un metro circa' at the boundary between the mid- and Upper Cretaceous close to the town of Gubbio in Marche–Umbria was the first mention of a horizon of black organic-rich shales that is now recognized to have global distribution (BONARELLI, 1891). Critical to the development of the Oceanic Anoxic Event concept was the finding of coeval (Cenomanian–Turonian boundary) organic-rich sediments on submarine plateaus (Shatsky Rise, Hess Rise) and basins (Mariana Basin) during Legs 32 (1973) and 89 (1982) of the Deep Sea Drilling Project in the Pacific Ocean (SCHLANGER & JENKYNS, 1976; SCHLANGER *et alii*, 1987). These Pacific occurrences indicate that the phenomenon – the C/T OAE - giving rise to these unusual deposits was global in nature and unrelated to local basin geometry: the driver for such events can be plausibly linked to an increase in plankton productivity, which may have been particularly intense in the equatorial regions of the world ocean. How much of the Pacific was affected by deposition of organic-rich sediment is unknown, because of the paucity of DSDP/ODP/IODP coverage of the key intervals. The role of palaeogeography in enhancing deposition of organic-matter cannot, however, be ignored because organic geochemical evidence from biomarkers derived from green sulphur bacteria suggests that particularly frequent and prolonged euxinic (sulphidic) conditions characterized the photic zone of the relatively restricted northern South Atlantic compared with the wider southern part of the South Atlantic and the North Atlantic (JENKYNS, 2010). Such conditions were particularly favourable to the preservation of organic matter. The positive carbon-isotope excursion that is a universal feature of the C/T OAE may have been largely driven by deposition of vast quantities of organic matter in the northern South Atlantic: on Demerara Rise, for example, the chemostratigraphic signatures of carbon isotopes and organic matter match each other very closely (ERBACHER *et alii*, 2005).

An interesting feature of the Livello Bonarelli itself is the effective lack of carbonate (<5 wt% to undetectable: TSIKOS *et alii*, 2004), despite its abundance in beds above and below, and low calcite contents are a feature of all OAE black shales. The question thus arises: should OAEs be considered as oceanic acidification events, characterized by a dramatic rise in the calcite compensation depth, as well as being productivity events (HÖNISH *et alii*, 2012)? Acidification was likely caused by the addition of carbon dioxide to the ocean–atmosphere system. Direct evidence for this phenomenon is lacking for the C/T-OAE, but the early Aptian Oceanic Anoxic Event (OAE 1a) and the early Toarcian Oceanic Anoxic Event (T-OAE) are characterized by a negative carbon-isotope excursion interrupting a broader positive trend, and the shift to lower values must be related to the introduction of methane and/or carbon dioxide to the atmosphere (JENKYNS, 2003). Detailed studies of Pacific and Italian sections affected by OAE 1a indicate changes in the nature of and preservation of calcareous nannoflora during this event, related to sequential introduction of such greenhouse gases (ERBA *et alii*, 2010).

The discovery of lower Aptian black shales in the Pacific Ocean during DSDP legs 17 (1971), 32 (1973), 33 (1973) and 62 (1978), in both basinal and plateau pelagic settings, also indicated the likely global impact of this OAE, something reinforced by the discovery of the Selli Level in the Marne or Scisti a Fucoidi in Marche–Umbria (COCCIONI *et alii*, 1987; SLITER, 1989). The presence of an equivalent to the Selli Level in Pacific platform carbonates (Resolution Guyot) found during ODP Leg 143 (1992) showed how even relatively shallow waters could be influenced by these high-productivity events (JENKYNS, 1995).

The regional nature of Lower Toarcian organic-rich black shales was understood by DAL PIAZ (1907): 'È una facies particolare che ha il suo massimo svillupo nella regione extraalpina, ma della quale, per quanto sporadici e limitati, non mancano esempi anche nel bacino mediterraneo.' Although no DSDP/ODP/IODP cores have penetrated this interval, the global spread of facies of this age is very impressive (JENKYNS *et alii*, 2002), and recent discoveries in a radiolarian chert sequence of a Japanese accretionary complex indicate that the deep ocean, as well as continental margins and shelf seas, were affected (GRÖCKE *et alii*, 2012).

All OAEs developed during intervals of high temperature in greenhouse periods of the Earth's history: rapid effusion of carbon dioxide from Large Igneous Provinces was the likely stimulant, causing not only acidification but also

UK

increased continental weathering and nutrient flux to the oceans, hence stimulating plankton productivity (JENKYNS, 2003; ERBA, 2004). Some proxies offer geochemical indices of changing redox conditions in oceans and seas (e.g. molybdenum isotopes ($\delta^{98/95}$Mo) in black shales, and sulphur isotopes (δ^{34}S), manganese and iodine in carbonates: PEARCE *et alii*. 2008; LU *et alii*; GILL *et alii*, 2012). Other proxies contrast the relative roles of magmatic/hydrothermal influence and continental weathering (^{87}Sr/^{86}Sr, calcium isotopes ($\delta^{42/44}$Ca), ^{187}Os/^{188}Os: FRIJIA & PARENTE, 2008; BLÄTTLER et al., 2011; BOTTINI *et alii*, 2012) and pinpoint the maximum effect of reactions between silicates and atmospheric carbon dioxide at the onset of OAEs. Drawdown of carbon dioxide by burial of organic matter and reaction with continental rocks ultimately returned the ocean–atmosphere to chemical and climatic equilibrium to terminate an OAE, but at the expense of massive change in seawater and sediment composition and over timescales of several hundred thousand years (JENKYNS, 2003).

Evolution of the Tyrrhenian Sea-Calabrian Arc system: The past and the present

ALBERTO MALINVERNO (*)

Key words: *Tyrrhenian Sea, Calabrian Arc, trench rollback, orogen extension.*

INTRODUCTION

The Tyrrhenian Sea is an extensional basin that formed in the last 10 Ma in the broad suture between the African and European plates. The convergent plate boundary is evident in the SE corner of the Tyrrhenian Sea, which contains a funnel-shaped Benioff zone (CHIARABBA *et alii*, 2005), a subducting slab imaged by seismic tomography (PIROMALLO & MORELLI, 2003), and the Aeolian islands Quaternary calc-alkaline volcanic arc (SERRI, 1990; FRANCALANCI & MANETTI, 1994; SAVELLI, 2002). Extension in the Tyrrhenian Sea took place at the same time as shortening in the arcuate Apenninic-Maghrebian thrust belt that surrounds the basin to the E and S. The maximum amount of extension is more than 300 km in a WNW-ESE direction between Sardinia and Calabria (MALINVERNO & RYAN, 1986), and is matched by a similar amount of shortening in the Southern Apennines (PATACCA & SCANDONE, 1989).

The key puzzle in the formation of the Tyrrhenian Sea is how large amounts of extension took place in a region of weak plate convergence. Africa and Europe converged by only about 80 km in a NW-SE direction in the last 10 Ma (MAZZOLI & HELMAN, 1994). After reviewing key constraints on the evolution of the Tyrrhenian Sea-Calabrian Arc system, this paper presents a working hypothesis on the outward migration of extension in the Tyrrhenian domain.

EVOLUTION OF THE TYRRHENIAN SEA-CALABRIAN ARC SYSTEM

The two cross-sections in Fig. 1 portray the initial condition of a Sardinia-Calabria transect just before the opening of the Tyrrhenian and its final geometry at the present time. These cross-sections are mainly constrained by seismic surveys and by the requirement of balancing cross-sectional areas.

The onset of the extension in the Tyrrhenian Sea has been dated to the Tortonian (~10 Ma) from ODP drilling results (KASTENS & MASCLE, 1990). The 10 Ma cross-section of Fig. 1 follows a narrow oceanic seaway that separated the N margin of Africa and the SW margin of the Adriatic platform; the presently subducting slab in the SE Tyrrhenian and the deepest portion of the Ionian Sea are the last remnants of this oceanic corridor (CATALANO *et alii*, 2001). An alternative interpretation places in this oceanic seaway a sliver of continental crust underlying an Apennine-Panormide carbonate platform that connects the Apenninic and Maghrebian domains (ARGNANI, 2005).

Many authors noted that the rifting of the Tyrrhenian took

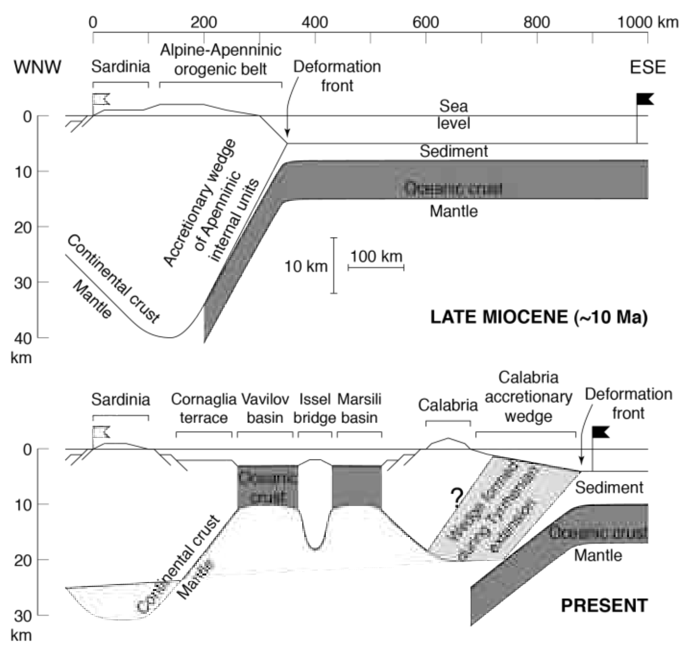

Fig. 1 – Cross-section from Sardinia to the present location of Calabria before the opening of the Tyrrhenian Sea (about 10 Ma; top) and at present (bottom). The Tyrrhenian Sea opens in a pre-existing Alpine-Apenninic orogenic belt, and during extension the accretionary wedge to the E of Calabria grows by incorporating sediments from the subducting plate. The white flag marks the western coastline of Sardinia, and the black flag a point on the subducting plate; because of Africa-Europe motion, the two plates converge by about 80 km in the last 10 Ma (MAZZOLI & HELMAN, 1994).

place in a pre-existing orogenic belt composed of Alpine and Apenninic units (ALVAREZ *et alii*, 1974; SCANDONE, 1979; DERCOURT *et alii*, 1986; KASTENS & MASCLE, 1990; PATACCA *et alii*, 1990; ROSENBAUM & LISTER, 2004). Key evidence for this conclusion is in the results of extensive sampling campaigns summarized by the late Renzo Sartori (SARTORI, 1986, 2005). These results show that the Tyrrhenian seafloor contains outcrops of continental basement and ophiolites metamorphosed during the Alpine cycle and of sedimentary rocks correlated to Apenninic units.

Just before the Tyrrhenian opening, the orogenic belt in Fig. 1 had on its eastern edge an accretionary wedge that formed during the subduction of African oceanic lithosphere up to the Tortonian and that was contained the internal units of the Apennines (ARGNANI, 2005). During the Tyrrhenian opening, the Apenninic deformation front migrated to the E and S and the sedimentary covers of the Adria and African margin were progressively incorporated in the orogenic wedge to form the southern Apennines and the Sicilian Maghrebides (LENTINI *et alii*, 1994; CELLO & MAZZOLI, 1999; PAROTTO & PRATURLON, 2004; ROSENBAUM & LISTER, 2004). Most of the shortening in the southern Apennines took place after 10 Ma, at the same time as extension in the Tyrrhenian basin (ROURE *et alii*, 1991). The deformation front moved the farthest to the southeast toward the subducting Ionian oceanic seaway. Sediments accreted or underplated from the Ionian basin formed a large accretionary wedge to the SE of Calabria (ROSSI & SARTORI, 1981; LENCI *et alii*, 2004; FINETTI, 2005).

Extension did not progress symmetrically in the Tyrrhenian, but migrated from the W to the E with time (KASTENS *et alii*, 1988; GUEGUEN *et alii*, 1997). The earliest center of extension was the Cornaglia Terrace W of Sardinia (Fig. 1), where there is clear evidence on seismic reflection profiles of pre-Messinian sediments. The Cornaglia Terrace had to be the deepest area at the time Messinian salt was deposited (~6 Ma), because the Messinian salt layer is clearly recognizable on seismic reflection lines only W of about 12°E longitude (FABBRI & CURZI, 1979; MALINVERNO *et alii*, 1981). After the deposition of the Messinian salt, extension shifted east to the Vavilov basin (KASTENS *et alii*, 1988). The Vavilov basin is bounded to the E by a bathymetric ridge with a relatively thick crust, the Issel bridge (SARTORI, 2003). A relic Pliocene calc-alkaline volcanic arc has been observed there, coeval to extension in the Vavilov basin (SARTORI, 1986; KASTENS *et alii*, 1988; ROSENBAUM & LISTER, 2004). Starting about 2 Ma, extension moved east once more to the Marsili basin (KASTENS *et alii*, 1988). The Paola basin, located east of the Marsili basin near the coast of Calabria (FABBRI *et alii*, 1981), is a deep sinkhole containing about 5 km of Pliocene and Quaternary sediments (BARONE *et alii*, 1982; FINETTI & DEL BEN, 1986; TRINCARDI *et alii*, 1995) and may be the site where extension has migrated most recently (GUEGUEN *et alii*, 1997).

The direction of maximum extension in the Tyrrhenian was approximately E-W when extension was active in the Cornaglia terrace and in the Vavilov basin, and then rotated to SE-NW during the formation of the Marsili basin (SARTORI, 2003). Extension rates averaged over the last 10 Ma are 40-50 km/Ma (PATACCA *et alii*, 1990; FACCENNA *et alii*, 1996; FACCENNA *et alii*, 2004). The extension rate was not constant in time, but reached a maximum of 60-100 km/Ma in the Messinian (~6-5 Ma) (ROSENBAUM & LISTER, 2004); this extension rate is matched by Messinian deformation rates of 80 km/Ma in the southern Apennines (PATACCA *et alii*, 1990). GPS data show that Calabria is not presently moving to the SE with respect to Sardinia (D'AGOSTINO & SELVAGGI, 2004; SERPELLONI *et alii*, 2005), suggesting that extension in the Tyrrhenian domain is not active at present.

The bottom cross-section in Fig. 1 shows the present-day geometry, with a large orogenic wedge composed of Ionian Sea sediments accreted or underplated while the oceanic seaway between the African and Adria margin was being subducted. The present-day crustal structure is given by the results of seismic experiments (STEINMETZ *et alii*, 1983; SCARASCIA *et alii*, 1994). The crustal structure in the deepest part of the Ionian Sea (4 km water depth) consists of approximately 6 km of sediments and 7 km of igneous crust, so that the Moho is 17 km below sea level (MAKRIS *et alii*, 1986; DE VOOGD *et alii*, 1992). The 20 km thickness of the Calabria accretionary wedge near the coast of Calabria is also constrained by seismic experiments that show the Ionian Moho at 30-35 km depth near the SE coast of Calabria (FERRUCCI *et alii*, 1991; SCARASCIA *et alii*, 1994). By offsetting the crustal section in the deep Ionian Sea to have a Moho 35 km deep and assuming that no sediment was added to the wedge, the minimum wedge thickness is 13-18 km. The cross-sectional area of the wedge formed during the Tyrrhenian extension in the bottom cross-section of Fig. 1 (light gray region) corresponds to approximately 80% of the sediment that covered the length of the Ionian basin subducted in the last 10 Ma. The total cross-sectional area of continental crust in the overriding plate in the 10 Ma cross-section balances the area of extended continental crust in the present-day cross-section. The total amount of extension in the Tyrrhenian Sea implied by the cross-sections of Fig. 1 is 370 km. If the Tyrrhenian started forming 10 Ma, this gives an average extension rate of 37 km/Ma, which matches the averages estimated by other authors (PATACCA *et alii*, 1990; FACCENNA *et alii*, 1996; FACCENNA *et alii*, 2004).

SUBDUCTION HINGE ROLLBACK AND OROGENIC EXTENSIONAL COLLAPSE

A widely proposed explanation for the formation of the Tyrrhenian Sea is based on the observation that the hinge of a subducting plate will migrate away from the overriding plate if the subducting plate has a vertical component of motion into the mantle (ELSASSER, 1971; RITSEMA, 1979). If the subduction hinge migrates, or "rolls back" faster than the plates converge, extension will take place in the overriding plate (DEWEY, 1980). Extension in the Tyrrhenian has therefore been explained by a SE rollback of the subduction hinge (DERCOURT *et alii*, 1986; FINETTI & DEL BEN, 1986; MALINVERNO & RYAN, 1986; REHAULT *et alii*, 1987; PATACCA & SCANDONE, 1989; PATACCA *et alii*, 1990; DOGLIONI, 1991; NUR *et alii*, 1991; FACCENNA *et alii*, 1996; FACCENNA *et alii*, 2004; ROSENBAUM & LISTER, 2004). This explanation has a solid kinematic basis: if two plates do not converge significantly while subduction continues, the hinge of the subducting plate has to roll back, causing extension in the overriding plate. Conversely, if hinge migration does not take place, subduction has to stop and leave an oceanic remnant.

Another mechanism proposed for the Tyrrhenian extension invokes the extensional collapse of a pre-existing orogenic belt (HORVÁTH & BERCKHEMER, 1982; DEWEY, 1988; CHANNELL & MARESCHAL, 1989). The driving force for extension in this case is the greater potential energy of an elevated mountain range with thick crust compared to nearby regions at lower elevations (ARTYUSHKOV, 1973; BOTT, 1982; MOLNAR & LYON-CAEN, 1988). Thinning of the lithospheric mantle beneath the mountain range (e.g., by small-scale convection) will additionally favor extension (PLATT & ENGLAND, 1993).

Rollback and orogenic collapse are often presented as alternatives, but in the Tyrrhenian region they acted together. In general, mountain belts can be kept at high elevations by boundary compressive forces due to plate convergence; an orogenic belt located at the edge of an overriding plate, however, will be able to extend by pushing away the subducting plate hinge (LE PICHON, 1982; DEWEY, 1988). Analog experiments by FACCENNA *et alii* (1996) confirm that an overriding lithospheric plate that is thicker and more buoyant than the subducting plate exerts an additional force on the subduction hinge that increases the rollback velocity. If the subduction hinge tends to roll back on its own, extension in the overriding plate will concentrate in the regions of thicker crust and higher elevation.

A HYPOTHESIS ON THE MIGRATION OF EXTENSION IN THE TYRRHENIAN SEA

The two mechanisms of subduction hinge rollback and orogenic collapse suggest a working hypothesis for the outward migration of extension in the Tyrrhenian Sea. The extension leading to the formation of the Tyrrhenian basin started ~10 Ma in the higher elevation areas of an embryonic Apenninic-Maghrebian orogenic belt. As the subduction hinge rolled back, the Apenninic-Maghrebian accretionary wedge grew at its outer edge by adding material scraped off from the thick sedimentary covers of the Ionian Sea and of the Adria and African margins. Hence, the site of maximum elevation in the overriding plate shifted outward, which could have led to a corresponding migration of the focus of extension. The rapid Late Pleistocene uplift of Calabria (FERRANTI *et alii*, 2006) may be an episode in this progressive shift of the maximum uplift in the Tyrrhenian domain. A related outward shift of the volcanic arc could also have played a role, increasing the local geothermal gradient and weakening the lithosphere. This working hypothesis can be tested by analog and computational geodynamic modeling.

Toward morphologic and morpho-tectonic syntheses of the Mediterranean Sea

JEAN MASCLE (*), GEORGES MASCLE (**)

Key words: *Geodynamic, Mediterranean Sea Morphotectonic, Synthesis.*

After more than 5 decades of sea going researches, conducted by tens of different laboratories in the Mediterranean Sea, we now face an extremely abundant set of data and scientific publications which appear sometimes difficult to use at a synthetic scale allowing to simply present and discuss the geological and geodynamic frameworks of the Mediterranean domain.

Fig.1 - Geological & Morphotectonic map of the Mediterranean domain.

To tentatively answer to this paradox, which consist to produce a simplified image/model from many and various data sources, we selected several major characteristics of the Mediterranean domain and we built, under Arcgis environment, a geological and morpho-tectonic synthesis, which results itself from the superposition of more than 25 distinct layers. Each layer is a compilation of a specific characteristic of the Mediterranean Sea such as for example, its morpho-bathymetry, the various active, or recently active, tectonic deformations including the presence of wide spread salt-driven gravity tectonics, or for example the location of fluid seepages and mud volcanoes.

The map stresses the strong contrast between the relatively young, now poorly deforming, Western Mediterranean sub-basins and the Mesozoic Eastern basin, bounded by passive margins to the South and active margins to the North.

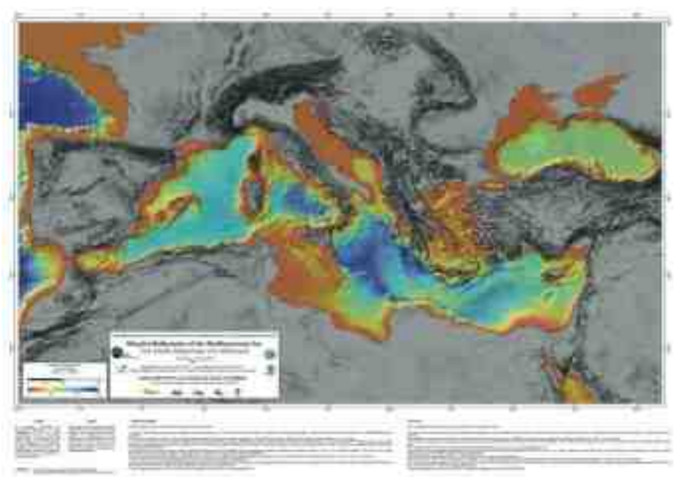

Fig. 2 - Morphobathymetric map of the Mediterranean Sea.

This morpho-tectonic synthesis has been included into a highly simplified onshore geological background aiming to stress the relationships between the Mediterranean Sea basins and their surrounding geological environment, particularly the various stable basements, sedimented platforms and tectonic belts resulting from the long term convergence between Africa and Europe.

The importance of climate in controlling high-frequency cyclic stacking patterns in fluvio-deltaic systems of tectonically-active basins

EMILIANO MUTTI (*)

Key words: *fluvio-deltaic systems, inertia- and friction-dominated periods, cyclic stacking patterns.*

ABSTRACT

In ancient tectonically-active basins fed by relatively small and high-gradient rivers, both marine and lacustrine fluvio-deltaic systems display similar vertical stacking patterns which are primarily controlled by high-frequency variations of sediment flux to the basin. These variations are superimposed over higher-order cycles of tectonic uplift and relative quiescence recorded by changes in the source areas, basin configuration and overall style of sedimentation. Spectacular examples of these cyclically stacked successions crop out in the upper Cretaceous and Paleogene deposits of the south-central Pyrenean foreland basin. Similar stacking patterns are also common in other basins (e.g., the Jurassic-Cretaceous Nequen basin, Argentina and the Tertiary Piedmont Basin, northwestern Italy).

Sediment flux to the sea controls the high-frequency stacking pattern of ancient fluvio-deltaic depositional systems through cyclic variations in flow efficiency which is mainly a function of the magnitude and sediment concentration of river outflows during floods. These variations result in periods of inertia- and friction-dominated jet flows followed by periods during which fluvial activity dramatically decreases. These cyclic variations, which are ultimately controlled by Milankowitch cycles, are recorded by m- to dam-thick facies successions that can be interpreted as the basic "building block" (in sequence-stratigraphic parlance) of tectonically-controlled depositional sequences.

Inertia-dominated periods are characterized by large-volume highly erosive hyperpycnal flows typically containing abundant skeletal debris and mudstone clasts. These highly-efficient flows bypass river mouths and carry sand to nearshore and shelfal regions forming m-thick packets of tabular graded sandstone beds with HCS alternating with muddier facies. These sandstones, which extend up to several km in shelfal regions and grade distally into prodeltaic sediments, are a typical and volumetrically dominant deltaic element herein referred to as "flood-generated delta-front sandstone lobes". Their facies tracts closely resemble those observed in deep-water turbidites. Unfortunately, because of the presence of HCS, these shallow-marine sediment gravity flow deposits have been and are still commonly mistaken in most literature for "storm-dominated" shoreface deposits.

Friction-dominated periods are expressed by mouth-bar progradation produced by river outflows of limited volume and efficiency (poorly-efficient flows) that dissipate their energy at river mouths and are thus able to carry seaward only their fine-grained sediment load through buoyant plumes and dilute hyperpycnal flows.

When rivers dramatically decrease their activity, fluvio-deltaic systems aggrade through marine mudstone facies that pass landward into flood-plain mudstones with paleosols.

Marine diffusion processes are restricted to local tidal reworking that occurs in river mouth regions and, more extensively, in large estuaries where fluvial processes mix with strong tidal action. Following decreased river activity, carbonate deposition may locally occur forming generally thin units at the top of fluvio-deltaic sandstones.

Sea-level variations probably play a minor role in high-frequency cyclic stacking patterns which appear essentially dominated by climate variations coupled with regional subsidence. Over longer periods of time relative sea-level variations and related stratigraphic unconformities separate thicker sedimentary packages as the result of local and regional structural deformation.

Several problems arise as to the sequence stratigraphic interpretation of these fluvio-deltaic systems and their cyclic stacking patterns. In particular, these problems concern the significance of the "shoreface" and "parasequence" concepts that can be misleading if not viewed within a robust framework of stratigraphic and facies constraints.

Formation and deformation of sedimentary basins: the feed-back from deep seismic (crustal) imagery and mantle tomographies

FRANÇOIS ROURE (*,**)

Key words: *crustal architecture, Moho, lithosphere, infracontinental mantle, rifts, passive margins, foothills, Alps, Apennines, Paris Basin, Pyrenees.*

INTRODUCTION

In the last twenty years, huge national and international efforts, frequently linking academy and industry, have been devoted to the recording of deep seismic profiles in many intracratonic sedimentary basins, foreland fold-and-thrust belts and offshore passive margins, thus providing a direct control on the structural configuration of the basement and the architecture of the crust in various geodynamic environments. Seemingly, needs for documenting also the current thickness of the mantle lithosphere and the fate of subducted lithospheric slabs have led to the development of more academic and new tomographic techniques. When put together, these various techniques now provide a direct access to the bulk 3D architecture of sedimentary basins, crystalline basement and Moho, as well as underlying mantle lithosphere. In this presentation, we shall use various deep seismic data sets (ECORS, CROP, COCORP, LITHOPROB, DEKORP, NFP20, SWAT), as well as more conventional seismic profiles from the industry, to document the overall geometry and geodynamic evolution of selected reference basins and thrust belts, mainly in the Mediterranean-Tethyan-Alpine realm, but also elsewhere in Europe and in the Southern and Northern American Cordilleras.

RIFTS, PASSIVE MARGINS AND INTRACRATONIC BASINS

The symetry versus asymetry of rift basins and conjugate passive margins are now well documented, despite the fact that the deep controls and lateral changes in the asymetry cannot always be clearly identified. Of prime importance is the change observed in the overall vertical motion between episodes of rifting and post-rift sags.

Thermal subsidence is not the only parameter controlling the long term evolution of passive margins and intracratonic basins. Accurate velocity models and gravimetric data account for the local occurrence of dense rock bodies at or near the Moho, accounting for underplatting of volcanic rocks (passive margins) or preservation of anomalous mantle (intracratonic basins), which may also account for long term subsidence of these basins.

COMPRESSIONAL BASINS

Various types of sedimentary basins, i.e., foreland, thrust-top, intra-mountain and back-arc basins, are also associated to tectonic wedges. They usually provide unique opportunities to study the timing of deformation, rates of vertical motion, as well as the coupling between surface and deeper processes involving the crust, the lithosphere, or even mantle dynamics in the vicinity of major plate boundaries.

The basement architecture of compressional basins still locally preserves the high-angle normal faults of the former passive margin undeformed, despite the fact that foreland inversion structures are likely to develop either prior of after the main episodes of thrust emplacement.

Important changes are also observed in the subsidence history of these basins, in relation to the delamination of the infracontinental mantle, slab detachment and/or asthenospheric upwelling beneath the hinterland, as documented by various case studies taken from the Mediterranean-Tethyan thrust belts, as well as from the North American Cordillera and Sub-Andean basins.

CONCLUSIONS

Despite the fact that deep seismic imagery and mantle tomography provide now accurate data on the current crustal and lithospheric architecture of sedimentary basins and orogens, further numerical and analogue modelling are still very important tools to test/validate various hypotheses on their overall

geodynamic evolution, i.e., the long term thermo-mechanical changes operating in the deep crust and upper mantle through times. Seemingly, source-to-sink studies combining the dating of unroofing in the orogens by means of paleo-thermometers with sequence stratigraphy in adjacent depocenters, constitute powerfull tools to unravel the geological records of the vertical motion and couplings between lithospheric-asthenospheric processes with surface topography and climate.

New Geoarchaeological Approaches to Assess Relative Sea-Level Rise on Recently Submerged Egyptian and Italian Coastal Margins

JEAN-DANIEL STANLEY (*)

Key words: *Calabria, compaction, geoarchaeology, neotectonics, Nile Delta, relative sea level, sea-level rise, seismicity, submergence, subsidence rate, uplift.*

THE PROBLEM

Study of submerged man-made structures and vestiges began in earnest in the latter part of the 1800s and early 1900s and, not surprisingly, most were located in the Mediterranean, that extraordinary repository of ancient coastal sites. Exploratory efforts accelerated rapidly, especially after the development of Scuba diving in the late 1940s. Archaeologists led the way (DIOLÉ, 1952), and were later joined by geographers and geologists who expanded efforts to better interpret the origin of sites now underwater (FLEMMING, 1969; MASTERS & FLEMMING, 1983). As technologies for studying the seafloor evolved—some of which are now routinely applied by geologists and geophysicists to systematically survey the seafloor and its subsurface—marine geoarchaeology 'came into its own' as a specific subfield. Thus, discussing topics concerning such marine research is particularly appropriate for the 86th Congress of the Geological Society of Italy given the overarching theme of "The Mediterranean, a geological repository between past and present."

In this context, recent observations that pertain to a series of presently submerged sites of ancient Greek and Roman origin positioned in two markedly different geological settings warrant examination herein. One set of coastal sites is positioned on the Nile Delta margin of northern Egypt (Fig. 1), a relatively stable geological area, while the other set of ancient vestiges is along the Calabrian margin (Fig. 3), recognized as one of Italy's most seismo-tectonically active sectors. During the late Holocene (since ~3000 years ago), these two vastly different geological sectors were both subjected to extensive site substrate lowering that resulted in remarkably similar average annual rates of subsidence and relative rise in sea level. Consideration of these seemingly paradoxical findings and their implications may provide insight into future protective measures for these vulnerable modern coastal margins.

(*)NMNH-Smithsonian Institution, Washington, D.C. USA
@-mail:stanleyd@si.edu

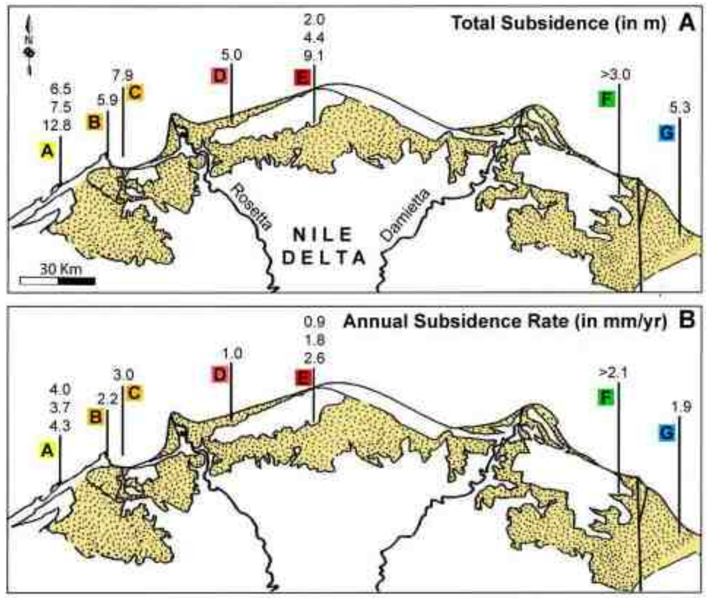

Fig. 1 – A, Map shows total subsidence (local relative sea-level elevation plus local vertical land motion) in meters at 7 Nile Delta margin sites (A-G). B, Long-term average annual subsidence rates in mm/yr, based on archaeological depths and ages. Three sets of numbers at sites A and E are data for 3 superposed archaeological levels (older at bottom, younger at top). Data derived from Table 1 in STANLEY & TOSCANO (2009).

NILE DELTA MARGIN SITES

Holocene stratigraphic sequences have been examined along the arcuate ~200 km-long northern Nile Delta margin (Fig. 1) that extends from ~30 km landward of the present delta coast to inner shelf areas (including those off Alexandria, and in Abu Qir Bay and Gulf of Tineh). Multi-disciplinary studies include those that detail the petrology and other aspects of >90 long continuous drill cores (some to 50 m in length) recovered on land and ~25 cores off shore; also evaluated are results of high-resolution subbottom seismic surveys and seafloor observations made on the Nile shelf. The surface elevation at most core recovery sites on land is only ~ 1 m above sea level. More than 400 radiocarbon dates indicate that the Holocene fluvio-marine delta began to form ~8000 to 7000 yrs ago (STANLEY & WARNE 1994, 1998; STANLEY *et alii*, 1996). Investigations detailing various multi-disciplinary facets of the delta's evolution have been published from 1986 to 2009 by the Mediterranean Basin Project (MEDIBA) group at the Smithsonian, in collaboration with numerous specialists in Egypt, Europe and North America.

The Holocene fluvio-marine deltaic sequence is positioned above a thick accumulation (to >5000 m) of strata that date back to the Miocene (SAID, 1981; SCHLUMBERGER, 1984). Subsurface facies dated and identified from sediment core analyses include beach, coastal dune, lagoon, marsh, fluvial and inner shelf units (STANLEY & WARNE, 1998). Although positioned in a relatively stable geological sector, the northern delta plain is delineated at both its NE (near Suez Canal) and NW (near Alexandria) margins by faults that have remained active in recent time (SAID, 1981; NEEV & FRIEDMAN, 1978). Moreover, the thickest Holocene deltaic sequences (>40 m) underlie Manzala Lagoon and are interpreted as sediment sink deposits that accumulated in a faulted pull-apart basin (STANLEY, 1988).

To assess submergence and relative sea-level rise along this delta plain margin, we calculated average long-term Holocene subsidence rates from east to west. We initially took into account at each core locality the total measured Holocene sediment thickness and radiocarbon age recorded at its base (Fig. 2; data in STANLEY *et alii*, 1996). However, the resulting rates based on these attributes alone proved unreliable as they generally do not take into account (1) missing stratigraphic sections (hiatuses) (GOODFRIEND & STANLEY, 1996) and (2) radiocarbon dates that tend to be too old due to sediment reworking and 'storage' phenomena affecting some delta core sequences (STANLEY, 2001). These factors result in subsidence rates that are generally lower than those obtained using depth and age of archaeological material (Fig. 2). We find that a more reliable method of calculating substrate subsidence rates on the delta margin (detailed in STANLEY & BERNASCONI, 2012) is to base them on archaeological information. Primarily, we examine the total amount of lowering of a reliably dated construction feature below present sea level (Fig. 1A), while accounting for its functional height relative to sea level at the time of and shortly after a feature's construction. For the latter, we used Holocene sea-level curves such as those geophysically modeled by LAMBECK *et alii* (2004).

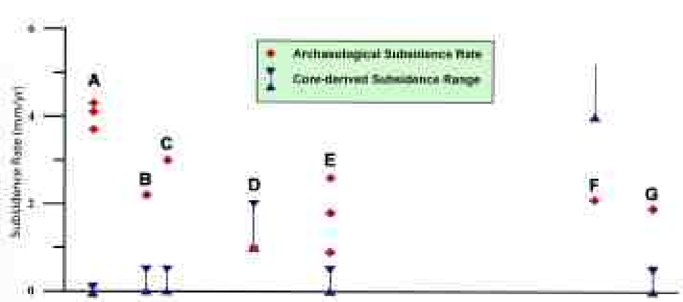

Fig. 2 – Graph compares Holocene subsidence rates derived from archaeological and depth data (from Fig. 1B) with those resulting from measurements of total Holocene sediment thickness and basal radiocarbon date in each core.

These data serve to measure substrate subsidence rates beneath 11 pre-Greek, Greek, Roman, and Byzantine archaeological structures and materials collected at 7 nearshore to inner shelf localities (see STANLEY & TOSCANO, 2009). These are: (A) submerged Alexandria's Eastern Harbor; (B, C) submerged ancient settlements of East Canopus and Herakleion in Abu Qir Bay; (D, E) buried localities on the NW and SE margins of Burullus Lagoon; (F) Tell Tinnis in Manzala Lagoon; and (G) Pelusium (Tel Farama) along the Gulf of Tineh. Total amount of lowering of all 11 archaeological horizons at the 7 sites ranges from >3.0 m to 12.8 m; the range of lowering for the 7 uppermost sites is 2.0 to 7.9 m (Fig. 1A). Using archaeological ages and associated data (STANLEY & TOSCANO, 2009), the calculated average subsidence rates for the youngest (uppermost) features at the 7 sites range from about 1.0 to 4.0 mm/yr (Figs. 1B, 2).

CALABRIAN MARGIN SITES

The geological and geographical settings of the present coast and inner shelf on the Calabrian margin differ markedly from those along the northern Nile Delta plain. Not only are Calabrian Holocene sequences much thinner, but both the land and offshore sectors of this margin are considerably more mobile with strata dislocated (faulted, folded, tilted) by powerful recent to on-going seismo-tectonic activity. These represent near-surface effects resulting from the convergence of the southern European and North African plates in this central Mediterranean region (MALINVERNO & RYAN, 1986; WESTAWAY, 1993; TORTORICI *et alii*, 1995). The elevated position of raised marine terraces and dated sedimentary sequences above present sea level is evidence of land uplift on the terrestrial side of Calabrian coastal margins since the early Pleistocene (MIYAUCHI *et alii*, 1994); some are raised to hundreds of meters at rates to 1 mm/yr, and locally even to 2 mm/yr (BIANCA *et alii*, 2011). Calabria's present shelf platforms display ample evidence of dislocation by faults and are much narrower than shelves formed in more geologically stable and sediment-rich regions such as off the Nile Delta. Newer methodologies used to examine the seafloor surface, such as high-resolution subbottom seismic profiles and multibeam sonar, record innumerable structural offsets, some as small as a few centimeters while others may be several meters in relief (STANLEY *et alii*, 2011). In addition, there is evidence of gravity flow deposits, such as slumps, that partially cover the shelves. However, to date relatively little work has closely correlated the neotectonic and recent depositional offshore features with dated seismo-tectonic events that affected this sector of the southern Italian margin.

Since 2003, geoarchaeological studies of various ancient Greek (*Magna Graecia*) and Roman sites have been conducted on Calabria's margin, sponsored by the Cities Under the Sea Project (CUSP) at the Smithsonian's National Museum of Natural History (synthesis in STANLEY & BERNASCONI, 2012). These are coordinated by the author of the present contribution and professor M.P. Bernasconi of the University of Calabria, with participation of Dr. M.T. Iannelli, Soprintendenza Archaeologica della Calabria, Reggio Calabria, and associated specialists in Italy and North America. Five sites have been examined to date (Fig. 3): (1) Sybaris-Thuri (margin in Gulf of

Taranto); (2) Hipponion-Vibo Valentia (Tyrrhenian Sea margin); and (3) Locri-Epizefiri, (4) Kaulonia, and (5) Kroton-Capo Colonna (Ionian margin). Of prime interest are ages of the

Fig. 3 – Location of ancient Greek centers in southern Italy, including the 5 buried and submerged sites (1-5).

archaeological structures and depths to which the features have become submerged (Fig. 4). As at sites on the Nile Delta margin, measurements of total subsidence have been made and record a lowering from 2 m to 13 m below present sea level (Fig. 4). Calculated estimates of average annual rate of subsidence take into account sea level at the time of construction and functional depth of structures relative to former sea level stand. A notable variation of subsidence rates is recorded from site to site: (1) 0.5 to 1.0 mm/yr; (2) 0.8 to 3.2 mm/yr; (3) ~1.6 mm/yr; (4) 1.6 to 2.4 mm/yr; and (5) ~4.0 mm/yr. Descriptions of the coastal facilities, methods used, measured subsidence rates, and geological factors controlling subsidence at each of the five above sites are presented in STANLEY & BERNASCONI (2012).

IMPLICATIONS

A notable variation in Holocene subsidence rate data collected to date has been recorded from site to site on both the Nile Delta and Calabrian margins. In addition to eustatic rise, other factors must be active to account for the wide variety of subsidence rates. Large marked differences in relative sea-level rise indicate significant influence of, among others factors, tectonically-driven vertical land motion, compaction of recent sediment, and reorganization/displacement of strata at depth. The close similarity in ranges of subsidence on the two very geologically different sectors is, at first glance, surprising. One might expect the Nile Delta margin, a considerably more tectonically stable setting, to have subsided at lower rates than the coastal sectors of the Calabrian arc, a particularly active zone. Instead, data based on archaeological findings record ranges of subsidence rates along both margins that center around 1.0-4.0 mm/yr (Figs. 1B, 4).

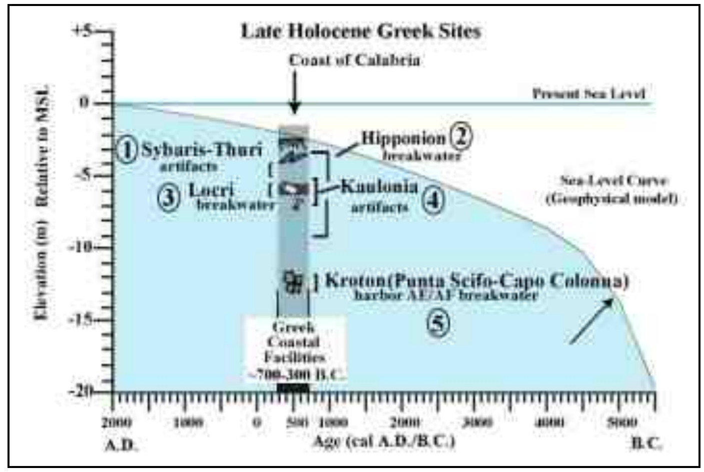

Fig. 4– Synthesis of 5 ancient submerged facilities on Calabrian margin showing their present depths beneath the Holocene sea-level curve of LAMBECK *et alii* (2004). Approximate average long-term rates of subsidence in mm/yr: (1) 0.5-1.0; (2) 0.8-3.2; (3) 1.6; (4) 1.6-2.4; and (5) 4.0.

The lowering of substrates underlying sites along the Nile Delta margin has likely occurred at a fairly gentle and consistent rate, in part due to readjustment at depth of very thick pre-Holocene strata. In addition, and particularly in the case of the Holocene units, thick accumulations of clayey silt from the river Nile (especially before the emplacement of the two Aswan dams during the last century) have been subject to considerable and rapid rates of compaction; these partially account for the relative sea-level rise to 4 mm/yr. The high rate of substrate lowering in the northwestern delta margin is most likely influenced by fault offset in the Alexandria and Abu Qir areas (Figs. 1B, 2). Other high rates are correlated with the thickest sections of Holocene sediment that accumulated on the northeastern margin.

In contrast, the Calabrian margins are affected by irregularly timed neotectonic pulses that induced faulting, stratal uplift and lowering, tilting, and folding. These have resulted in the formation of narrow dislocated shelf platforms that are covered by modest and uneven thicknesses of Holocene sediment. This seismo-tectonic activity has episodically resulted in the reworking of deposits on the shelf seafloor, formation of submerged terraces and relief features, and triggering of tsunamis such as the one that caused catastrophic damage along the Tyrrhenian coast of SW Calabria in September 1905.

Integration of archaeological and geological data as proposed here can be used to better interpret the recent history of the two present Mediterranean nearshore settings and perhaps also serve to predict their future evolution. Although the Nile Delta margin has evolved more gently and regularly during the late Holocene, the consequences of sediment compaction, substantial subsidence, and the minimal addition of new Nile sediment to the plain have become a serious concern. These three factors, acting together, have led to a substantial increase in rates of relative sea-level rise. The northern third of the delta plain surface area lies within only ~1 m elevation above sea level. This extensive low-lying sector is occupied by a rapidly growing population approximating 10 million, and includes a substantial part of the already reduced agricultural land in northern Egypt. Availability of subsidence rate data can be used to help coastal engineers formulate and implement protective coastal measures at the most susceptible localities, and agricultural managers to better identify those subsiding land areas most subject to salt intrusion into the groundwater. In contrast, the more episodic nature of subsidence along different sectors of the Calabrian margin in the late Holocene hampers predictions as to the specific timing and location of the next major seismo-tectonic events. Consequently, implementing effective protective measures in the region remains a challenge. However, if the past serves as a key to the present, records regarding an increasing number of areas subject to significant subsidence and associated relative sea-level rise in the recent geological past are now available to coastal engineers, providing them with potentially valuable information for addressing present and future coastal protection concerns.

Deformazioni oblique nel sistema orogenico Alpi-Appennino: vincoli cinematici

FERNANDO CALAMITA (*), SILVIO SENO (**) & ENRICO TAVARNELLI (***)

Key words: *Transpressione/transtensione, tettonica trasversale, deformazioni oblique, vincoli cinematici, Alpi, Appennino.*

RIASSUNTO

La continuità laterale delle catene orogeniche è caratteristicamente interrotta da lineamenti trasversali od obliqui la cui attività è coeva con la messa in posto delle principali unità tettoniche: tuttavia molte strutture trasversali sono riconducibili a discontinuità paleogeografiche ereditate da eventi pre-orogenici, oppure a deformazioni successive alle principali fasi di costruzione delle catene. I lineamenti trasversali gocano un ruolo importante nell'evoluzione dei sistemi orogenici in quanto spesso determinano variazioni significative nello stile della deformazione. Le peculiarità dei lineamenti trasversali possono essere messe in evidenza attraverso il contributo di studi multidisciplinari che combinano analisi strutturale, macrotettonica, geodinamica, indagini geofisiche e modellazioni sia numeriche che analogiche. In questo lavoro vengono illustrati i caratteri cinematici principali di alcuni lineamenti trasversali che interrompono la continuità laterale delle principali strutture compressive del sistema Alpi-Appennino. Sono analizzati nel dettaglio lineamenti trasversali presenti nelle Alpi Liguri, nell'Appennino settentrionale, nella zona di giunzione fra l'arco umbro-marchigiano e l'arco laziale-abruzzese ed infine strutture con cinematica complessa rinvenute lungo il limite fra l'Appennino centrale e l'Appennino meridionale. Le associazioni strutturali documentate per questi settori, la cui cinematica risulta estremamente complessa, forniscono la base analitica per un modello di deformazione che trova adeguata collocazione nei canoni della deformazione transpressiva.

Il confronto fra le strutture trasversali documentate in questo studio con analoghe associazioni rinvenute in sistemi transpressivi sia fossili che attivi indica che la presenza di lineamenti paleogeografici obliqui e/o trasversali rispetto alla direzione del trasporto tettonico ha determinato un significativo controllo nei processi di ripartizione della deformazione, caratteristici dei regimi tettonici transpressivi.

L'influenza della Linea Scicli-Ragusa sulla Tettonica Quaternaria e la Pericolosità Geologica presso l'abitato di Scicli (Sicilia sud-orientale)

COCO G. (°), CORRAO M. (°), DIPASQUALE M. (*°), OCCHIPINTI R. (°), PETRALIA M. (°°), TAVARNELLI E. (*)

Termini chiave: *Amplificazione sismica, Linea Scicli-Ragusa, Tettonica Quaternaria, Transpressione.*

INTRODUZIONE

La nota ha lo scopo di evidenziare la pericolosità geologica lungo una serie di faglie di origine quaternaria riscontrate in rilievi di campagna in un'areale – C. da Imbastita-Zagarone - presente presso la zona SE dell'abitato di Scicli.

Tali cinematismi, legati all'importante zona di taglio regionale rappresentata dalla Linea Scicli Ragusa (GHISETTI, 1980), sono rappresentati in affioramento da strutture associate a regimi locali transpressivi e transtensivi ben evidenziati dai rilievi effettuati.
Morfologicamente nell'area si riconosce un'estesa sella morfo-tettonica il cui sviluppo è legato ad importanti strutture tettoniche miste di età quaternaria.

Nell'area sono state effettuate inoltre una serie di misure strumentali (tomografie sismiche e misure di rumore sismico – Metodo Nakamura) allo scopo rispettivamente di verificare: **A**) le caratteristiche sismiche dei terreni; le cui variazioni laterali sono state messe in luce grazie all'elaborazione di un certo numero di sismostratigrafie. **B**) le possibili caratteristiche di amplificazione del sito mettendo in risalto gli specifici evidenti aspetti di pericolosità geologica e sismica del sito dovuti allo stile tettonico ivi presente.

La nota pertanto riporta un *case-history* che vuole porre l'attenzione in un'area particolarmente vulnerabile per la presenza della più importante struttura tettonica dell'altopiano ibleo (linea Scicli-Ragusa) al rischio sismico che, a parere degli scriventi, necessiterebbe di adeguate caratterizzazioni di microzonazione sismica.

INQUADRAMENTO GEOLOGICO DELLA SICILIA SE

In Sicilia l'avampaese è costituito dal Plateau Ibleo, da tempo considerato parte della crosta continentale africana, ubicato nella parte sud-orientale dell'isola. Il Plateau Ibleo si presenta come un grosso *horst* allungato in direzione NE-SO e delimitato a NO dall'Avanfossa Gela-Catania e ad oriente dalla Scarpata Ibleo-Maltese; la parte centrale e più elevata del Plateau costituisce l'Altipiano Calcareo sensu strictu, delimitato a NO dal sistema di faglie denominato Comiso-Chiaramonte, che ribassano le successioni carbonatiche al di sotto delle coperture Plio-Quaternarie della Piana di Vittoria, e a SE viene ribassato in corrispondenza della Depressione di Ispica-Capo Passero (sistema Pozzallo-Ispica-Rosolini).

L'intero Plateau Ibleo è interessato principalmente da faglie aventi orientazione preferenziale NNE-SSO, NO-SE e E-O.
La medesima orientazione si riscontra nel già evidenziato sistema della Linea Scicli-Ragusa, che taglia longitudinalmente l'Altopiano Ibleo e presenta evidenze di trascorrenza destra.

L'Altopiano ibleo è costituito da una potente successione carbonatica, di età meso-cenozoica, la cui stratigrafia è ben conosciuta grazie alle numerose trivellazioni petrolifere effettuate negli anni '50-'70 del secolo scorso.

In affioramento le successioni maggiormente presenti sono date dalle alternanze calcareo-marnoso-argillose eoceniche-mioceniche delle Formazioni Amerillo, Ragusa e Tellaro.

MORFOLOGIA E GEOLOGIA DELL'AREA IN STUDIO

La zona di C. da Imbastita-Zagarone è caratterizzata da una morfologia collinare con la presenza di una serie di rilievi isolati i cui assi maggiori si sviluppano in direzione NNE-SSO; il maggiore dei quali è dato da C. zo Pelato e da una serie di selle morfo-tettoniche con asse principale con medesima orientazione coincidente con la zona di taglio principale.

In quest'area (Fig. 1) affiorano diffusamente le marne giallastre di età Tortoniana della F. ne Tellaro con, al tetto, spessori variabili di Trubi pliocenici e/o biocalcereniti quaternarie di colore giallo-rossastro a cementazione variabile.

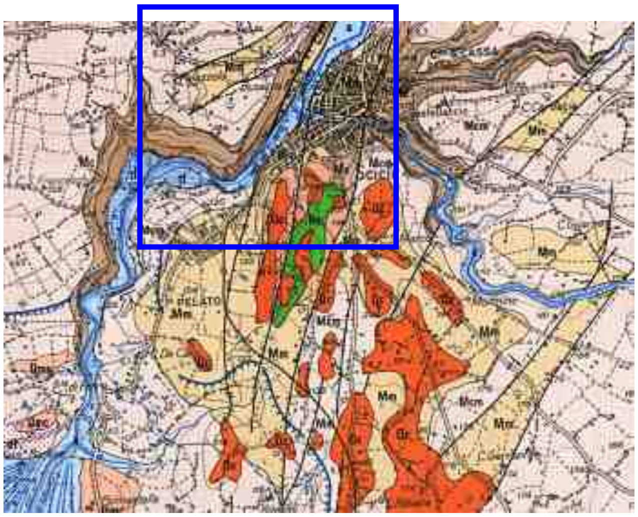

Fig. 1 - Inquadramento dell'area in studio (C.da Imbastita-Zagarone - da Grasso, 1995)

EVIDENZE DI NEOTETTONICA

Nell'area si riconoscono prevalentemente faglie a componente diretta-trascorrente che risultano tagliare (GRASSO, 1995) terreni di età quaternaria (calcareniti) con direzioni medie NNE-SSO, associate all'importante struttura di taglio conosciuta in letteratura geologia come Linea Scicli-Ragusa.

I rilievi di dettaglio condotti in affioramenti-chiave hanno permesso anche di mettere in evidenza una componente di movimento transpressiva nelle deformazioni fragili che interessano le calcareniti di età quaternaria (Fig. 2). Su tali affioramenti è stata eseguita una serie di misure strutturali alla scala mesoscopica in esposizioni significative dal punto di vista cinematico.

INDAGINI E RILIEVI

L'esecuzione di una serie di indagini di geofisiche di seguito descritte ha permesso di affinare ulteriormente le conoscenze dell'area in studio; in sintesi sono state condotte:

- *tomografie sismiche in onde P*; effettuate nelle zone nelle quali dai rilievi geologico-strutturali era possibile ipotizzare la presenza, al di sotto degli spessori colluviali superficiali, di possibili zone di faglia;
- *misure di rumore sismico in array*; al fine di determinare i possibili fenomeni di amplificazione sismica e la riposta in frequenza di sito oltre le possibili polarizzazioni dei segnali indicativi di presenza di discontinuità tettoniche sepolte sotto le coperture eluviali.
- anali di stratigrafie presenti nell'area.

I principali risultati delle indagini geofisiche condotte nell'area oggetto di studio sono sinteticamente descritti come segue.

Le tomografie sismiche effettuate - con direzione trasversale alla sella morfo-tettonica - hanno permesso di verificare, tramite l'elaborazione di sezioni sismiche interpretate, intervalli di Vp compresi in un range tra 350 m/s e 3000 m/s con profondità di investigazioni di circa 35 metri dal p.c.

Le velocità sono così suddividibili: A. Vp <1200 m/s: 1° sismo strato; B. 1200< Vp < 1600 m/s; 2° sismo strato; C. 1600< 2200 < m/s

Le tomografie hanno mostrato importanti variazioni laterali della velocità lungo le sezioni che interessano esclusivamente i terreni calcarei-calcarenitico evidenziando una morfologia complessa del substrato, che appare dislocato secondo possibili movimenti diretto.

Fig. 2 – Evidenze di movimenti transpressivi presso la zona di faglia interessanti le calcareniti quaternarie (C.da Zagarone – Imbastita).

Le misure di rumore sismico mostrano un'evidente polarizzazione (fig. 3) dello stesso rumore sismico in prossimita' di discontinuità tettoniche al di sotto delle coltri superficiali tratti nei quali il vettore del rumore sismico si dispone in direzione circa N-S.

La relativa complessità delle distribuzioni azimuthali delle polarizzazioni sembra far evidenziare un assetto strutturale con presenza di possibili ampie fasce di fatturazione che interessano i livelli pleistocenici e potrebbero determinare delle zone di potenziale riattivazione sismogenetica e/o di rottura cosismica.

CONCLUSIONI

I risultati degli studi illustrati preliminarmente in questa nota hanno consentito di mettere in evidenza gli effetti di pericolosità geologica causata dalla presenza, presso la zona a SE dell'abitato di Scicli (C.da Imbastita–Zagarone), di un'importante sella morfotettonica allungata in direzione NNE-SSO, il cui sviluppo è legato alla presenza di faglie quaternarie riconducibili alla zona di taglio della Linea Scicli-Ragusa. Le faglie iteressano orizzonti calcarenitici di età quaternaria diffusamente affioranti nella zona.

La zona di sella è stata attentamente studiata tramite rilievi geologico-strutturali - attraverso la raccolta di dati mesoscopici

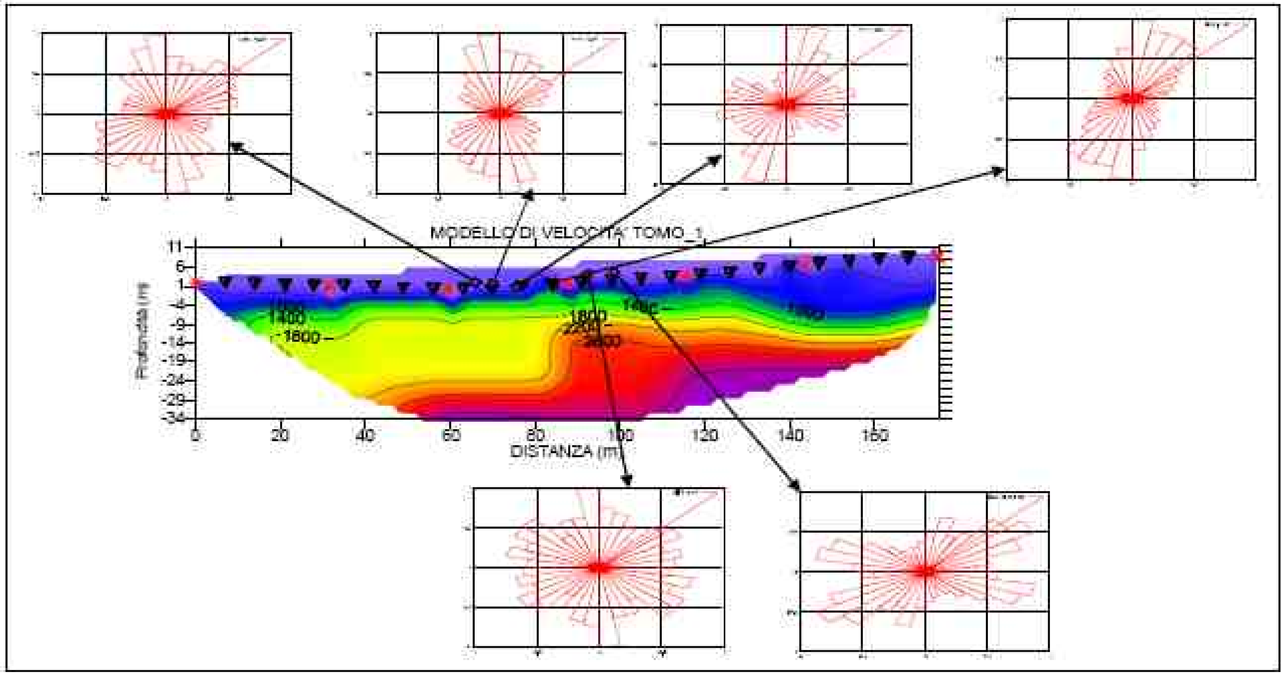

Fig. 3 – evidenze di polarizzazione presenti presso la stesa tomografica A.

condotta su un numero significativo di stazioni di misura – che hanno messo in evidenza la presenza di una componente di movimento transpressiva nelle faglie che interessano le calcareniti quaternarie.

Le zona è stata inoltre attentamente analizzata grazie all'esecuzione di misure geofisiche (tomografie e misure di rumore sismico) che hanno permesso di elaborare delle sismostratigrafie evidenzianti la presenza di faglie sepolte al di sotto delle coltri colluviali. E' stato possibile riconoscere, in tali fasce, l'esistenza di particolari condizioni di amplificazione e l'esistenza di ben precisi fenomeni di polarizzazione del segnale in prossimità di discontinuità già indicate dalle sismostratigrafie.

Con questa nota si intende pertanto mettere in correlazione le evidenze geologico-strutturali condotte alla scala mesoscopica in affioramenti-chiave, con i dati strumentali di natura geofisica (sismografie tomografiche e misure di rumore sismico), allo scopo di fornire una prima caratterizzazione delle condizioni di pericolosità geologica e rischio sismico dell'area oggetto di studio nei dintorni dell'abitato di Scicli (Ragusa).

Structural setting of the easternmost Dauphinois: stratigraphic and tectonic characters from the Ventimiglia area.

GIORGIO DALLAGIOVANNA (*), ALESSANDRO DECARLIS (*), MATTEO MAINO (*),
SILVIO SENO (*) & GIOVANNI TOSCANI (*)

Key words: *Dauphinois, Foreland basin, Ligurian Alps.*

INTRODUCTION

Since 2010, a detailed structural and stratigraphic mapping has been performed north of Ventimiglia (IM), between the Roya and Nervia valleys, by the Pavia University surveyors for the Risknat-Interreg project (Regione Liguria). The investigated area is constituted by a thick Dauphinois succession of sedimentary rocks. The post- Cretaceous Dauphinois units near the boundary between Italy and France are formed by a well-known succession: the “Priabonian trilogy”. It is formed by rocks that deposited in the Alpine underfilled peripheral foreland basin. A thick succession of Cretaceous marly limestones (Calcari e calcari marnosi di Trucco) forms the pre-Cenozoic basement, top-bounded by a regional unconformity (mostly an angular unconformity with rarer paraconcordance evidences) sealing up late Cretaceous and Paleocene deposits. The following transgression caused the deposition of marine-continental transitional deposits (conglomerates, sandstones and marls of the Microcodium Formation) during the Early Eocene. The vertical evolution of these deposits in the developing Alpine foreland basin is represented by the nummulitic limestones and calcarenites of the Calcareniti di Capo member, belonging to a shallow platform environment (about few to a hundred meters depth). The deepening trend bring to the sedimentation of marls and pelites of Marne di Olivetta San Michele Formation and finally to the turbidite sandstones of the Ventimiglia Flysch (corresponding to the Italian sub-basin deposit of the Gres d’Annot turbidite system).

The field mapping of the study area evidenced the presence of several kilometric thrusts (Abellio thrust system) that juxtaposes two tectonic elements made up by the same, above described Cretaceous-Eocene succession. The units has been informally named “M. Terca unit” (the upper) and “Roja unit” (the lower). The thrusts are roughly NNE-SSW oriented; the amount of west-transport of the M. Terca unit is probably limited but significantly diminishes toward the South. This assumption is supported by observing the amplitude and geometry of the associated drag folds. The thrust is interrupted by a lateral ramp located northward near the M. Gouta area and reaches the coast near Ventimiglia toward the South. The geometry of the thrust has been also reconstructed through digital modelling in order to understand the real implications of its anticlockwise rotation.

The Abellio thrust has been tentatively dated as Late Oligocene-Early Miocene, when the north-west Alpine compressive thrust fronts propagated in the Helvetic-Dauphinois zone. Interesting implications may come from its position, as the Abellio thrust could be considered the southermost onland structure affecting the Dauphinois succession. Its transport was probably also influenced by the interactions between the complex geometry of dispersal blocks that followed the rifting of Greater Iberia (causing the anticlockwise rotation of the Corsica-Sardinia) and the Alpine-Apennine orogens.

Inherited discontinuities in curved belt development: the oblique thrust front of the Central-Northern Apennines

ALESSANDRA DI DOMENICA (*), ANTONIO TURTÙ (*), SARA SATOLLI (*) & FERNANDO CALAMITA (*)

Key words: *Central-Northern Apennines, inversion tectonics, oblique discontinuities, Quaternary normal faults*.

INTRODUCTION

The Apennines represent a fold and thrust belt characterised by curved thrust fronts defined by NNE-SSW- and WNW-ESE-trending oblique thrust ramps such as the Olevano-Antrodoco-Sibillini (OAS) thrust and the Gran Sasso (GS) thrust, respectively (*Fig. 1*). These oblique features controlled the Neogene build-up of the chain reactivating pre-existing discontinuities which influenced the architecture of the Adria paleomargin (CALAMITA *et alii*, 2003).

The axial part of the Apennine chain is characterised by intense seismicity related to the Quaternary activity of the NW-SE-trending normal faults which are organised into 15-35 km-long fault systems (CALAMITA & PIZZI, 1994; PIZZI & GALADINI, 2009). These normal faults involve both hanging wall and footwall blocks of the NNE-SSW and WNW-ESE oblique thrust ramps and are responsible of the development of Quaternary intramontane basins located in the backlimb of the anticlines. The amount of cumulative downthrow evaluated for these faults can reach one or two thousand of meters, but only the 50% of the geological downthrow is generally related to Quaternary normal faulting, as reconstructed by PIZZI & SCISCIANI (2000).

Although the extension-compression-extension sequence has been well documented in the Apennines since the 1960s, different interpretation have been proposed about the contrasting relationships between thrusts and normal faults.

The NW-SE normal faults have been considered as Quaternary displacing the NNE-SSW-trending OAS oblique thrust (CALAMITA & PIZZI, 1994; D'AGOSTINO *et alii*, 1998; MAZZOLI *et alii*, 2005). Differently, ALBERTI *et alii* (1996), TAVARNELLI *et alii* (2004), PIZZI & GALADINI (2009) and DI DOMENICA *et alii* (in press) recognised a pre-thrusting activity of these faults terminating against the OAS thrust.

The relationships between the NNE-SSW-trending oblique thrusts and the NW-SE-trending normal faults allowed us to assess the relative chronology of deformation.

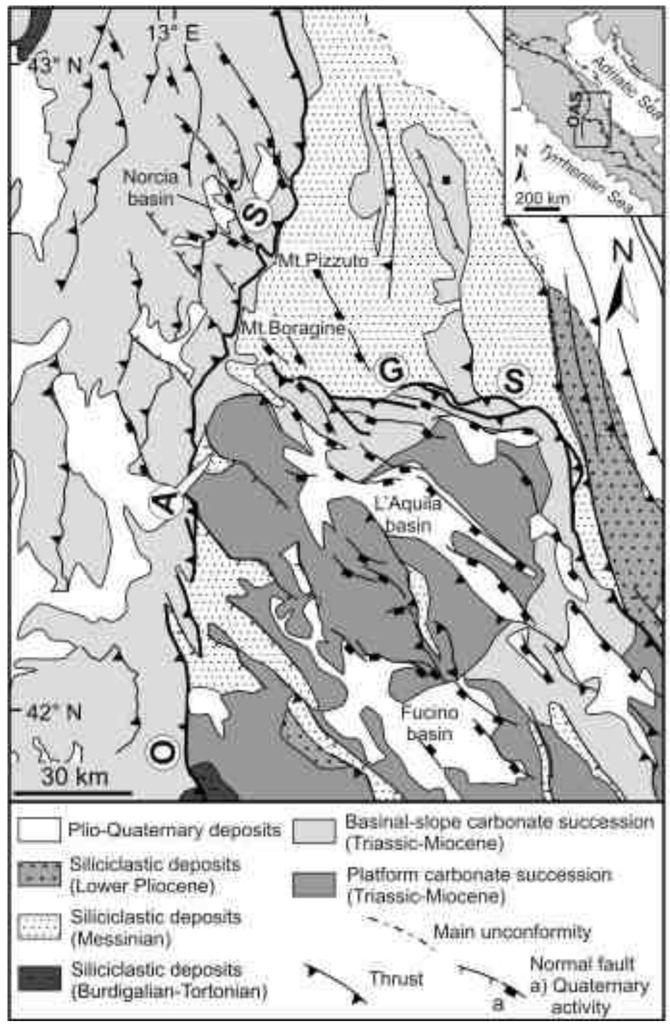

Fig. 1 – Structural map of the Central-Northern Apennines. OAS = Olevano-Antrodoco-Sibillini oblique thrust; GS = Gran Sasso oblique thrus

INVERSION TECTONICS

Along the oblique thrust ramps of the Central-Northern Apennines is possible to observe their crosscutting relationships with the NW-SE-trending normal faults. These normal faults stop

Lavoro eseguito nell'ambito dei progetti MIUR PRIN 2008 e MIUR-ex 60% (F. Calamita).

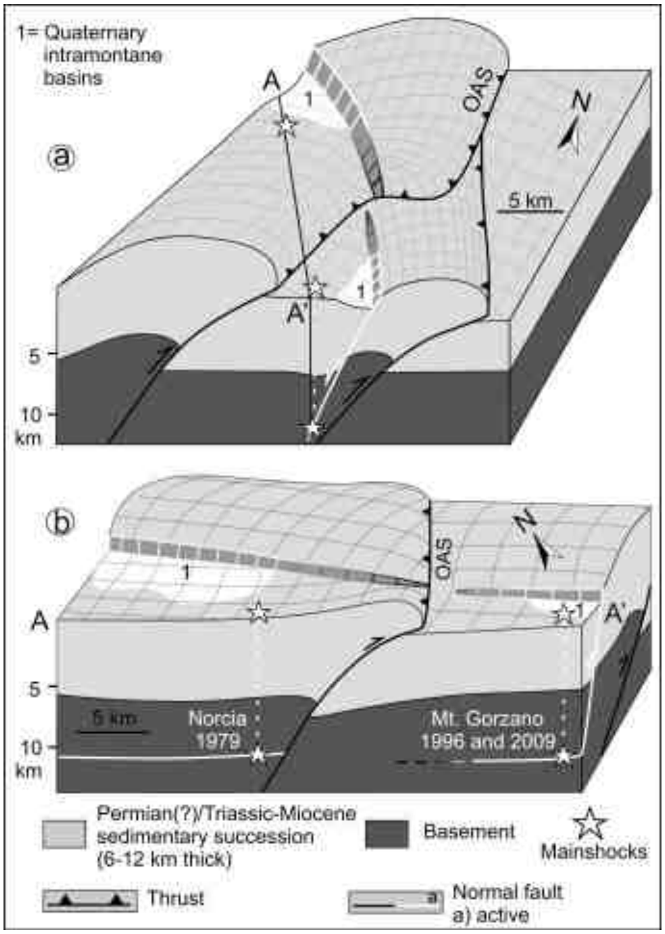

Fig. 2 – a) Block diagram that schematises the 3D relationships between the NW-SE-trending normal faults and the NNE-SSW-trending OAS thrust. Quaternary intramontane basins (1), developed at a distance of 4-8 km from the OAS thrust trace, are related to the reactivation of pre-thrusting normal faults as documented by seismic activity. b) A schematic block diagram along the A-A' section shows the crustal OAS oblique thrust ramp that compartmentalises the Quaternary growth of the NW-SE-trending normal faults and related seismicity.

against the oblique thrust planes which preserve their continuity along strike. This is clear from the stratigraphic separation diagrams performed in two sites along the OAS thrust where the Norcia-Mt. Fema fault system and the Mt. Boragine fault are confined in the hanging wall of the OAS oblique thrust without displacing it and without involving the footwall succession.

Moreover, detailed mesostructural analysis allowed us to recognise peculiar features such as buttressing geometry involving the NW-SE normal fault planes that testify the pre-thrusting activity of these normal faults.

At the same time, some of these normal faults show geological, structural and morphotectonic evidence of Quaternary activity some kilometres away from their cut-off points with the thrust plane (*Figs. 2* and *3 III*).

Hence, the NW-SE-trending normal faults experienced both pre- and Quaternary post-thrusting activity without affecting the continuity of the thrusts.

Moreover, the location of earthquake epicentres and hypocentres indicates that Quaternary normal faults and related seismicity are segmented and compartmentalised by the oblique thrusts (TAVARNELLI *et alii*, 2004). The NNE-SSW OAS and the WNW-ESE Gran Sasso oblique thrust ramps define three indipendent sectors of the Quaternary extensional seismic activity and act as barriers for the NW-SE-trending normal fault propagation and associated seismicity (PIZZI & GALADINI, 2009).

The geological framework reconstructed through the analysis of the crosscutting relationships between oblique thrusts and normal faults, allowed us to define an inversion tectonic model

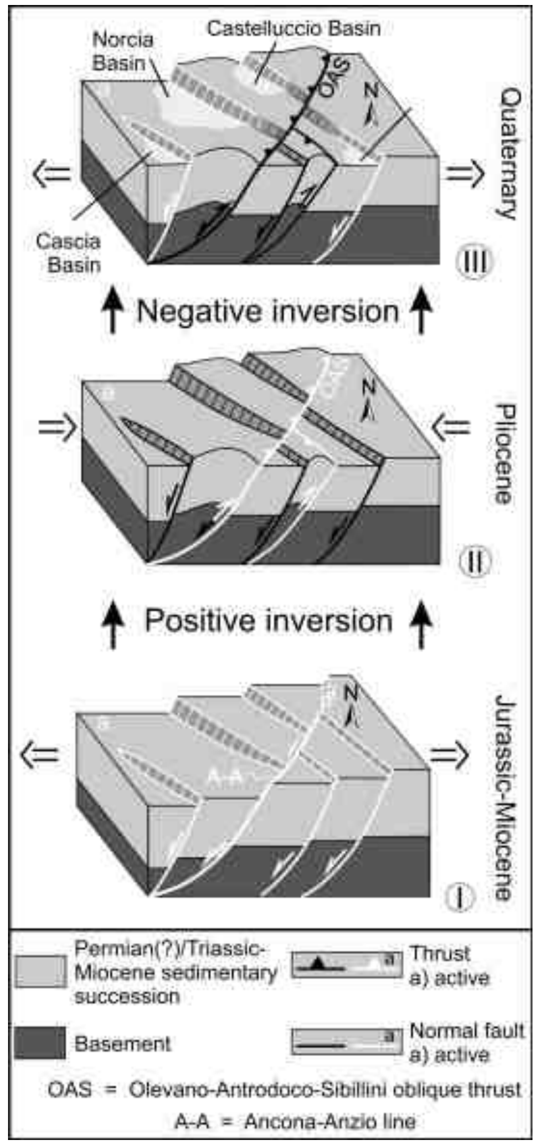

Fig. 3 – Block diagram showing the inversion tectonic model. I) NW-SE- and NNE-SSW-trending pre-thrusting normal faults were displaced and reactivated by thrusts, respectively, during the Pliocene positive inversion tectonic event (II). III) During the Quaternary inversion tectonic event, the NW-SE-trending pre-thrusting normal faults have been reactivated. The reactivation developed intramontane basins and seismic activity.

(*Fig. 3*) in which, during the Neogene, the NNE-SSW-trending pre-existing discontinuities (*e.g.*, Ancona-Anzio fault, CASTELLARIN *et alii*, 1982) were reactivated as oblique thrust ramps and the NW-SE-trending normal faults were passively translated in the hanging wall of the thrusts with shortcut trajectory. These NW-SE normal faults were successively reactivated during the Quaternary extensional event some kilometres away from the intersection with the thrust planes. This short distance of reactivation of the Quaternary normal faults suggests a sharp increase of the dip angle of the thrust planes also according to the reactivation of pre-existing normal faults realised by thrusts (*e.g.* Ancona-Anzio fault reactivated as the OAS thrust).

CONCLUSION

Oblique features in curved orogenic belts represent regional discontinuities that played a fundamental role in the definition of the present-day geological and structural framework of the chain and still influence its post-thrusting evolution.

A paleogeographic role played by the NNE-SSW and WNW-ESE oblique features of the Apennine chain is well documented in literature on the basis of stratigraphic and structural observations (*e.g.* the Ancona-Anzio fault, CASTELLARIN *et alii*, 1982, and the N-S-trending arm of the Gran Sasso range, BIGI *et al.*, 1995). These oblique lineaments, in fact, represented important pre-thrusting features separating different paleogeographic domains. The presence of NW-SE pre-thrusting normal faults has been also recognised through stratigraphic and structural analysis.

Successively, during the Neogene build-up of the chain the NNE-SSW- and WNW-ESE-trending pre-thrusting discontinuities were reactivated as regional oblique thrust ramps which involved, through shortcut trajectories, the NW-SE-trending pre-thrusting normal faults. The reactivation of pre-existing discontinuities controls the curved shape to the thrust fronts of the Apennines.

The oblique thrust ramps compartmentalise the growth of the NW-SE-trending Quaternary normal faults being crucial in the seismic hazard assessment.

Nuovi contributi sismologici e geologico-strutturali a supporto di un modello sismotettonico della zona di cerniera tra la Sicilia settentrionale ed il Tirreno meridionale

ALESSANDRA GIORGIANNI (*), DARIO LUZIO (*), ATTILIO SULLI (*), GIUSEPPE GIUNTA (*), PATRIZIA CAPIZZI (*), RAFFAELE MARTORANA (*)

Key words: meccanismi focali, morfobatimetria, sismotettonica, Tirreno meridionale

La Sicilia settentrionale ed il suo antistante offshore tirrenico costituiscono una parte della Catena Maghrebide la cui architettura è il risultato di una evoluzione tettonica multi-fase avvenuta dall'Oligocene superiore-Miocene inferiore fino al presente. A partire dal Pliocene inferiore, l'evoluzione tettonica regionale dell'area è associata all'attività di una complessa griglia strutturale collegata all'esistenza di una estesa zona di taglio destro, ad andamento W-E, che si estende per oltre 300 km dall'allineamento Ustica-Eolie, fino al "Rift di Pantelleria". Le principali strutture tettoniche, riscontrate sia a scala regionale che alla scala meso-scala, sono rappresentate da sistemi di faglie trascorrenti destre ad andamento variabile da NW-SE fino a W-E, e sistemi di faglie trascorrenti a cinematica sinistra ad andamento variabile da N-S a NE-SW; entrambi sono responsabili dell'esistenza di zone di restraining in sollevamento e zone di releasing in abbassamento.

Queste ultime sono colmate da sedimenti clastici di età plio-pleistocenica e vengono spesso bordate da faglie estensionali a geometria listrica. Tali strutture producono accomodamenti e rotazioni di blocchi disarticolati nella zona di cerniera tra il Margine Tirrenico meridionale caratterizzato da processi di assottigliamento crostale e la porzione emersa dell'orogene Siciliano dove invece è presente una crosta moderatamente inspessita.

All'interno della zona di cerniera si manifesta una diffusa attività sismica, localizzata principalmente in una fascia compresa tra 10 e 20 km di profondità, che si concentra intorno a piani ad alto angolo, con geometria coerente con i sistemi riscontrati nelle zone emerse dell'orogene (Giunta et al., 2009)

Le soluzioni focali mostrano meccanismi transpressionali, compressionali, transtensionali ed estensionali in risposta alla estrema eterogeneità dei volumi rocciosi coinvolti, effetto dell'evoluzione polifasica dell'area.

Per potere definire meglio un modello sismotettonico proposto per quest'area, sono state portate avanti ricerche multidisciplinari, attraverso analisi geologico-strutturali, geofisiche e statistiche in alcune aree chiave, ubicate sia nel settore onshore che nel settore offshore. Nel primo è stata ricostruita nel dettaglio la distribuzione della deformazione fragile connessa con l'evoluzione di una zona di taglio destra, nel secondo l'assetto strutturale è stato interpretato attraverso analisi morfobatimetriche integrate con i dati derivanti da carte geologiche del Bacino Tirrenico meridionale.

Inoltre, è stato condotto un nuovo studio sismologico su una parte della sequenza sismica avvenuta nel 2002, utilizzando un database derivato dall'integrazione dei dati registrati dalle stazioni della Rete Sismica Nazionale con quelli registrati, in una finestra temporale di quattro mesi, da 7 stazioni di una rete temporanea installata dall'INGV. In particolare, circa 40 eventi sismici registrati da più di 40 stazioni, avvenuti tra Settembre e Dicembre 2002, sono stati rilocalizzati utilizzando una procedura basata sul software HYPODD, utilizzando un modello di velocità a 8 strati affinato rilocalizzando qualche centinaio di eventi sismici del Tirreno meridionale.

I meccanismi focali degli eventi rilocalizzati con questa procedura sono stati determinati utilizzando il software FPFIT (Reasemberg & Oppenheimer, 1985). L'analisi degli eventi di questa sequenza ha permesso di evidenziare la complessità strutturale e di stimare alcune proprietà geometriche dominanti del volume sismogenetico.

Per potere caratterizzare meglio la geometria del volume sismogenetico coinvolto nella sequenza sismica è stata fatta l'analisi della variazione dello stress di Coulomb indotta dall'evento principale. I risultati di questa analisi evidenziano una geometria generale coerente con un stile deformazionale compatibile con quello ricostruito nelle zone ubicate nel settore onshore.

Uno studio dei meccanismi focali condotto anche su circa 100 eventi sismici della sequenza di Pollina (Madonie orientali) del 1992-93, selezionati in base al valore della magnitudo locale, ha consentito di determinare le tipologie dominanti di meccanismi focali e le orientazioni degli assi principali di stress. Inoltre, l'integrazione con uno studio tomografico delle strutture più superficiali, ha evidenziato la stretta connessione tra le ubicazioni ipocentrali e le zone di massima eterogeneità laterale della distribuzione di velocità delle onde sismiche. Nel complesso gli elementi acquisiti

(*) Dipartimento di Scienze della Terra e del Mare – Università di Palermo

attraverso questa analisi mostrano una buona compatibilità con il modello deformazionale generale ricostruito per l'area.

Tale modello è stato infine confrontato anche con gli elementi derivanti dallo studio di due recenti sequenze sismiche minori che hanno interessato il settore più settentrionale dell'area siciliana tra il 2010 ed il 2012. In particolare, tali sequenze hanno interessato l'area di Caprileone nel messinese e l'offshore di Isola delle Femmine ad ovest di Palermo.

In quest'ultimo settore i dati morfobatimetrici ad alta risoluzione (ecoscandaglio multifascio) evidenziano la presenza di strutture morfologiche verosimilmente collegabili a due sistemi strutturali ad andamento ENE-WSW e NNW-SSE.

Il contributo delle faglie longitudinali e trasversali nell'evoluzione delle Maghrebidi siciliane e dei margini peri-caraibici

GIUSEPPE GIUNTA (*) & ALESSANDRA GIORGIANNI (*)

Key words: *Strike slip faults, tectonic evolution, Sicilian Maghrebides,Caribbean Plate margins.*

Le strutture longitudinali e trasversali rivestono una grande importanza nell'evoluzione della Catena Maghrebide siciliana e dei margini della Placca Caraibica, contribuendo in maniera determinante all'assetto di tali *belt* deformati.

1) Sistema trascorrente destro delle Maghrebidi nord-siciliane. La catena Maghrebide siciliana è un orogene collisionale, a direzione E-W, indotto dalla rotazione antioraria della placca Africana stabile, ed é composta da unità embriciate a vergenza meridionale, con associati bacini di tipo *piggy-back*, che sovrascorrono su un avampaese da poco deformato a indeformato. Ciascun stadio di trasporto tettonico, sin dal Miocene è stato accompagnato da episodi di inversione negativa (a vergenza settentrionale) nella porzione più interna della catena in costruzione (GIUNTA *et alii* 2000). Più recentemente, dal Pliocene, l'evoluzione del bacino Tirrenico ha determinato una larga fascia trascorrente destra (GHISETTI & VEZZANI, 1984; GIUNTA *et alii*, 2000), estesa dall'allineamento Ustica-Eolie al Canale di Sicilia, che include la zona di cerniera tra la Sicilia settentrionale e il basso Tirreno.

Questa fascia di deformazione è caratterizzata da una fitta maglia di faglie recenti ad alto angolo, per lo più trascorrenti, che forma una zona di taglio longitudinale alla catena. Lungo tale zona si denota la presenza di settori in subsidenza (*releasing*) ed in sollevamento (*restraining*), connessi a sistemi di faglie sintetiche e antitetiche di vario ordine di grandezza (GIUNTA *et alii*, 2000), e di bacini Plio-Pleistocenici diacronicamente subsidenti verso est interpretati come depressioni strutturali tipo *semi-graben*.

Numerosi segmenti del succitato sistema di faglie sono sismicamente attivi, con terremoti superficiali (intensità tra M=2 e M=6), più profondi in Sicilia orientale. I meccanismi focali dei terremoti si adattano bene a un regime tettonico trascorrente e/o transpressionale riconosciuto attraverso analisi strutturali in Sicilia settentrionale (GIUNTA *et alii*, 2008).

2) Sistema trascorrente sinistro di Motagua-Polochic in Guatemala. Il sistema di faglie Motagua-Polochic rappresenta la porzione occidentale del limite tra la Placca Caraibica e quella Nord-Americana, che attraversa il Guatemala centrale ed orientale connettendo la fossa meso-americana con il bacino di Cayman (GIUNTA, 1993; PINDELL & BARRETT, 1990). Trattasi di una zona di taglio sinistro formatasi tra i blocchi continentali Maya e Chortis nel Cretaceo Medio (GIUNTA *et alii*, 2002), che oggi rappresenta una tipica "struttura a fiore" evoluta in un persistente campo di sforzi trascorrenti (FINCH & DENGO, 1990; GIUNTA *et alii*, 2002 d). Il Lago Izabal, un ampio bacino *pull-apart* caratterizzato da una configurazione asimmetrica del cuneo sedimentario, e le strutture "*pop-up*" di Sierra Chuacus e Las Minas sono le maggiori evidenze regionali della zona di taglio sviluppatesi sin dal Mio-Pliocene. Il bacino di Izabal si è impostato nella zona di sovrapposizione dei segmenti transtensionali delle sopradette faglie, traslando progressivamente il depocentro del bacino verso SW.

3) Sistema trascorrente destro El Pilar in Venezuela settentrionale. Lungo la Cordigliera de la Costa e la Serrania del Interior, nel Venezuela settentrionale, si ha il limite tra le placche Caraibica e Sud-Americana (PINDELL & BARRETT, 1990; GIUNTA *et alii*, 2002c). Questa complessa zona di deformazione consiste in una fascia allungata per circa 1000 km in senso E-W, larga al massimo 250 km, che connette le Ande settentrionali con l'arco delle Piccole Antille (LALLEMANT, 1996). La tettonica recente delle cordigliere del Venezuela settentrionale consiste in una complicata griglia di faglie *strike-slip*, con connessi sistemi sintetici ed antitetici, dove la faglia di El Pilar rappresenta la zona principale di dislocazione destra. L'analisi strutturale di numerose faglie longitudinali e in particolare trasversali permette di ricostruire un campo deformazionale regionale non-coassiale sin dal Cretaceo (GIUNTA *et alii*, 2002). Il margine di placca era già completamente sviluppato nel tardo Terziario come zona di taglio destrale, attualmente caraterizzata da elevata sismicità. La cinematica delle faglie attive, ricavabile dai meccanismi focali di terremoti crostali è in accordo con gli indicatori cinematici rilevati sui piani di faglia (AUDEMARD *et alii*, 2004).

Senza voler entrare nel merito di possibili correlazioni tra le fasi evolutive delle due regioni geologiche in esame, si vuole porre l'accento soltanto sul significato dei sistemi trasversali e longitudinali indotti da campi di sforzi variabili nel tempo, e sulle risposte in termini di distribuzione della deformazione.

(*) Dipartimento di Scienze della Terra e del Mare – Università di Palermo

Le strutture longitudinali possono avere le caratteristiche di faglie a componente orizzontale, che determinano la formazione di zone di *releasing* e di *restraining*, oppure essere la risultanza dell'aggiustamento isostatico dell'orogene, ed avere geometria ad alto angolo e componente estensionale. Spesso tali strutture riattivano sistemi paleotettonici o rampe di *thrust* più antichi.

Nel caso dei sistemi trasversali, questi possono determinarsi per un accomodamento delle unità tettoniche in risposta a campi di sforzi obliqui, con conseguente deformazione non coassiale, o per grandi differenze di competenza nelle litologie delle unità tettoniche lungo l'asse dell'orogene, o ancora per emergenza di rampe laterali di *thrust*.

Nella maggioranza dei casi siciliani e caraibici entrambi i sistemi contribuiscono ad ulteriori raccorciamenti dell'orogene. In particolare, sia nelle Maghrebidi siciliane che nei margini settentrionale e meridionale della Placca Caraibica si tratta di deformazioni non coassiali legate a campi di sforzi obliqui con elevata componente tangenziale. Alcune di queste strutture sono oggi ancora simicamente attive pur avendo assunto nel tempo caratteristiche differenti, altre invece sono simicamente inattive perché risultato dell'evoluzione di originarie faglie crostali non più radicate, la cui porzione più superficiale è stata coinvolta nel raccorciamento.

L'analisi strutturale di alcuni sistemi di faglie appartenenti alla complicata griglia che intaglia sia il margine settentrionale siciliano che i margini della Placa Caraibica, dimostra che si tratta di faglie a prevalente componente orizzontale delle quali, quelle ad andamento trasversale, sono divise in sintetiche o antitetiche. Le evidenze di terreno mostrano che la maggior parte delle faglie trascorrenti conosciute accomodano la deformazione obliqua lungo alcuni segmenti, attraverso lo sviluppo di strutture di secondo ordine con geometrie *en echelon*, e componenti di scivolamento sia inverse che normali.

Nel caso della Sicilia tali strutture possono essere ricondotte ad un modello che prevede una rotazione antioraria dell'avampaese stabile combinato con l'apertura del Bacino Tirrenico che, nel raccorciare le Maghrebidi siciliane, provoca anche una rotazione oraria degli elementi disarticolati che compongono l'orogene stesso che in ultima analisi favorisce l'accentuazione della curvatura dell'Arco Calabro.

Per la Placca Caraibica il margine settentrionale ed il margine meridionale sono *belt* non coassiali legati all'inserimento tra le due croste continentali delle placche Nord- e Sud-Americana, di un vasto Plateau oceanico cretacico-terziario, di cui è costituito il fondo del Mar dei Caraibi, con deriva di tale Plateau verso est, permettendo la formazione dell'Arco delle Piccole Antille e la deformazione dei suoi margini settentrionale e meridionale lungo le terminazioni delle placche continentali adiacenti.

Un'ipotesi ritenuta abbastanza verosimile proposta per la Placca Caraibica potrebbe essere quella del progressivo "spostamento" verso Est di due punti tripli a Nord e a Sud del Plateau Oceanico che condiziona l'evoluzione dei *belt* collisionali e contemporaneamente l'accentuazione dell'Arco delle Piccole Antille sempre più verso Est.

Un tale modello ancorché semplicistico, potrebbe essere applicato anche per le Maghrebidi Siciliane con un ipotetico punto triplo ubicato tra l'avampaese ed il Tirrreno che, a partire dal Miocene superiore tende a spostarsi verso Est, creando le odierne Maghrebidi Siciliane e consentendo la curvatura dell'Arco Calabro.

Structural analysis of foliated fault zones of the Umbria-Marche Apennines (Central Italy)

GABRIELE LENA (*), MASSIMILIANO R. BARCHI (**), WALTER ALVAREZ (**) & FABRIZIO FELICI (°)

Key words: *Umbria-Marche Apennines, S-C cataclasites, shallow level shear zone*

INTRODUCTION

Several examples of foliated fault zones, characterised by a penetrative S-C fabric at a mesoscopic scale, dominated by pressure-solution deformation mechanisms, are exposed in the Umbria-Marche region. These fault rocks are developed at shallow depth (D< 3 km) in sedimentary rocks (pelagic limestones and marls), commonly associated to major thrust faults (e.g. Lavecchia, 1985; Barchi & Lemmi, 1996). However, they have also been mapped, associated to normal faults and strike-slip faults (e.g. Collettini et al., 2003).

Here we present the structural pattern of the Scheggia Thrust Zone (STZ), a spectacularly exposed shear zone localized along the Scheggia-Foligno Line (Barchi et al., 2012), an important tectonic boundary, dividing the Umbria-pre Apennines (characterised by extensive outcrops of Miocene turbidites and by relatively low elevation) from the adjacent, easternmost Umbria-Marche ridge (a belt of major anticlines, with extensive exposures of Mesozoic-Paleogene carbonates, forming the major mountain range of the region).

We performed a detailed mesostructural analysis along several outcrops of the STZ, aimed to: i) a detailed qualitative and quantitative description of a significant example of S-C fabric, developed in sedimentary rocks at shallow crustal levels (< 3km); ii) the reconstruction of the structural meso and macro-architecture of the shear-related damage zone; iii) the study of the factors, controlling the genesis and evolution of the analyzed tectonic pattern.

STRUCTURAL ANALYSIS

The STZ is related to a SW-dipping thrust with down-section trajectory, producing the tectonic superposition of younger on older rocks (fig. 1a). The hangingwall of the thrust consists of a Miocene succession, made of hemipelagites and turbidite sandstones (Schlier, Marnoso Arenacea and Mt. Vicino Fms.), cropping out along the M. Serra Maggio syncline. The footwall is represented by the backlimb of the NNW-SSE trending Mt. Nerone-Mt.Cucco anticline, where a Cretaceous-Paleogene multilayer crops out, consisting of limestines and marls (Scaglia Rossa, Scaglia Variegata and Scaglia Cinerea Fms.).

The shear zone is exposed along natural gorges, where it is possible to recognise different structural associations (bands), related to progressively increasing magnitude of deformation, as we approach the fault core, which is well exposed in a recent quarry (fig. 1b), along the Flaminia National Road, affecting the Scaglia Variegata and Scaglia Cinerea Fms.

The S-C fabric (fig. 2a-c) consists of:

i) gently SW dipping, closely spaced (5 to 10 cm), frequently striated **C planes**, cutting through the SW dipping strata with a down-section trajectory, with a top-to-the-NE sense of shear and dip-slip slicks; C-surfaces are parallel to the main tectonic contact;

ii) a dense (0.3 to 3 cm spaced) pattern of high angle NE vergent **S foliation**; the foliation surfaces are often characterized by mm-thick calcite slickensides; S-Surfaces are generated by pressure-solution processes: however, they are often re-opened and filled with striated calcite, indicating that they are re-activated as minor thrust faults;

rare and widely spaced (20 to 50 cm) sub-horizontal **C' planes** (synthetic to the C planes) ; these shear planes cut previous S-C foliation.

Steeper reverse shear planes, 15 to 25 cm spaced, here named C2 planes obliquely dissect the previous S-C fabric. C2 planes cut through the relicts of bedding sub-parallel or steeper, displace and rotate the previous S foliation and they also deform or reactivate C and S planes (with a staircase trajectory); no new S foliation is generated, connected to the C2 thrusts. The slip surfaces are characterized by dip-slip or slightly oblique-slicks; sometimes the C planes or C2 planes correspond to sheared bedding surfaces localized between calcareous beds and marl strata. Many NW-SE striking, generally SW-dipping **calcite veins** occur within the fault zone: most of these veins are parallel to the S-surfaces. Locally, these veins are involved into NE verging asymmetrically folds, coherently oriented with the sense of transport of the shear zone. Few remnants of the primary

Serra Maggio syncline (Schlier, 8; Marnoso Arenacea Fms, 9) on the Umbria-Marche basinal succession, represented by the backlimb of the NNW-SSE trending Mt. Nerone-Mt.Cucco anticline, (mesozoic carbonate multiplayer 1-4; Scaglia Rossa fm., 5; Scaglia Variegata fm., 6; Scaglia Cinerea Fm.7); b) Landscape and line drawing of the STZ: study outcrop in the white square;

stratification are locally preserved, recognizable in the rhythmic alternation of reddish marls-whitish limestone with cherty layers. **Boudinage** of brittle cherty layers is also observed locally. All the kinematic indicators (slickensides) in the S foliation, C and C2 surfaces are coherent with the top-to-the-NE tectonic transport.

The distribution of the dip angles of the different structural features within the fault zone (fig. 2c), showing that: (i) - C-planes are at shallow angle respect to bedding (down-section trajectory); (ii) S-planes are systematically steeper than both bedding and C-planes, forming an angle of about 50° with C-planes; (iii) - C2 planes are parallel or steeper than bedding.

FINAL REMARKS

Foliated fault rocks, dominated by pressure-solution mechanisms, where cataclastic deformation is subordinated to almost absent, can be developed at shallow depth (1 to 3 km) in sedimentary rocks. The Scheggia STZ is a significant example of such fault zones. From a geometrical and cinematic point of view, these fabrics are strictly analogue to the S/C fabrics developed at larger depth in ductile regime (Berthè et al., 1979).

Different structural styles have been observed within the STZ, due to the influence of different control factors, such as i) lithology (competent vs. less competent strata) ii) anisotropy of the involved rocks, iii) fluid-assisted deformation and iv) strain intensity (distance by the fault core).

In particular, the spacing of both C-planes and S-planes is controlled mainly by two factors: (i) - the distance from the main tectonic contact (the pattern is more closely spaced close to the main thrust); (ii) - the lithology of the protolith (fig. 2b): in the marly levels S-surfaces are flattened (i.e. the angle between S and C decreases) and more closely spaced than in calcareous (more competent) beds (Alvarez et al., 1978).

As expected, within the STZ, the magnitude of deformation

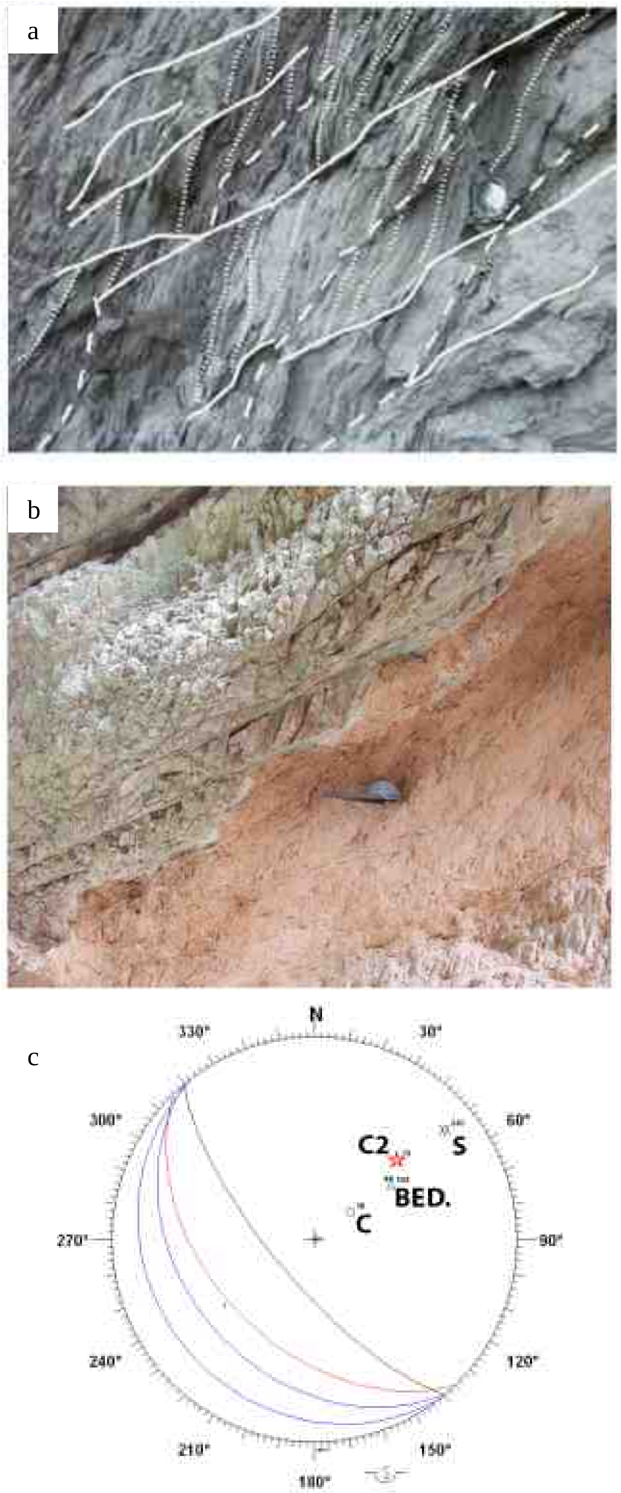

Fig. 2 – a) Tectonic pattern of the S-C fabric recognized along the STZ, affected by steeper reverse shear plane, C2; b) effects of lithology on the spacing and attitude of the S-foliation c) The stereonet shows the down section trajectories of the C planes respect the bedding.

decreases with the distance from the main tectonic contact; however, far from the fault core, the magnitude of deformation is lithologically controlled: almost undeformed calcareous beds are alternated to intensely sheared intervals, localised along weak, marly horizons.

The interpretation of a seismic profile suggests that the STZ is the surface expression of two different thrusts, splaying-out from two décollements, located at different depth within the pelagic multilayer. The C2 planes would be related to the second thrust event, splaying out from the deeper décollement. Our conclusion is that the STZ underwent two co-axial compressional events, occurred soon after, or during, the Mt. Nerone-Mt. Cucco anticline growth, as suggested by the down-section trajectory.

Cross-strike Discontinuities in the Moine Thrust Belt of NW Scotland; their identity, tectonic significance, and evolution

GRAHAM LESLIE (1), MAARTEN KRABBENDAM (1), MICHAEL KELLY (2), KATHRYN GOODENOUGH (1), STUART CLARKE (2) AND GRAHAM WILLIAMS (2)

Key words: *Moine Thrust Belt, Scotland, transverse zones*.

ABSTRACT

Abrupt lateral changes in thrust geometry occur in many mountain-building fold-and-thrust belts. Whilst many works have dealt with palinspastic reconstructions and transport-direction-parallel balanced cross-sections, far fewer show a full three-dimensional architecture, or examine how these lateral variations in thrust architecture can be linked via so-called 'transverse zones' that demarcate different segments of the thrust belt. When identified, these transverse zones are commonly thought to be related to kinematic responses to irregularities generated across pre-existing, sometimes re-activated, sub-décollement basement faults, contrasts in pre-thrusting cover strata deformation across basement faults, development of duplex structures/antiformal stacks, and/or along-strike variations in mechanical stratigraphy. In many cases however the causative structure is concealed, either by distal parts of the thrust belt or by the foreland basin and so must be deduced from the overall structural architecture (Krabbendam & Leslie, 2010).

In NW Scotland, the classic WNW-vergent Caledonian Moine Thrust Belt (MTB) incorporates a variety of crustal-scale segments. North of the Loch Maree Fault, the MTB is characterised by imbricate thrust stacks as exemplified by the classic Assynt region whereas, to the south of Loch Maree and above the Kishorn-Kinlochewe thrusts, the southern MTB is more accurately referred to as a fold-and-thrust belt. Thrust-dominated sectors are typically foreland-propagating whereas fold-and-thrust-dominated sectors will often contain evidence for repeated switching between foreland-, and hinterland-propagating accommodation of contraction. There are excellent examples, at a variety of scales, of the structural architectures in the transverse zones that segment the MTB. This presentation will examine a number of these. The amplitude and complexity of the disturbance associated with the transverse zone is typically much greater than amplitude of any irregularity identified in the basement below the thrust belt.

In the Assynt Culmination of the Moine Thrust Belt, the Traligill Transverse Zone trends sub-parallel to the thrust transport direction, and is associated with an *en echelon* fault system cutting thrusts, with discontinuity of the thrust and thrust sheet architecture, and with oblique fold and thrust structures. This transverse zone is developed above a basement cross-fault which records repeated brittle reactivation of a Proterozoic shear zone. Thrusting thus deformed a sedimentary sequence that was already disrupted by faults aligned sub-parallel to the thrust transport direction.

In the southern MTB east of the Lochalsh Syncline on the Lochalsh peninsula, at least six separate thrust sheets can be identified. Brittle-ductile contraction in the middle to upper crust has considerably shortened successions already deformed by ductile folding and non-coaxial shear in the mid- to upper crust. These six thrust sheets alternate right-way-up and inverted successions and structurally higher thrusts truncate the underlying thrust sheet, demonstrating a hinterland propagating thrust sequence. Inverted successions show penetrative non-coaxial deformation whereas thrust sheets carrying a right-way-up succession show far less internal deformation and locally, perfectly preserve internal depositional contacts. The Moine Thrust (s.s) truncates the lower two of these thrust sheets and truncates the axial trace of the Lochalsh Syncline on Skye.

In the Kinlochewe district where the Loch Maree Fault Zone (LMF) transects the MTB, a fold-and thrust architecture including completely inverted slabs of Torridonian/Lewisian rocks can be clearly identified on the northern wall of the LMF. This architecture is in sharp contrast to classically imbricated repetitions of Torridonian-Cambrian rocks on the southern wall of the LMF. The compartmentalisation is suggested to be a response to a significant offset of the pre-thrust template that generated a transport-parallel lateral ramp or sidewall during transport.

The Loch Maree transverse zone marks the southward change to the fold-and-thrust architecture in the southern MTB but the still younger Achnashellach Culmination bulges up this fold-and-thrust system, and so demonstrates a return to foreland-propagating thrusting in the later stages of development of the MTB south of the Loch Maree Transverse

Zone. The (brittle) Moine Thrust then truncated all of the structural elements beneath, indicating a final hinterland-propagating episode of movement all along the MTB suggesting that influence of the transverse zones diminished in time as the thrust belt evolved.

Three-dimensional visualisations of these complexities are challenging to construct and deliver to the geological community – this presentation will includes examples of progress in rendering fold and thrust surfaces in 3D (Figs. 1 & 2).

Seismotectonic implications of transversal discontinuities in the Apennine belt

ENZO MANTOVANI (*), MARCELLO VITI (*), DANIELE BABBUCCI (*) & NICOLA CENNI (*)

Key words: *Seismotectonics, Apennines, Central Mediterranean.*

Since the late Messinian, the tectonic evolution of the Apennine belt has mainly been controlled by belt parallel shortening (MANTOVANI *et alii*, 2009, 2011, 2012a,b; VITI *et alii*, 2011). This mechanism was accommodated by the lateral escape of orogenic wedges at the expense of the Adriatic foreland. The differentiated extrusion patterns of such wedges required the generation or reactivation of transversal discontinuities, such the Sangro-Volturno and Olevano-Antrodoco, characterized by transpressional tectonics (e.g., TAVARNELLI *et alii*, 2004; SATOLLI & CALAMITA, 2008). Due to major changes of boundary conditions in the Central Mediterranean region, around the late Pleistocene, the roughly northward motion of the Adriatic plate has accelerated emphasizing belt parallel shortening in the Apennines. In particular, this process has been accommodated by the lateral escape of wedges from the outer belt, mainly constituted by the Molise-Sannio wedge, in the southern Apennines, the eastern sector of the Lazio-Abruzzi carbonate platform, in the Central Apennines and the Northern Apennines (Fig.1). The extruding material, mainly constituted by the sedimentary cover, has been decoupled by its crustal basement through low angle fault systems rooted inside the mechanically weak Triassic evaporites (Anidriti di Burano).

The proposed kinematic/tectonic interpretation is compatible with the complex pattern of extensional and compressional deformation that has developed at the inner and outer sides of the extruding wedges. In particular, it is worth noting that the relatively faster NEward lateral escape of the Molise-Sannio and Romagna-Marche-Umbria wedges has produced considerable transtensional strain in the two zones where the major Neapolitan and Roman volcanism took place. In this regard, it must be considered that a transtensional strain field is the most favorable regime for the generation of the crustal fractures that allow magma uprising. Furthermore, the proposed tectonic scheme provides plausible explanations for the peculiar distribution in space and time of strong earthquakes during the major seismic crises that affected the Apennine belt since 1300 (MANTOVANI *et alii*, 2010, 2011, 2012a,b). The considered examples suggest that the activation of the main decoupling border of the Molise-Sannio wedge, i.e. the Irpinia-Benevento-Matese seismic zone, emphasizes shear stress at the main longitudinal fault systems (L'Aquila and Fucino) of the Lazio-Abruzzi platform. The activations of the above zones have then preceded the strongest shocks in the Northern Apennines. The computation of the post seismic relaxation induced by major earthquakes (e.g. VITI *et alii*, 2003) may help to explain the time pattern of strong events in these sequences.

The fact that the proposed kinematic/tectonic context is still going on is indicated by its compatibility with the pattern of horizontal velocities derived by the observations of a dense network of GPS permanent stations (CENNI *et alii*, 2012).

Along-strike variation of fault-related folding in a curve-shaped foreland fold-and-thrust belt: a case from the Northern Apennines

PAOLO PACE (*), SARA SATOLLI (*) & FERNANDO CALAMITA (*)

Key words: *Northern-Apennines, Curved thrust-belts, Fault-bend folding, Fault-propagation folding, Positive inversion tectonics*

INTRODUCTION

In compressive belts shortening is mainly accommodated by both folds and thrusts with complex mutual interactions. Their geometric and chronological relationships can be easily understood in foreland fold-and-thrust belts (e.g., TAVARNELLI, 1993) and it is fundamental to development of kinematic models and the reconstruction of the structural setting (CALAMITA, 1990).

Thrust-related folds are characterised by typical fold profiles: first-mode fault-bend folds show a gently-dipping forelimb, whereas in fault-propagation folds a steep-to-overturned dipping front-limb develops on a blind thrust ramp tip, which progressively propagates through the multilayer (e.g., SUPPE, 1983; SUPPE, 1985; SUPPE & MEDWEDEFF, 1990). When blind-thrusting occurs fault-propagation folds are most likely to be developed, as in the case of the Apennine anticlines (TAVARNELLI, 1993). So that, fault-propagation fold can be unambiguously distinguished from second-mode fault-bend folds. In addition, several studies experienced that most fault-bend folds are first-mode and thus the second-mode is quite rare (SUPPE, 1983).

Several experimental studies revealed that the thrust-related folding mechanism is mainly controlled by the mechanical characteristics of the involved multilayer (e.g., CHESTER *et alii*, 1991; CHESTER & CHESTER, 1990; MITRA, 2005).

During inversion tectonics, the fault-related folding mechanism could be related to different inversion tectonic processes: i) the compressive reactivation of normal faults produces fault-bend folds, accompanied by minor fault-propagation folding at the thrust leading edge (MITRA, 1993); ii) shortcut thrust trajectories through normal faults usually realise fault-propagation folds (e.g., BOND & MCCLAY, 1995).

The Central-Northern Apennines (Fig. 1) are characterised by thrusts associated with overturned or recumbent box folds (CALAMITA, 1990) involving the Meso-Cenozoic mechanically-layered Umbria-Marche sedimentary cover. Different interpretation have long been proposed to explain folds in the Apennines: buckling (LAVECCHIA, 1985), blind-thrusting (CALAMITA, 1990), or fault-propagation folding (TAVARNELLI, 1993). Thrusts and related folds development was strongly influenced by the Adria Mesozoic structural heritage that implied contrasting styles of fault reactivation within the Central Apennine curve-shaped thrust-belt (CALAMITA *et alii*, 2011).

The structural-geological analysis allows us to unravel the

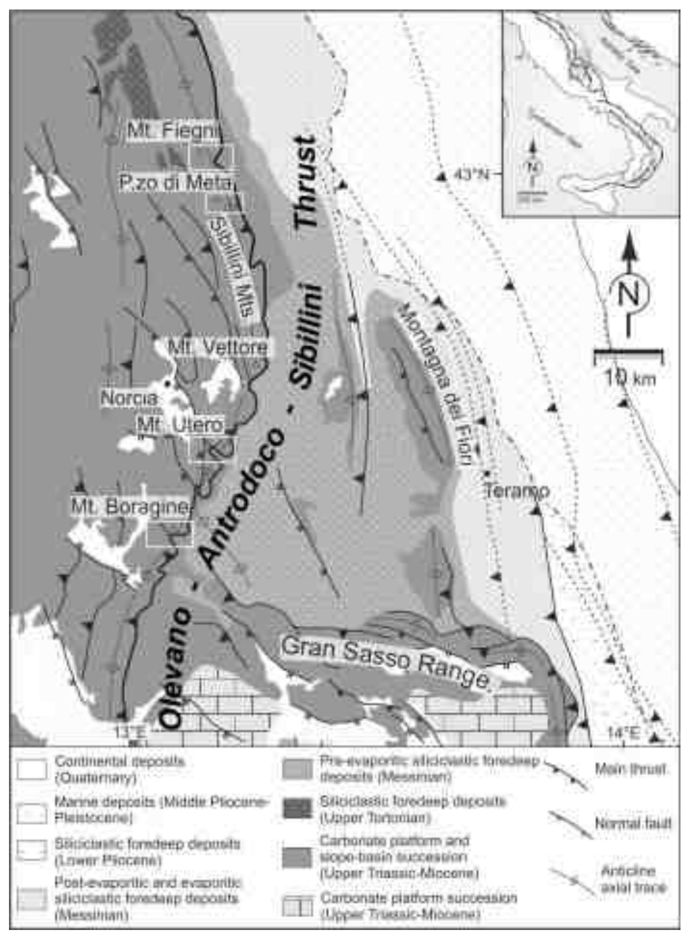

Fig. 1 – Schematic geological-structural map of the analysed Olevano-Antrodoco-Sibillini (OAS) curved thrust in the Northern Apennines of Italy.

geometrical differences between NNE-SSW-trending reactivation anticlines and the NW-SE-trending shortcut anticlines respectively related to the oblique and frontal ramps of the Olevano-Antrodoco-Sibillini (OAS) thrust. The latter represents the outer front of the Northern Apennines (CALAMITA & DEIANA, 1988) and consists of a single, physically continuous curved feature characterised by a maximum thrust displacement in the Mt. Vettore apical zone (MAZZOLI *et alii*, 2005; Fig. 1). The sections considered in this work are located northward and southward of Mt. Vettore, respectively (Fig. 1). In these areas the shortening value (4-5 km) and the tectonic transport direction (striking N60-70) are both coherent.

FAULT-BEND FOLDS

Southward of Mt. Vettore, the hanging-wall anticlines (Fig. 2 a,b) display a NNE-SSW orientation and are upright-to-inclined. Generally, their forelimbs are constituted by the Jurassic-Cretaceous succession dipping moderately (30-40°) towards ESE. Minor overturned folds and splay thrusts affect the top of the Maiolica-Scaglia succession along the leading edge of the OAS thrust (Fig. 2 a,b).

The hanging-wall macro-anticlines, along the NNE-SSW-trending OAS oblique thrust ramp (e.g., Mt. Boragine, Mt. Utero anticlines), are considered as fault-bend folds associated with the reactivation of the NNE-SSW-trending pre-thrusting normal faults. Subordinate fault-propagation folds developed at the leading edge of the thrust accompanied the main fault-bend folding process (Fig. 3 c).

FAULT-PROPAGATION FOLDS

Northward of Mt. Vettore, the OAS thrust exhibits a NW-SE orientation, parallel to the overturned hanging-wall anticlines axial trend. The anticlines (e.g., Mt. Fiegni, Pizzo di Meta anticlines) display a box profile, where sub-horizontal beds of the Calcare Massiccio Fm. are juxtaposed by high-angle blind thrusts on the vertical-to-overturned pelagic succession representing the typical features of a fault-propagation fold (Fig. 2 c,d). Pre-thrusting normal faults usually characterise the anticlines back limb.

Along the NW-SE OAS frontal thrust ramp the hanging-wall anticlines are likewise to be blind-thrusting fault-propagation folds. The thrust propagated through the pre-existing normal faults along a shortcut trajectory followed by a thrust breakthrough of the overturned syncline (Fig. 3 d).

CONCLUSIONS

The surface geological and structural data combined with balanced cross-sections allow us to interpret the upright-to-inclined macro-anticlines in the hanging wall of the NNE-SSW-trending OAS thrust as fault-bend folds (Fig. 2 a,b). They are connected to the compressive reactivation of the NNE-SSW-trending Jurassic and Miocene pre-thrusting normal fault as the Neogene OAS oblique thrust ramp (i.e., fault-bend reactivation anticlines; Fig. 3 c). In contrast, north of the Mt. Vettore, the NNW-SSE/NW-SE-trending overturned macro-anticlines represent fault-propagation folds (Fig. 2 c,d) along the OAS frontal thrust ramp, propagated through normal faults along a shortcut trajectory (i.e., fault-propagation shortcut anticlines; Fig. 3 d). During the Neogene propagation of the OAS frontal thrust ramp, the blind thrust of the Calcare Massiccio Fm. and related overturned anticline in the pelagic succession were developed, followed by thrust breakthrough.

The along-strike variation from fault-bend to fault-propagation fold in the curve-shaped OAS thrust of the Northern Apennines chain is related to an inversion tectonics scenario. Our result shows that in orogenic belts fault-bend and fault-propagation folding are admissible along a single curved thrust controlled by structural heritage (Fig. 3). This coexistence occurs in differently-oriented arms (i.e., frontal and oblique thrust ramps) with coherent thrust displacement and involving the same mechanically heterogeneous multilayer

Positive flower structures as reactivated normal faults along oblique thrust ramps: examples from the Apulian structures, Central-Southern Apennines

PAOLO PACE (*), VITTORIO SCISCIANI (*), FERNANDO CALAMITA (*) & WERTER PALTRINIERI (*)

Key words: *Buried Apulian structures, Fault reactivation, Inversion tectonics, Positive flower structures, Sangro-Volturno thrust*

INTRODUCTION

Positive flowers, also termed “Palm-tree” or “Push-up” structures, are well-established transpressional uplifts of intraplate wrench/strike-slip tectonics occurring within restraining bends or stepovers (e.g., WILCOX *et alii*., 1973). Notwithstanding the worldwide examples of such features in strike-slip tectonic regimes, positive flower structures (PFS) are likewise discovered to develop during positive inversion tectonics (e.g., COOPER & WARREN, 2010). Because of their importance to provide high-productive structural traps, positive flowers are well-examined throughout a widespread variety of inversion scenarios in sedimentary basins (e.g., dip-slip inversion, strike-slip inversion, transpressional inversion). Nevertheless, structural inversion of pre-existing extensional features not always includes positive flowers development. For instance in the Northern Apennines, transpressional inversion along the Olevano-Antrodoco-Sibillini thrust promoted fault-bend and fault-propagation folding within the same mechanical multilayer, respectively controlled by positive reactivation and by thrust shortcut of pre-existing normal faults.

PFS related to the compressive reactivation of extant normal faults are mostly discovered throughout seismic interpretation. Sometimes, this could be very difficult because seismic imaging is commonly very poor due to the steep stratal and fault dips as well as significant along-strike variations in structural geometries. So that, erroneous interpretations could be provided as consequence of the ambiguous tectonic significance of such structures (HARDING, 1985). In order to clarify this dichotomy and to avoid misinterpretation, understanding the regional tectonic framework is fundamental.

In this contribution, seismic expressions of PFS from the buried Apulian structures of the Central-Southern Apennines are described and their tectonic context is reconstructed by a carefully interpretation of the seismic data supported by an objective identification of the structural association.

REGIONAL TECTONIC FRAMEWORK

The Sangro-Volturno line constitutes a NNE-SSW-trending oblique thrust ramp of the Central-Southern Apennines (SATOLLI & CALAMITA, 2008; with references therein). In its hanging wall, NW-SE thrust and folds branching off from the Sangro-Volturno

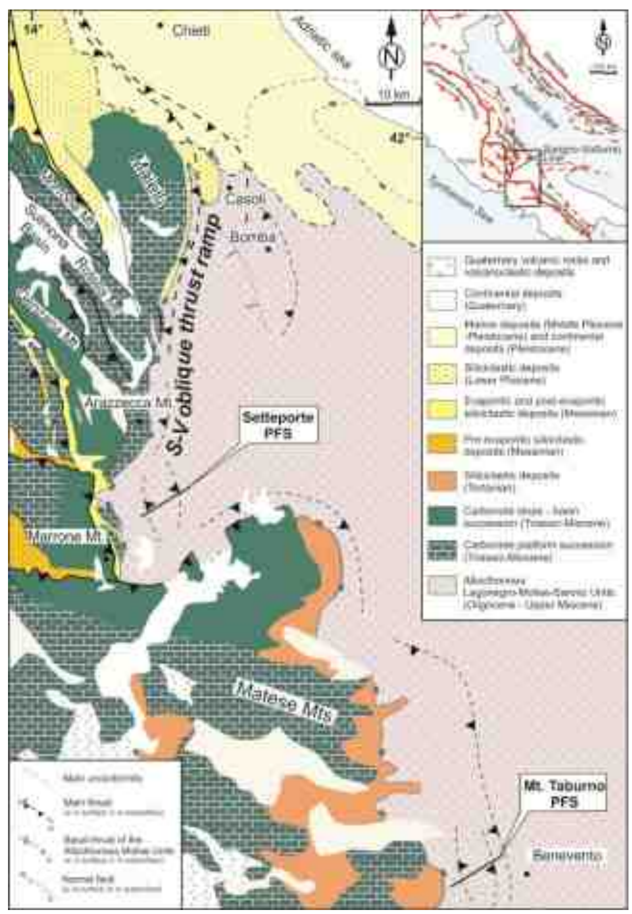

Fig. 1 – Simplified structural-geological map across the Sangro-Volturno (S-V) oblique thrust ramp adjoining the Central Apennine to the Southern Apennine.

thrust (SVT) involve the Apulain and Lazio-Abruzzi platforms and slope-to-basin carbonate successions, whereas in its footwall the compressive Apulian structures are buried underneath the Molise allochthonous thrust-sheet. Thrust-related anticlines, in both the hanging wall and the footwall of the SVT, are associated with pre- and syn-orogenic normal faults heritage (CALAMITA *et alii*, 2009).

It has been recently recognised, that in the Central Apennines inversion tectonics processes realise contrasting styles of fault reactivation: inherited normal faults were traspressively reactivated (i.e., reactivation anticlines) or displaced by thrust shortcuts (i.e., shortcut anticlines) depending on their orientation with respect to the new compressive stress field (CALAMITA *et alii*, 2011). Similar inversion structures likewise occur along the southernmost sector of the SVT (Fig. 1). In this area the positive reactivation of a Permian-Triassic platform-to-basin normal fault results in the Mt. Marrone reactivation anticline, while a thrust shortcut with respect to the NW-SE-trending normal fault is developed within the Mt. Arazzecca structure (PACE *et alii*, 2011).

SETTEPORTE PFS

The Setteporte structure is an uplift hidden under the sole thrust of the Molise allochthonous units, belonging to the SVT zone (Fig. 1). This transpressional anticline (ESESTIME *et alii*, 2006) is composed by N-S- and NNW-SSE-trending trusts and back thrusts (NICOLAI & GAMBINI, 2007) affecting the Triassic-Miocene Apulian carbonates. Upward branching convex-up thrust faults produce a clear reverse offset of the top of the Apulian platform reflector as can be easily detected on seismic (Fig. 2). The axial culmination of the anticline occurs at ca. 1600 m, progressively deepening toward SW (3154 m underneath the Fonteviva 1 well) and NE, up to approximately 3200 km. At depth high-amplitude low-frequency seismic reflections can be attributed to the transition from the Upper Triassic anhydrites and dolomites (Burano Fm.) at the base of the Apulian platform carbonates to the underlying Permian-Triassic sedimentary sequence (e.g., Puglia 1 well), so they represent the base of the Apulian platfotm/top of the Permian-Triassic succession horizon. They are roughly horizontal and cut by fault plane located slightly SE-ward with respect to the crest zone of the structure (Fig. 2). A growth sequence can be inferred from downlap terminations of a reflections package within the Permian-Triassic succession and their opposite abrupt interruption against the fault plane, suggesting an extensional activity of this fault.

From the overall seismic interpretation of the structure and the time-to-depth conversion the Setteporte anticline can be considered a positive flower related to the transpressional reactivation of a pre-existing (Permian-Triassic) normal fault.

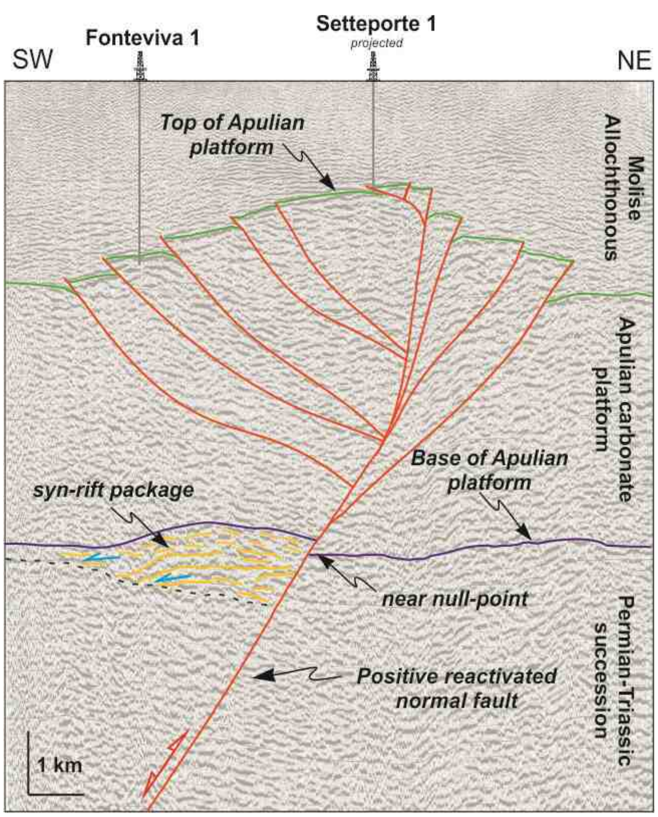

Fig. 2 –Time-to-depth converted line-drawing of a seismic line (2D Move, Midland Valley) across the Setteporte PFS (location in Fig.1).

MT. TABURNO PFS

The Mt. Taburno structure is an Apulian transpressional uplift (ESESTIME *et alii*, 2006) covered by the Lagonegro-Molise-Sannio allochthonous units in the Southern Apennine (Fig. 1). The anticline is defined by NNW-SSE-trending thrust and back thrusts (NICOLAI & GAMBINI, 2007) part of a major N-S oblique thrust ramp at the trailing-edge of the buried Apulian chain. The Mt. Taburno 1 well ties the top of the Apulian platform reflector at 2093 m that is the axial culmination of the structure. Moving outward from the narrow crest zone the signal becomes gently inclined in both directions (W- and E-dipping) and is flat at approximately 3700 m. The symmetric anticline is described by the reflector truncated by several thrust faults arranged in a flower-like geometry and producing small offsets on both limbs (Fig. 3). At ca. 7000 m a high reflective beam appears with a roughly continue flat geometry and potentially corresponds to the base of the Apulian platform/top of the Permian-Triassic succession. Deeper seismic reflections within the Permian-Triassic sequence show a SW-downward separation directly below the axial culmination of Mt. Taburno structure (Fig. 3).

The aforementioned seismic configuration of the key horizons allows us to hypothesise that the Mt. Taburno PFS is related to the compressive reactivation of a Permian-Triassic extensional fault. In this perspective, the intersection between the reactivated fault plane and the flat base of the Apulian platform/ top of the Permian-Triassic succession constitutes the null-point of inversion.

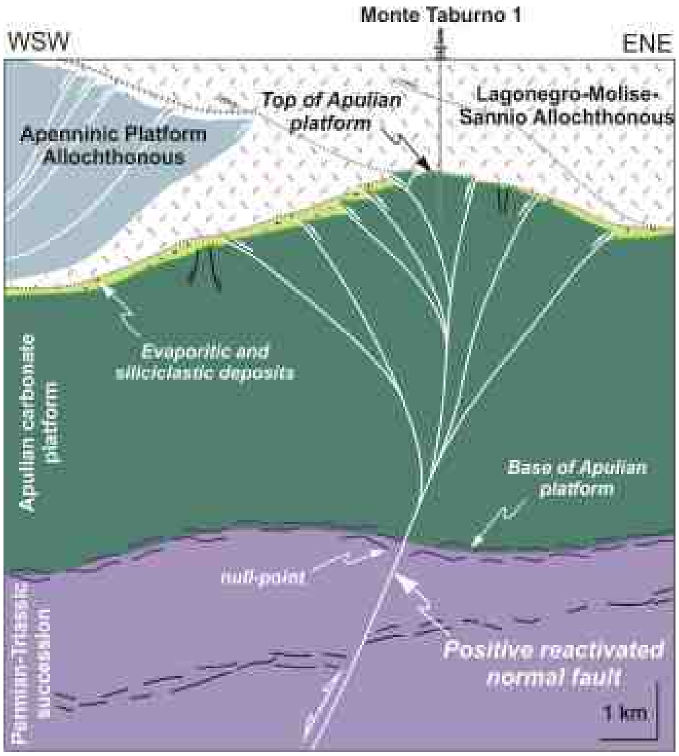

Fig. 3 – Cross-section from the time-to-depth converted seismic line (location in Fig. 1) showing the characteristic features an inverted normal fault in the Mt. Taburno PFS.

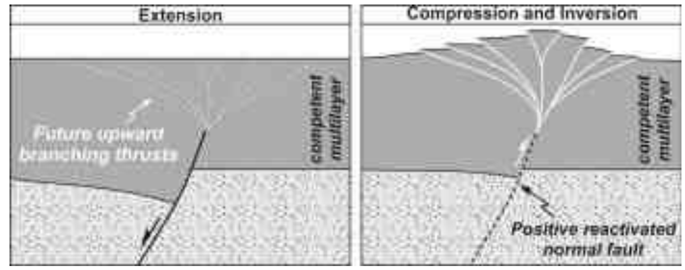

Fig. 4 – Cartoon showing the development of a positive flower structures during the transpressional reactivation (right) of a pre-existing normal fault (left) within a thick competent multilayer.

CONCLUSIONS

In the Central-Southern Apennines, the positive normal fault reactivation is promoted along N-S oblique thrust ramps (CALAMITA *et alii*, 2011) as the SVT. A critical seismic interpretation of the narrow uplifts (i.e., Setteporte and Mt. Taburno anticlines) close to oblique thrust ramps revealed that positive flower structures have been developed in response to the transpressional reactivation of Permian-Triassic extensional faults. The tectonic inversion process occurs within the thick competent unit of the Apulian carbonate platform. This interpretation strictly deal with the regional tectonic framework of the Central-Southern Apennines, characterised by the diffuse positive inversion of pre-orogenic (e.g., Permian-Triassic) normal faults (e.g., SHINER *et alii*, 2004).

In conclusion, positive flowers can be easily recognised as due to either wrench or inversion tectonics when are examined critically with respect to the related structural association allowing the tectonic context to be reconstructed. In addition, when a pre-existing normal fault undergoes to transpressional inversion along an oblique thrust ramp and within a thick competent multilayer (e.g., Apulian platform) positive flower structures are most likely to be developed (Fig. 4).

Structural inheritance in two circum-Mediterranean fold-and-thrust belts: Preliminary results from a comparison

PAOLO PACE (*), VITTORIO SCISCIANI (*) & FERNANDO CALAMITA (*)

Key words: *Curved thrust-belt, Central-Northern Apennines, Eastern High Atlas, Inversion tectonics, Structural inheritance.*

INTRODUCTION

It has long been demonstrated that the structural inheritance of pre-existing rift-related faults can substantially influence the structural evolution of later compressional tectonics (e.g., BUTLER *et alii*, 2006). The existence of pre-existing extensional faults is now being recognised within many orogenic belts and it is noteworthy that the intra-continental contractional deformation is likewise accommodated by the reactivation of former structures during positive inversion tectonics (e.g., COOPER & WILLIAMS, 1989; LETOUZEY, 1990; COWARD, 1994). In the circum-Mediterranean Alpine-Apennine system, the pre-orogenic crustal template can include arrays of extensional faults. These inherited features may undergo to simple fault reactivation or show complex inversion tectonics interactions (e.g., TAVARNELLI, 1996; SCISCIANI *et alii*, 2002). Commonly, within curved thrust-belts important lateral variations in tectonic structure coincide with changes in stratigraphic setting, so that inherited broad elements of the continental margin play a fundamental role and may be preferentially reactivated, generating salient and recesses along the orogenic belt (e.g., MARSHAK, 2004). On a large-scale, the pattern of these inherited rift cross-faults profoundly "tram-lined" the three-dimensional thrust system development, mostly in curved thrust-belts such as the Alps, the Apennines and Maghrebides (e.g., BUTLER *et alii*, 2006; CALAMITA *et alii*, 2009).

In this short note, we attempt to unravel the analogies on geometrics and kinematics between orogenic and intra-continental curved thrust-belts that suffered structural inheritance, by comparing the structural setting of the Central-Northern Apennines of Italy to ones of the Eastern High Atlas of North Africa (Fig. 1).

THE CENTRAL-NORTHERN APENNINES

The overall geometry of the Apennine fold-and-thrust belt has been strongly influenced by the heritage of normal faults, which dismembered the Adria paleomargin during the Triassic and Early Jurassic extensional events (D'ARGENIO & ALVAREZ, 1980). During the latter, a broad normal fault (i.e., Ancona-Anzio Line, CASTELLARIN *et alii*, 1978) separated the wide pre-existing Triassic-Lower Jurassic carbonate platform into persistent carbonate platform (Lazio-Abruzzi) and pelagic (Umbria-Marche) domains (Fig. 1 a). So that, this regional basin-bounding paleodiscontinuity with the overall extensional template exerted a severe control on the location of the Neogene thrust ramps development (e.g., TAVARNELLI, 1996; SCISCIANI, 2009). During the NE-SW compressional tectonics, the ancient Ancona-Anzio normal fault system was transpressionally reactivated as the Olevano-Antrodoco oblique thrust ramp (CALAMITA *et alii*, 2011; with references therein). Along with the Mts. Sibillini frontal thrust ramp it constitutes the Olevano-Antrodoco-Sibillini thrust (OAS) representing the outer curved thrust front of the Northern Apennine (CALAMITA & DEIANA, 1988). The NNW-SSE and NW-SE-trending thrust and related folds merge toward the OAS defining the inherited curve shape of the Central-Northern Apennine orogenic belt (Fig. 1 a).

THE HIGH ATLAS

The ENE-WSW-trending High Atlas fold-and-thrust belt transects the North Africa from the Atlantic coast of Morocco into Algeria (Saharan Atlas) and Tunisia (Tunisian Atlas). This belt together with its NW-SE branch in Morocco knows as Middle Atlas constitutes the Atlas system of Maghreb (Fig. 1 b). The Atlas system is an intra-continental, autochthonous thrust-belt developed as result of the Alpine cycle (MICHARD *et alii*, 2008; with references therein). Despite its moderate crustal shortening, the Atlas mountain belt is one of the most prominent topographic expressions of North Africa, spanning more than

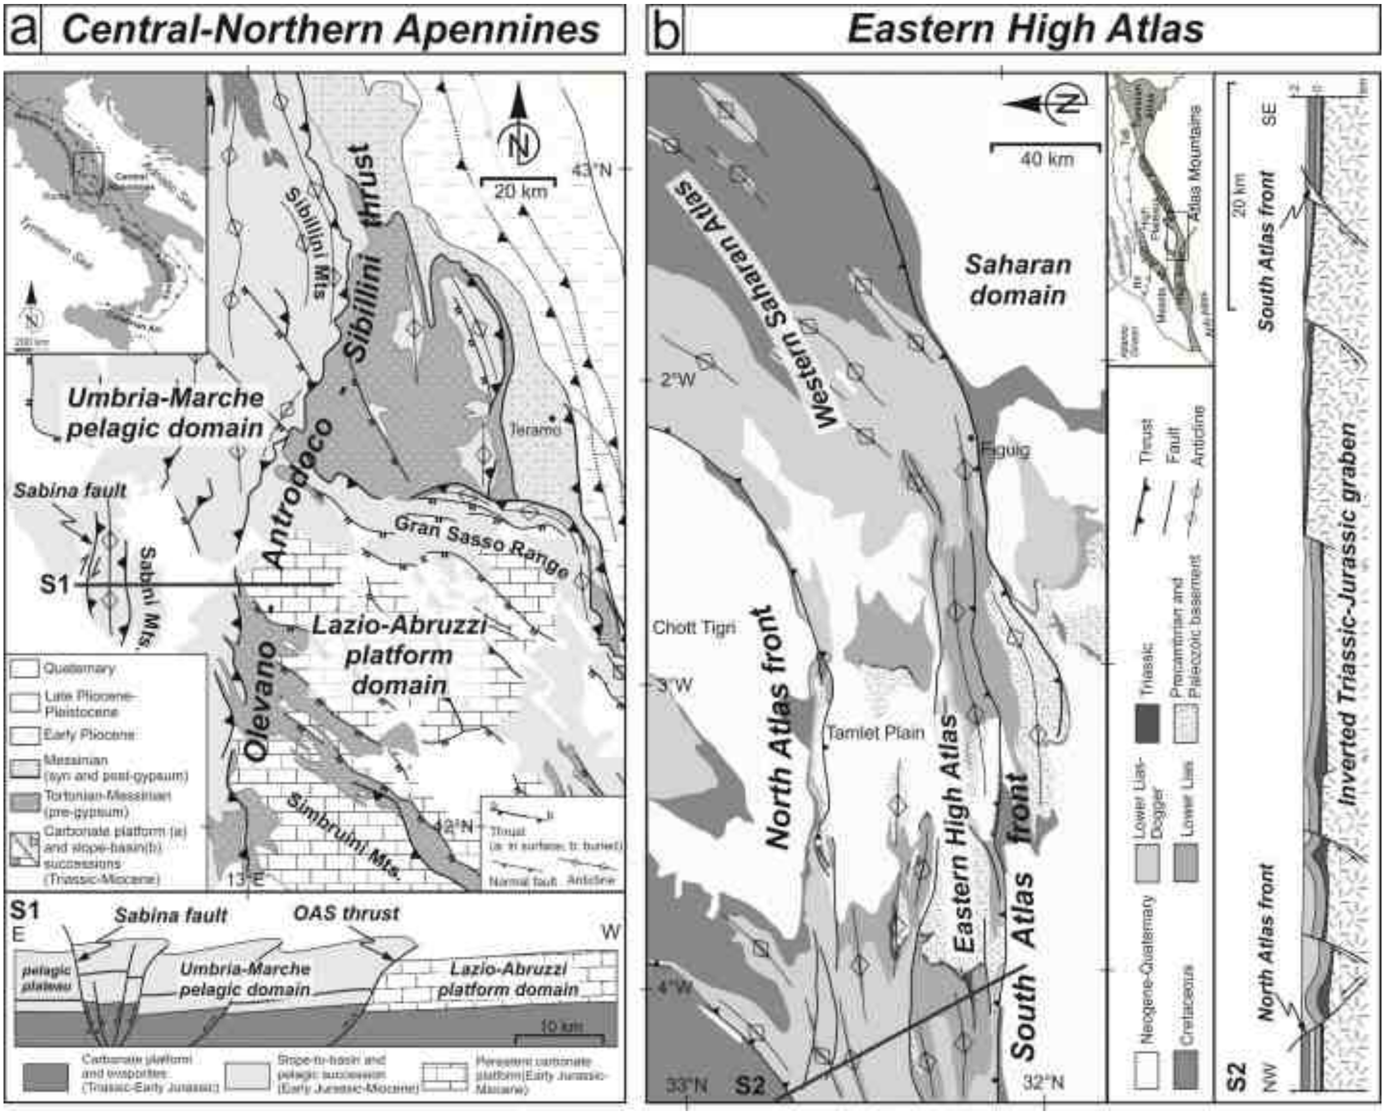

Fig. 1 – a) Simplified structural-geological map of the Central-Northern Apennines and schematic cross-section (S1) across the N-S-trending OAS transpressionally inverted oblique thrust ramp (modified from CALAMITA *et alii*, 2011); b) simplified structural-geological map of the junction area between the Eastern High Atlas of Morocco and the Western Saharan Atlas of Algeria (modified from SAADI *et alii*, 1985), geological cross-section (S2) across the Eastern High Atlas showing the transpressional inversion of the Triassic-Jurassic rift basin bordered by the North Atlas front and the E-W-trending oblique segment of the South Atlas front.

2000 km and rising over 4000 m in elevation (TEIXELL *et alii*, 2003).

The North Africa margin experienced two rifting episodes during the Permian-Middle Triassic and the Late Triassic-Early Jurassic time onwards related to the Central Atlantic rifting and to the development of the Maghrebian part of the Alpine Tethys, respectively. A complex normal fault pattern was achieved from the two extensional phases: NE-SW Atlantic-related normal and ENE-WSW Tethyan left-lateral strike-slip/normal faults (ELLOUZ *et alii*, 2003; for review).

The High Atlas results from the weak positive inversion of Triassic-Jurassic rift basins (BEAUCHAMP *et alii*, 1999) during the Cenozoic Alpine NNW-SSE/NW-SE compression involving the pre-Mesozoic basement and the sedimentary cover (Fig. 1 b). The High Atlas is separated from the south-west African craton (i.e., Anti-Atlas and Saharan domain) by a clear physiographic boundary known as South-Atlas front (SAF, FRIZON DE LAMOTTE *et alii*, 2000). In the Eastern High Atlas the SAF juxtapose a thick Triassic-Jurassic succession onto a much reduced succession characteristic of the Saharan platform (e.g., Ks-1 well; TEIXELL *et alii*, 2003), where in some areas the Cretaceous sedimentary rocks directly overlie the Precambian or Paleozoic basement (e.g., EL HARFI *et alii*, 2006). This stratigraphic variation across the SAF clearly suggests that this oblique thrust resulted from the transpressional inversion of a pre-existing basement-involved normal fault during the NNW-SSE/NW-SE Cenozoic compression, as well as it is for the North Atlas front (TEIXELL *et alii*, 2003; EL HARFI *et alii*, 2006; Fig. 1 b). Within this context, the NE-SW thin-skinned thrusts of the Central High Atlas and the Western Saharian Atlas (e.g., BRACÉNE *et alii*, 1998; BEAUCHAMP *et alii*, 1999) respectively branch toward the ENE-WSW thick-skinned inverted oblique thrust of the Eastern High Atlas, defining a curve shape of the SAF (Fig. 1 b).

CONCLUDING REMARKS

This preliminary comparison between the Central-Northern Apennines and the western sector of the High Atlas, clearly evidence that the curved geometry of thrust systems is strongly influenced by inherited structures in both orogenic and intra-continental belts. Moreover, thick-skinned transpressional inversion is promoted along oblique thrusts (e.g., the N-S-trending OAS and the E-W-trending SAF) that preferentially reactivate pre-existing extensional features.

Finally, the High Atlas with its stunning exposures represents a key area to investigate the expression of basement-involved tectonic inversion. So that, comparisons with other thrust belts can give further constraints to understanding and applying concepts of thick-skinned inversion tectonics, as for the case of the Apennines here proposed.

Structural analysis of some tectonic lines within 348 “Antrodoco” sheet

ANDREA PIETROSANTE (*), DOMENICO BERTI (**) & RINALDA DI STEFANO (**)

Key words: *slickenside lineations, stress tensor, structural analysis, tear-fault, thrust.*

ABSTRACT

Within the Italian national geological mapping project (CARG, geological maps at 1:50.000 scale) SUO-CAR service of ISPRA is performing the sheet 348 “Antrodoco”. Several problems about stratigraphic relations and structural setting has been surveyed involving Latium-Abruzzi carbonate platform (Nuria-Giano-Gabbia-Calvo mountains) with respect to slope deposits of transition zone of Umbria-Sabina and Gran-Sasso basin.

Paleogeographic relations between sedimentary environments may be hidden either by platform drowning succession or syn-orogenic tectonic events. In this regard several studies remark the role of thrust Gabbia-Cagno for the carbonate platform close to transition-basin areas, so that it would be responsible for a remarkable structural shortening.

The ongoing geological mapping, by Geological Survey of Italy (ISPRA), supports the role played by Gabbia-Cagno thrust; nevertheless new questions about shortening extent, fault plane geometry, times and kinds of structural deformations, are rising up. This paper aims to define kinematics characters of a confined zone of the thrust (Termine-Menzano), answering, when possible, to the questions above, by survey methodologies typical of the structural analysis.

Analysis was carried out by measuring structural elements and collecting them in two main datasets. Dataset A nearby “Cava di Sabbia” just north of Termine village, dataset B nearby “Cava di Pietrisco” SE of Piana di Cascina (Fig. 1).

To calculate stress tensor parameters, inversion method by ANGELIER (1984, 1990) has been used. Stress analysis has been carried out with no assumption concerning the orientation of fault planes relative to stress axes, so that reactivated faults are taken into account as well as newly created ones, unlike Anderson’s model in which conjugate fault systems are supposed.

(*) Via Pietralata, 228 00158 Roma.
(**) ISPRA - Servizio Geologico d'Italia Via Vitaliano Brancati, 60. 00144 ROMA.

Two fault populations has been detected by stress analysis within compressive structures. The first one with dip-slip slickenside lineations and horizontal main stress ($\sigma1$) N65°. The second one with leading oblique slickenside lineations could be related to sub-horizontal $\sigma1$ N55°.

Stress analysis revealed intermediate stress $\sigma2$ value greater for dip-slip reverse faults population than for oblique-slip ones. The differences observed in the geometry of deformation and stress tensor of two faults populations could be explained if we assume two different compressive phases of deformation. In the first phase, acting along SW-NE direction, fault planes arise according to conjugate fault system model. The second phase also is characterized by a sub-horizontal SW-NE trending maximum tension axis that has been responsible for oblique motion on former fault planes. Moreover second phase rotate former fault planes producing the current disposition.

With regards to extensional structures, stress tensor shows stress axis with same direction as compressive ones, with exchange between $\sigma1$ and $\sigma3$.

Oblique lineations of the compressive faults give as result a

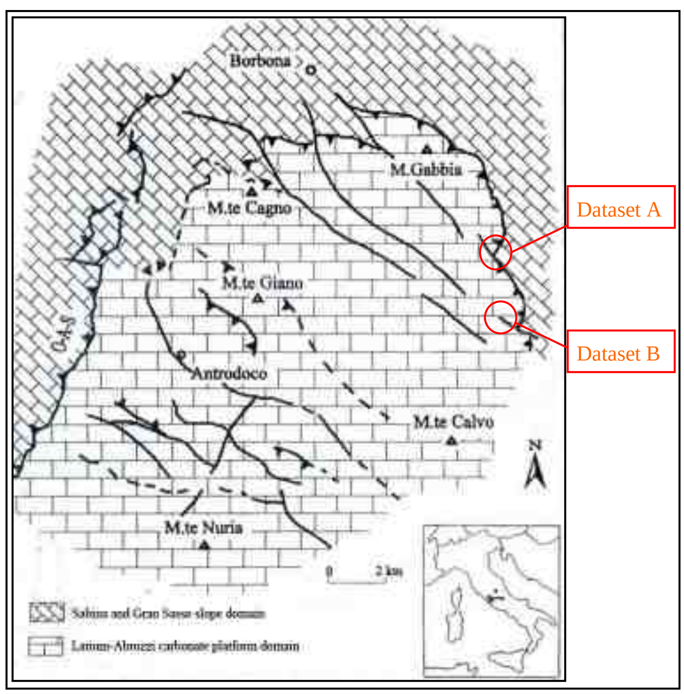

Fig. 1 – Simplified geological and structural sketch of Gabbia-Cagno thrust. The study areas are highlighted in red circles.

stress tensor that is consistent with vergence to NE of compressive structures in central Apennines. Nevertheless dip-slip faults population has been rotated clockwise around 10°, actually showing σ1 direction around N65°, according to Giano-Gabbia thrust geometry, the latter also rotated clockwise along Termine-Menzano ridge.

Therefore stress analysis justify present day setting with a first tectonic compressive phase generating fault planes and a second compressive phase generating both rotation of fault planes and motion along former fault planes (oblique slickenslide lineations).

In that framework shear-zone between Cagnano Amiterno and Termine could be a tear-fault linked to rotational deformation. Thrust suddenly changes orientation across tear-fault, passing from NW-SE orientation at south, to N-S at north.

Such a mechanism may have been triggered repeatedly along Termine-Menzano part of Gabbia-Cagno thrust, generating the clockwise rotation we now can see.

Moreover across tear-fault, sedimentary environment changes at footwall of thrust, from edge platform deposits to proximal slope.

Therefore it might be thought that Giano-Gabbia thrust reactivated discontinuity lines, probably acting in syn-sedimentary phase also having a control role in the transition zone geometry that evolved from platform ridge to basin.

Oblique vs. frontal thrust shear zones: The curve-shaped Olevano-Antrodoco-Sibillini thrust (Central-Northern Apennines, Italy)

ANTONIO TURTÙ (*), SARA SATOLLI (*) & FERNANDO CALAMITA (*)

Key words: *SC and S tectonites, thrust shear zones, vorticity analysis, Central-Northern Apennines (Italy).*

INTRODUCTION

Tectonites developing in simple shear regime are characterized by SC fabric, delineated by the association of two main foliations (named S and C). The angle between C and S is 45° at the initial stage of deformation. It decreases to 0° with progressive shear while the density of the C surfaces increase and synthetic (R) and reverse antithetic (R') discontinuities develop respectively at ca. 15° and 75° relative to C. At the last stage of deformation, the S and C planes become sub-parallel, defining an S tectonite (BERTHÈ *et al.*, 1979).

Moreover, many case studies have indicated that in real shear zones the deformation deviates from simple shear including a pure shear component, suggesting the necessity to determine the degree of non-coaxiality, using the kinematic vorticity number (W_k) or the sectional kinematic vorticity number (W_n) that are equal for plain strain (e.g., XIPOLIAS, 2010).

We analyzed tectonites associated with shear zone, related to NNE-SSW oblique ramp and NW-SE frontal ramp of the Olevano-Antrodoco-Sibillini (OAS) thrust, through the W_n parameter valuation, as a tool to constrain the mode and timing of thrust emplacement and evolution relative to folding in the Central-Northern Apennines of Italy.

REGIONAL SETTING

The Apennines are a fold-and-thrust belt which originated during the Neogene-Quaternary time interval, affecting the Triassic to Miocene sedimentary cover successions deposited on the Adria promontory of the African plate. The outer sector of the Northern Apennines is characterized by the OAS thrust, whose age of emplacement dates back to upper Messinian-lower Pliocene interval (CALAMITA *et al.*, 1990). It accommodates the juxtaposition of the pelagic succession of the pelagic Umbria-Marche domain on the Oligocene-Miocene marly and siliciclastic deposits (Fig. 1a). The OAS thrust is defined by frontal NW-SE-trending and oblique NNE-SSW-trending thrust ramps to the North and to the South with respect to the Apical Zone (namely, Mt. Vettore; Fig. 1a) . The NNE-SSW trending OAS thrust surface is antiformally folded by NW-SE to NNW-SSE trending anticlines developed in the footwall.

STRUCTURAL ANALYSIS

We document SC and S tectonites, represented by foliated cataclasite, associated with brittle-ductile shear zones of the NW-SE frontal ramp (Fiastrone and Infernaccio sites, Fig. 1) and NNE-SSW-trending oblique ramp (Mt. Boragine and Vallescura sites, Fig. 1) of the OAS salient thrust, respectively.

The SC tectonites involve Scaglia Rossa Fm. (at Fiastrone site) and Scaglia Cinerea Fm. (at Infernaccio site). They are characterized by shear planes (C) parallel to the OAS thrust and by pressure-solution cleavage (S), which is oriented at 37-42° to C planes. Synthetic R and reverse antithetic R' shear planes, oriented respectively at 15-35° and 87° to C planes, are present (Fig. 1b). The structural association consists also of calcite tension veins and calcite shear veins on C.

At Mt. Boragine and Vallescura sites (Fig. 1b), S tectonites show a pervasive cleavage (S) oriented sub-parallel to the main thrust (ca. 15°) with stylolites related to pressure solution mechanism. The shear zones are crenulated both by spaced to pervasive conjugated synthetic (E) and antithetic (E') normal shear planes. Pervasive E and E' planes can be recognized at mesoscopic scale forming an angle of ca. 35° with respect to the thrust plane. At outcrop scale conjugate sets of synthetic and antithetic extensional planes are more spaced and crenulate the OAS thrust plane, involving its hanging-wall and footwall blocks. They result steeper compared to pervasive planes, showing an orientation of 35-45° (E) and 36-47° (E').

DISCUSSION

The structural association reconstructed in the SC tectonites is compatible with N60° tectonic transport. The value of W_n=0,86-0,98 calculated in the SC tectonites, and related to the OAS frontal ramp, is typical of a simple-shear-dominated deformation (Fig. 2).

The structural association of S tectonites is characterized by S

(*) Dipartimento di Ingegneria e Geologia, Università degli Studi "G. d'Annunzio" di Chieti-Pescara, Via dei Vestini 30, 66100, Chieti, Italy

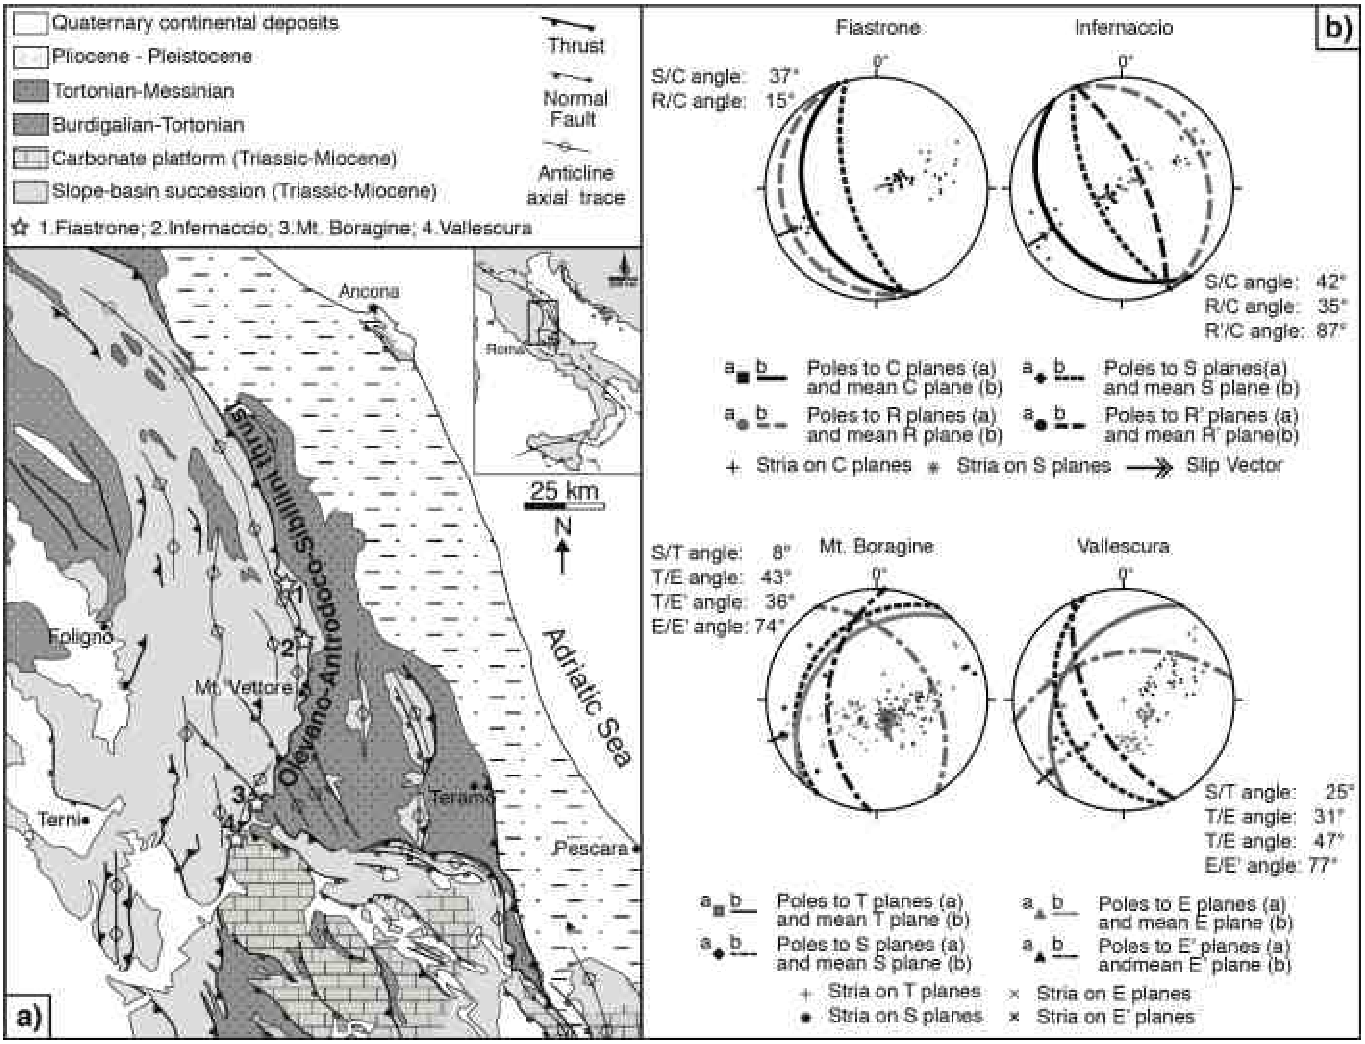

Fig. 1 – a) Schematic geological map of the Central-Northern Apennines (Italy) with location of the analyzed sites. b) Geometric and kinematic analysis of the analyzed sites (equal area projections on the lower hamisfere). Angle between the elements of the structural association are also showed.

fabrics sub-parallel to the thrust plane with a slip vector oriented N60-70°, compatible with the kinematics of the NW-SE-trending OAS frontal ramps. The W_n values related to the S tectonites ranges from 0,55-0,34 (for the pervasive synthetic shear planes E) to 0,17-0,00 (for high angle and more spaced synthetic E planes crenulating the thrust plane both at Vallescura and Mt. Boragine) suggesting a shifting from sub-simple to dominant pure-shear deformation. The different strain pattern recognized along the OAS thrust ramp is compatible with the growth of footwall anticlines during syn- and post- OAS thrusting phases, respectively (Fig. 2). After the OAS thrust emplacement, the growth of complete footwall anticlines caused the OAS thrust plane folding and the outer arc-stretching deformation. The latter is accommodated by spaced and high-angle conjugate shear planes that crenulated the OAS thrust plane and its footwall and hanging wall blocks (Fig. 2).

CONCLUDING REMARKS

The reconstructed strain evolution is in agreement with an in sequence fold and thrust propagation towards the Adriatic foreland, as reconstructed by ALBERTI *et al.* (1996) and CALAMITA *et al.* (2011) and with the interpretation of the Northern Apennines as a progressive arc (CIFELLI & MATTEI, 2010).

Vorticity analysis (through the computing of W_n parameters) in addition to the classic structural techniques is a useful tool to perform detailed analysis of thrust shear zones in order to better define kinematics and deformation mechanisms, and can be a constraints for mode and timing of thrust and development of related folds.

Apatite fission-track analysis of the tectonic effects of the Arabia-Eurasia collision

IRENE ALBINO (1), WILLIAM CAVAZZA (1), MASSIMILIANO ZATTIN (2), ARAL I. OKAY (3), SHOTA ADAMIA (4) & NINO SADRADZE (5)

ABSTRACT

Key words: *Anatolian Plateau, Eastern Pontides, exhumation, Lesser Caucasus, low-temperature thermocronology.*

Present-day geological setting of Turkey is the result of complex geodynamic processes that involved the Tethyan domain during Paleozoic and Mesozoic time. Turkey is made of numerous continental fragments that during the evolution of the Paleotethys and Neotethys riffed off from either sides of these two oceanic domains and eventually collided with the opposite continental margins (e.g. OKAY & TUYSUZ 1999; STAMPFLI & HOCHARD 2009).

Geologically, Turkey can be divided into three main tectonic units: the Pontides, the Anatolide-Tauride Block and the Arabia platform (OKAY, 2008); the Pontides show Laurasian stratigraphic affinities whereas the Anatolide-Tauride Block and the Arabian Platform are tectonically and stratigraphically related to Gondwana (SENGOR & YILMAZ 1981, OKAY & TUYSUZ, 1999).

The last main important tectonic event in Tukey was the Oligo-Miocene collision between Arabian and Eurasia. Collision led to the development of (i) the Bitlis-Zagros orogenic belt, (ii) the North and East Anatolian fault systems (ARMIJO *et alii*, 1999), (iii) the structural inversion of the Caucasian basins (SAINTOT *et alii*, 2006) and (iv) widespread deformation in the Turkish-Armenian-Iranian plateau (OKAY *et alii* 2010). Despite the importance of the event, the exact age of the collision is poorly constrained, some studies place it in the upper Cretaceous (HALL, 1976; BERBERIAN & KING, 1986; ALAVI, 1994), upper Eocene-Oligocene (JOLIVET & FACCENNA, 2000 ; AGARD *et alii*, 2005; Allen & Armstrong, 2008), middle Miocene (SENGOR *et alii*, 1985; DEWEY *et alii*, 1986; ROBERTSON *et alii*, 2007; OKAY *et alii*, 2010).

The integration of new apatite fission-track (AFT) data from the eastern Pontides, the Lesser Caucasus (Adjara-Trialeti zone), and the eastern part of the Anatolian plateau with preexisting data from the Bitlis suture has provided insights on the syn-and post-collisional evolution not only of eastern Anatolia but also of the entire Eastern Mediterranean area.

The 38 AFT samples collected have a wide spatial distribution and include different types of rocks: Paleogene sandstones and magmatic rocks with Cretaceous-to-Eocene intrusion ages. Despite the diversity of lithological samples and the wide spatial distribution of the data shows a well defined geographic trend. Exhumation along the Black Sea coast occurred in the Middle Miocene, mirroring the age of collision between the Eurasian and Arabian plates along the 2,400-km long Bitlis-Zagros suture zone some 200 km to the south. Exhumation in the Anatolian Plateau occurred in the Paleogene (with a cluster of ages in the Middle-Late Eocene), coevally with the development of the Izmir-Ankara-Erzincan suture.

Using HeFty program inverse modeling was performed on four sample with a single-age grain population and high numbers of measured tracks. Results of modelling provide more quantitative constraints on their cooling paths, pointing out that the Anatolian Plateau did not exhume a new partial annealing zone and thus is not recorded by the apatite fission tracks.

The Apulian platform and the structural styles along the front of the Hellenide fold belt (south-eastern Adriatic)

ANDREA ARGNANI (*)

RIASSUNTO

La piattaforma apula e lo stie strutturale al fronte delle Ellenidi nell'Adriatico sud-orientale.

Il fronte ovest-vergente della catena Ellenide e il suo avampaese adriatico sono stati investigati utilizzando profili sismici acquisiti durante vari rilievi geofisici, espressamente effettuati nel Mare Adriatico meridionale. Lungo questo margine convergente la collisione continentale osservata in Albania e nella Grecia nord-occidentale passa a subduzione oceanica a sud di Cefalonia. Lo stile strutturale della parte esterna della catena e l'evoluzione dell'avampaese sono controllati dalla natura delle unita' paleogeografiche mesozoiche che sono state accrezionate alla catena. In Albania settentrionale, dove sono accrezionate le unita' bacinali del dominio ionico, la topografia della catena e' ridotta e la depressione dell'avanfossa accentuata. In Albania meridionale e Grecia nord-occidentale, dove sono accrezionate le unita' della piattaforma apula, la topografia della catena' e' accentuata e la depressione dell'avanfossa ridotta. A sud di Cefalonia, invece, le unita' della piattaforma apula sono impilate e sradicate dal substrato mentre e' in corso una subduzione oceanica. Dalla ricostruzione strutturale si possono trarre delle considerazioni sulla paleogeografia mesozoica del Mediterraneo orientale.

Key words*: Hellenides, multichannel seismics, southern Adriatic, thrust front*

INTRODUCTION

Along strike variations in structural style occur at all scales, from outcrops to Fold-and-Thrust Belts (FTBs), as shape and size of thrust faults are mainly controlled by strength heterogeneity and anisotropy of the rock units (PRICE, 1988). The front of the W-verging Hellenide fold-and-thrust belt and its adjacent foreland (Fig. 1) have been investigated using a grid of seismic reflection profiles, purposely acquired in the Southern Adriatic Sea (Fig. 2; ARGNANI *et alii*, 1993, 1994, 1996). This contribution aims at showing that the size and width of the Apulian carbonate platform domain is greatly affecting the evolution of the thrust front. A marked along-strike change in structural style has been observed at the front of the Hellenides, where the Apulian and Ionian domains are involved, and such a change is closely related to the nature of the Mesozoic domain, either platform or basin, which the thrust front impinges onto. Moreover, the style of accretion of the Apulian units gives some hints on the Mesozoic palaeogeography.

GEOLOGICAL SETTING

Two are the relevant geological elements in the region: the Adria domain and the Hellenide thrust front (Fig. 1).

Adria

The continental extension that caused the opening of the Tethyan ocean, during the early Mesozoic, gave rise to a system of epicontinental pelagic basins and carbonate platforms (e.g., ZAPPATERRA, 1994). Most of the sediments belonging to these depositional settings are now stacked within the Alpine-

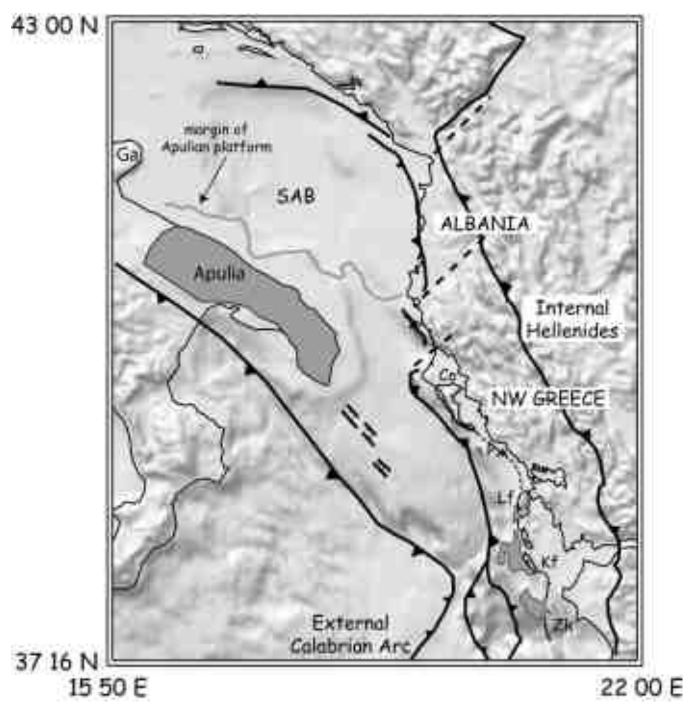

Fig. 1 – Shaded topography of the south-eastern Adriatic with the main morphological and tectonic features indicated. Co Corfu, Px Paxos, Lf Lefkas, Kf Kephalonia, Zk Zakintos, SAB Southern Adriatic Basin.

(*) ISMAR-CNR, Via Gobetti 101, 40129 Bologna, Italy

Mediterranean FTBs, from the Betic cordillera to Turkey. This system of platforms and basins typically characterises the southern Tethyan margin (BIJU-DUVAL *et alii*, 1977; DERCOURT *et alii*, 1993). Relatively undeformed portions of this Tethyan margin crop out at Present in the Adriatic Promontory, of which the Apulian Platform is an outstanding example. In the region comprised between the southern Adriatic Sea and Ionian Sea the original relationships between

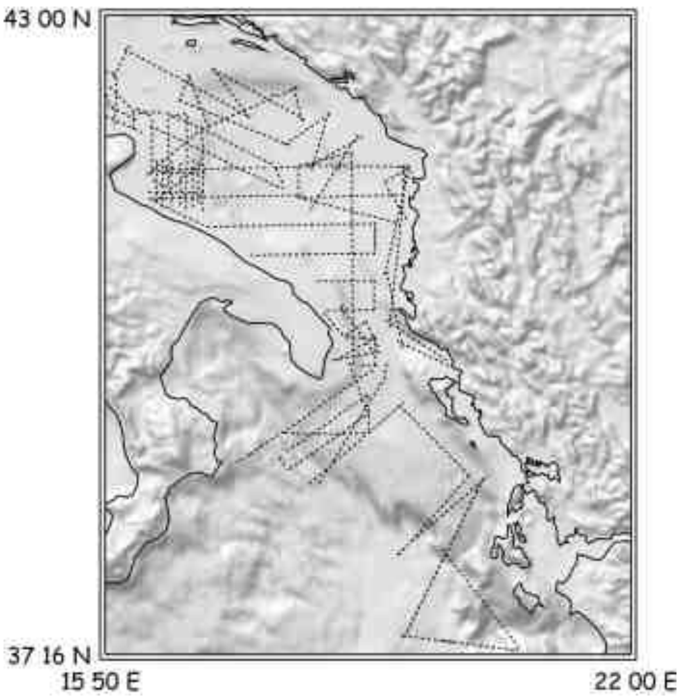

Fig. 2 – Shaded topography of the south-eastern Adriatic with the location of multichannel seismic profiles.

the Apulian Platform and its adjacent basins are still preserved and can be investigated through geophysical surveys.

Hellenides

The W-verging Hellenides FTB runs along the eastern boundary of Adriatic Promontory, from Albania to the Peloponnesos (Fig. 1). The intense seismic activity and compressional focal mechanisms indicate that this fold-and-thrust belt is currently deforming (e.g., VANNUCCI et al., 2004). Paleomagnetic data from the thrusted terranes of the Hellenides indicate a 40-45 degrees clockwise rotation since early Miocene (e.g., VAN HINSBERGEN *et alii*, 2005).

MAIN RESULTS

The Hellenide thrust front presents a marked variation in structural style from Albania to Kefalonia.

Major differences are due to the Mesozoic paleogeographic setting of the Adria region, namely by the different topographic expression of the Apulian platform and Ionian basin, both deposited on continental crust thinned during the Tethyan ocean opening. In northern Albania, where the basinal Ionian domain is accreted, the topography of the FTB is subdued whereas the Neogene foredeep basin is remarkably deep.

In southern Albania and NW Greece, where the Apulian platform unit is accreted, the topography of the FTB is elevated close to the coastline. On the other hand, the foredeep clastic sediments are rather thin in this area when compared to the northern portion of the foredeep.

In the southern part of the study area (Kefalonia and Zakintos) a major role is played by the occurrence of the oceanic substrate (present-day Ionian Sea) which is currently subducted. Here the Apulian platform carbonates are sheared off their continental substrate and stacked in the eastern Mediterranean accretionary wedge.

The Apulian platform is resting on a continental crust substrate and its width decreases to the SE. The width of this continental paleogeographic domain controls the evolution of the rolling back subduction in the NW corner of the Eastern Mediterranean. Slab retreat occurred only where the continental substrate is narrow enough to be scraped off without jamming the subduction.

3D Outcrop Modeling: the Oligo-Miocene Carbonate System of the Maiella Mountain, Rapina Mountain area – Abruzzo Region, Italy

VERONICA CAMPAGNONI (°), LAURA TOMASSETTI(*), MARCO BRANDANO (*), LORENZO LIPPARINI (°) & ALESSANDRO ROMI (§)

Key words: *Carbonate Ramp System, Digital Outcrop 3D Model, Maiella Oligo-Miocene Facies*

The use of outcropping geological analogues is proven to be a robust approach to collect data, ideas and geological understanding, also to integrate and improve the reservoir modelling in the subsurface.

In this respect, Medoilgas Italia, Sapienza University of Rome and Schlumberger are collaborating in a project dedicated to the 3D outcrop modeling for an Oligo-Miocene carbonate ramp deposits.

The aim of this work is to share the results obtained on a first modelling exercise, on the Maiella Mountain Oligo-Miocene outcrops (the Bolognano Formation) in the Rapina Mountain area, where a well-exposed example of a homoclinal carbonate ramp allowed to study in detail the associated depositional geometries and facies distribution. The Bolognano Formation exposed carbonate succession consists of four main lithostratigraphic units from the base to the top:

1) at the base, cross-bedded bioclastic grainstone to packstone dominated by larger benthic foraminifers, bryozoan fragments and red algae debris (Lepidocyclina unit, Oligocene in age);

2) above, bioturbated cross-bedded planktonic wackestone to packstone (Planktonic marl unit, Chattian-Aquitanian in age), unconformably overlaid by

3) cross bedded packstone to grainstone, where the skeletal fraction is dominated by bryozoan, mollusc and echinoid fragments (Bryozoan unit, Burdigalian-Langhian in age). In this unit at the top, a 30cm-thick *Heterostegina*-rich bed is present, passing to the uppermost unit,

4) marly wackstone to floatstone dominated by red algal nodules and bivalves (Red Algal unit, Serravallian in age).

Starting from detailed field observation, both on facies and geometries, a workflow was defined to create a 3D model at different scales of a specific area. The final objective was to reconstruct geometrical and facies relationships observed in the outcrops and existing in the subsurface, including a simple 3D fault model.

This process (Fig. 1) consists of combining field spatial data sets with the goal of locking traditional field observations into a full integrated 3D digital model, such as:

- Topographic 3D model: DEM loading with a detailed digitalization from topographic maps with the integration of points of interest with GPS on outcrops.
- Outcrop Stratigraphic Sections: a stratigraphic logs description has been transferred in a verticalized stratigraphic log in Petrel as pseudowells.
- 3D Geological Map: transferring of observed geological limits and faults, formation's boundaries and points of interest including dip/azimuth information into the digital model.
- Geometrical and structural model: combined outcrop data directly used to build a corner-point geocellular 3D grid, incorporating faults observed in the field, and surfaces in accordance to identified stratigraphic framework.
- Facies Model: facies relationships have been modelled inside the 3D geocellular grid.

The Crosia-Calopezzati basin (Cosenza, Calabria): a paradigm of coastal to open-marine correlation

LUCA CAPRARO (*) , LUIGI CAROBENE (**) & MASSIMILIANO GHINASSI (*)

Key words: *Pleistocene, Crosia-Calopezzati, Calabria, open-marine.*

INTRODUCTION

Study of the Plio-Pleistocene open marine successions that are exposed along the coasts of Ionian Calabria (Southern Italy) was, and still is, a "hot topic" for Earth scientists worldwide. These succession were especially investigated because they holds a uniquely exposed and complete stratigraphic record, suitable to high-precise reconstruction of environmental and oceanographic dynamics during "critical" time intervals in the Pliocene and Pleistocene that eventually led to present-day climates. Furthermore, study on these open marine sediments, which are characterized by a peculiar lithological variability and locally cyclically organized, led to the reconstruction of a succession of biotic events chronologically tuned by means of astrocyclostratigraphy (Hilgen, 1991). However, even if significantly improved, the study of open marine sediments itself cannot render a complete picture of the climatic and environmental dynamics that occurred during the late Pliocene to Early Pleistocene interval in the central Mediterranean area. Indeed, deep-water successions permit reconstructing in detail the paleoclimatic and paleoenvironmental history in the hemipelagic dominion, but little information is provided on the corresponding processes in the coastal and terrestrial settings.

The present study focuses on the Crosia-Calopezzati Basin (Cosenza, Ionian Calabria), which provides a rare opportunity of directly comparing the deep-marine and the marginal to coastal records, which are here well exposed and characterized by high sedimentation rates, suitable to high-resolution studies.

GEOLOGICAL OUTLINES

The Crosia-Calopezzati area is located in between the late Neogene Crotone Basin and the coeval Crati Basin (Ogniben, 1962). Both rest on top of the Calabrian accretionary wedge (Fig. 5.3), the internal part of which experimented a major extensional phase during Middle and Upper Pliocene, followed by a contractional strain event during the Lower Pleistocene (Van Dijk 1992, 1993; Sheepers 1994). Thereafter, regional tectonics established during the Middle Pleistocene a "stress-release phase" characterized by transpressional tectonics, with block rotations and the beginning of an isostatic adjustment. These conditions led to the general uplifting of the area (Capraro *et al*., 2011). The Plio-Pleistocene Crosia-Calopezzati marine succession unconformably overlays a N-NE dipping Miocene (Messinian?) bedrock. This succession, at least 250 m thick, is made of dominant mud with subordinate sands, and is overlain by four main orders of marine terraces.

(*) Department of Geosciences, University of Padova. Via Gradenigo 6, 35131 Padova, Italy

(**) DiSTAV, University of Genova, Corso Europa 26, 16132 Genova, Italy

TECTONO-SEDIMENTARY EVOLUTION

Depositional hystory of the Crosia-Calopezzati Basin, which begun at the Plio-Plestocene boundary, is documented by a transgressive event that led to the drowning of the Miocene bedrock and accumulation of a fining upward, 10-20m thick interval consisting of basal nearshore sand grading upward into bioturbated, open-marine mud. Mud deposition was rapidly interrupted by the onset of a regressive phase, which fostered the accumulation of a 35-60 m thick, coarsening upward interval culminating with accumulation of well-stratified, nearshore sand. Such regressive phase was interrupted by a rapid landward shift of the coastline, which occurred at about 1.25 Ma (uppermost part of the "large" *Gephyrocapsa* biozone) and forced starvation in the area with development of a basin-scale, shell-rich key layer. this transgressive event permitted the accumulation of 5-250 m thick muddy deposits, and formation of several sapropel-like layers in the Crosia area, whereas the Calopezzati sector was affected by tectonically-induced, gravitative collapses associated with a NE-SW trending normal fault. Open marine sedimentation persisted during the "small" *Gephyrocapsa* Zone, while the onset of normal regressive conditions occurred at the base of *P. Lacunosa* biozone (about 0.95 Ma). Normal regression, which accumulated a 10-30 m thick sandy interval, persisted until Middle Pleistocene times, when the regional uplift caused a marked relative sea-level fall and development of marine terraces.

The progressive decrease in inclination of the NNE dipping beds forming the Plio-Pleistocene deposits suggests a progressive uplift of the southern basin margin, which is associated with a coeval subsidence of the northern areas. The uplift of the southern margin documents a SSW-NNE tectonic shortening, which is consistent with sin-depositional NW-SE normal faults. Such a structural setting is consistent with the marked flooding event which leaded to formation of the basin-scale, shell rich horizon at the top of the first regressive sandy interval. On the contrary, the final uplift of the basin was probably associated with the onset of the extensional tectonics which caused development of normal faults parallel to the modern coastline.

Crustal structures of the Sicily orogene along the SIRIPRO seismic profile

CATALANO R. (*), VALENTI V. (*), ALBANESE C. (*), SULLI A. (*), GASPARO MORTICELLI M. (*), ACCAINO F.(**), TINIVELLA U. (**), GIUSTINIANI M. (**), ZANOLLA C. (**), AVELLONE G. (*), BASILONE L. (*).

Key words: *crustal multichannel seismic profile, gravity anomaly, sicilian fold and thrust belt.*

INTRODUCTION

The crust under central Sicily has been investigated by the multidisciplinary research SIRIPRO (SIsmica a RIflessione PROfonda) Project (cofinanced by MIUR Italian Research Minister, scientific leader R. Catalano) that foresaw a 106-km-long deep seismic reflection profile (Fig. 1), together with refraction, gravimetric and magnetotelluric data. The profile starts near Termini Imerese on the Tyrrhenian coast, crosses the northern Sicilian chain, the Caltanissetta trough in central Sicily, and ends on the southern coast near Gela, close to the outcroppings of the Iblean plateau, foreland of the Sicilian–Maghrebian fold and thrust belt (Fig. 1).

The study area is a sector of the Apennines-Tyrrhenian system recently described as a result of both post-collisional convergence between Africa and Europe and roll-back of the subduction hinge of the Ionian lithosphere (e.g. MALINVERNO & RYAN, 1986; DOGLIONI *et alii*, 1991, 1999; FACCENNA *et alii*, 2004; FINETTI *et alii*, 2005).

Previous studies and current published data on Sicily well illustrate the outcropping and shallow-seated thrust wedge, but they are not able to anchor it to the crustal and lithospheric structure. Away from the refraction data, little is known on the deep structures and the characters of the crust. This because the direct deepest data are shallower than 10 km, arising from the interpretation of commercial seismic reflection profiles.

Main objectives of the project mostly deal with the nature and thickness of the crust in the chain-foreland areas and depth and geometry of the Moho, essential to hypothesize subduction models and improve knowledge about the relationships between the African and the Tyrrhenian/European crusts.

Combining different geological and geophysical results, we propose a geological-geodynamic reconstruction of the study area and suggest the basics for forthcoming crust-mantle studies.

METHODS

Previous investigations were focused on the acquisition, processing and preliminary interpretation of the seismic profile (ACCAINO *et alii*, 2011).

The present study includes re-processing of the seismic data, velocity and gravity modellings, structural-stratigraphic analyses and extensive field mapping.

Seismic facies analysis of the commercial seismic reflection lines (ENI courtesy, BELLO *et alii*, 2000), tying the Siripro profile, have been used to constrain the crustal geological interpretation.

The results of the Siripro profile interpretation were merged and compared with the ray tracing modeling from refraction studies (DSS and WARR profiles).

RESULTS

Geological and geophysical results provided geometries and features of the main fold and thrust belt, the Gela thrust wedge and the occurrence of Plio-Pleistocene thrust-top to modern foredeep basins, the very steep NW-ward regional monocline foreland, suggesting inflection of the crust, the deep Caltanissetta trough imaged, for the first time, at about 17 km , the top of the poorly-defined crystalline basement and the inferred crust/mantle boundary.

CONCLUSIONS

a) The described thrust systems are composed of rock bodies, pertaining to the African crust, decoupled atop the assumed crystalline basement, as already reported from Apenninic sectors.

b) The progressive underthrusting of more external platform units, beneath the already deformed tectonic wedge, reflects an orderly progression of the deformation from higher to lower levels of the original multilayer.

c) The collected data support a crust involvement neither in the deeper duplexes formation of the chain, nor in the recent

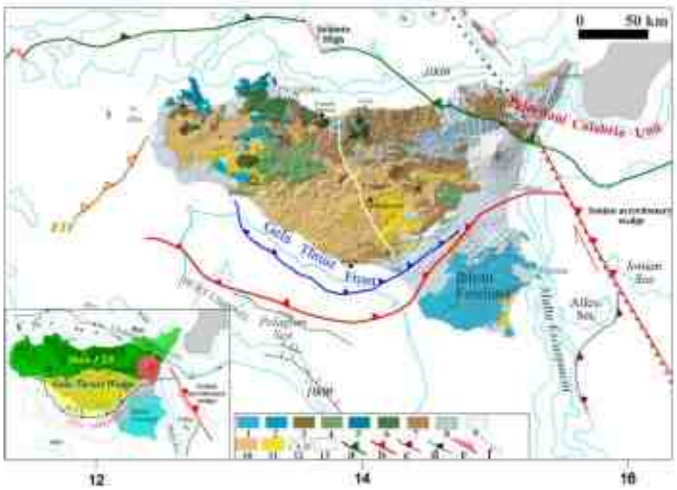

Fig. 1. Structural map of Sicily (modified from CATALANO *et al.,* 2000 a). 1) Iblean units; 2) shelf to pelagic carbonate (Trapanese–Saccense) units; 3) shelf to deep-water carbonate (Monte Genuardo) units; 4) deep-water carbonate (Sicanian) units; 5) shelf carbonate (Panormide) units; 6) slope to deep-water (Imerese–Panormide) units; 7) Miocene Flyschs; 8) Sicilide units; 9) Calabrian–Peloritani units; 10) Miocene–Pliocene syntectonic deposits; 11) Plio-Pleistocene syntectonic deposits; 12) Plio-Quaternary volcanic rocks; 13) Pleistocene deposits; a) Kabylian–Calabrian thrust front; b) Maghrebian–Sicilian thrust front; c) Ionian accretionary wedge thrust front; d) thrusts; e) faults with strike-slip component; f) hypothetic continental oceanic boundary (modified by CATALANO *et al.,* 2000 a). In white bold line the location of SIRIPRO profile. In the left-hand corner, the main elements characterizing the collisional complex of Sicily.

tectonic uplift and deformation, suggesting a thin-skinned tectonic style.

d) Along the Siripro line the calculated shortening of about 60 km derives from the forward transport of the carbonate platform layer, since neither shortening nor internal imbrication of the Meso-Cenozoic deep-water carbonates thrust units and Miocene clastics have been considered.

e) The trailing edge of the external carbonate units could be located at about 50 km from the Sicily northern coast, at the Solunto High (Fig. 1), where the Kabylo-Calabrian crystalline units ("European" crust) overthrust the submerged extension of the outcropping Sicilian-Maghrebian wedge (PEPE *et alii*, 2005).

f) The African Moho, shallowing from NNW to SSE, can be identified in the northern sector around 40 km, while beneath the Caltanissetta trough and the Iblean southern sector can be imaged, respectively, at 33-34 and 27-28 km.

g) The seismically interpreted "Tyrrhenian Moho" at a depth of about 25 km, corresponding to the higher density body estimated by the gravimetric modelling, is envisaged in the innermost sector of the profile.

h) Crustal features highlighted by the Siripro profile, such as 1) the 20-24 km almost-thick orogenic wedge, entirely buried below a shallow topography, recalling the 25 km thick, low Vp values presumed by CHIARABBA *et alii* (2008), 2) the strong flexural bending of the regional monocline down to about 20 km, in the Caltanissetta trough, 3) the strong negative gravity anomaly (more than -100 mGal) associated to the steepest part of the monocline, and 4) the positive gravity anomaly in the northern Sicily coast, associated with an high density body inside the crust, appear important constrains for the hypothesis of the occurrence of an upper mantle wedge (DOGLIONI *et alii*, 1999) overlying the African crust.

i) The stacking of the huge tectonic wedge progressively involving its foreland could be the surface effect of the SE-ward retreat of the African slab laterally attached to the Ionian slab (CHIARABBA *et alii*, 2008).

Plio-Pleistocene tectonics in the Marche-Abruzzi peri-Adriatic belt

E. CENTAMORE (*), F. DRAMIS (**) & G. FUBELLI (**)

Key words: *Active structures, geomorphological evolution, peri-Adriatic belt, stratigraphic analysis.*

Geological field work supported by stratigraphic analysis and the interpretation of oil exploration borehole data and seismic sections allowed reconstructing the late stages of Apennine orogenesis that were responsible of the present morphostructural setting of the Marche-Abruzzi peri-Adriatic belt.

In the Upper Pliocene, a wedge-top basin (Marche-Abruzzi peri-Adriatic basin) started forming in the Marche-Abruzzi peri-Adriatic Sector, following the eastward migration of the Apennine thrust belt building. Some NNW-SSE trending ridges, consisting of complex anticlines, located at the hanging-wall of buried thrusts (the western Agugliano-Ortezzano-Bellante Villadegna Ridge, detached across the Triassic deposits, and the eastern Porto S. Giorgio-Roseto-Maiella and Montesilvano-Lanciano Ridges, detached across the Messinian evaporites), and several transversal/oblique faults are the most relevant structural elements of the basin (ORI et alii, 1991; CASNEDI R. & SERAFINI, 1994; CENTAMORE & NISIO 2003; CENTAMORE & ROSSI, 2009).

During the Upper Pliocene-Lower Pleistocene, the basin has been affected by compressive tectonics, as evidenced by the continuous growth of the ridges, by the occurrence of detachment folds in the core sectors of the inter-ridge synforms, and by the strike-slip movements of transversal/oblique faults (BALLY *et alii*, 1986; CENTAMORE & ROSSI, 2009). In the easternmost sector of the basin, the sedimentary sequence underwent eastward tilting joined with the eastward shifting of the coast line. In the same time interval, low-angle, east-dipping normal faults, interpreted by some authors as back thrust (BALLY *et alii*, 1986), dislocated the anticlines forelimbs.

In the Early Middle Pleistocene, due to further tilting, the peri-Adriatic belt eventually emerged, forming a wide alluvial plain bordered to the west by a series of coalescent alluvial fans and, to the east, by a line of coastal lagoons. In this first emerging phase, the plain was characterized by a parallel drainage pattern, perpendicular to the Apennine trend. In the following times, a complex intense tectonics affected the peri-Adriatic belt, inducing significant changes in the previous morphostructural/morphohydrographic setting. Late compressive pulses are evidenced by the occurrence of gentle folds and tiltings affecting Sicilian deposits on the Abruzzi coastal ridges as well as by the strike-slip movement of transversal/oblique faults displacing alluvial deposits of Middle to Upper Pleistocene age (CENTAMORE & NISIO, 2003).

Moreover, NNE-SSW trending strike-slip faults and NNW-SSE striking normal faults, likely interpretable as surface accommodation structures of the buried growing anticlines, caused the offsetting of rivers. In the same time, a set of fault steps, arranged in a staircase pattern, formed along the coastal belt.

All the above structures have been active, even if with kinematic inversions, up to recent times controlling the geomorphological evolution of the emerged sectors of the Marche-Abruzzi peri-Adriatic belt. Such activity is confirmed by the regional seismicity, characterized by compressive and strike-slip mechanisms (CONSOLE et alii, 1989; RIGUZZI *et alii*, 1989; FREPOLI & AMATO, 1997).

Based on these data, some considerations can be drawn about the geodynamic evolution of the investigated sector: 1. the eastward tilting events, the low angle, east-dipping normal faults cutting the forelimbs of the growth-anticlines, rooted in main thrust yelding surface, and the undulations involving Lower Pleistocene sediments, may be referred to compressional stress, as indicated also by the focal mechanisms of recent earthquakes; 2. these phenomena may be related to the late stages of the eastward migration of a broad range arching system; 3. the geodynamic context responsible for their activation may be referred to a first order, large scale process of astenospheric bulging (LOCARDI & NICOLICH, 1992; D'AGOSTINO *et alii*, 2001).

Studio preliminare delle facies evaporitiche e carbonatiche del Messiniano della Stretta di Catanzaro (Calabria Centrale)

GIUSEPPE CIANFLONE G. (*), ROCCO DOMINICI (*) & MAURIZIO SONNINO

Key words: *Catanzaro Trough, evapotitic facies, Messinian Salinity Crisis*

Nel settore nord-orientale della Stretta di Catanzaro affiora una successione mio-pliocenica caratterizzata da unità stratigrafico-deposizionali evaporitiche e calcaree, clastiche e primarie, messiniane (FERRINI & TESTA, 1997).

Le unità evaporitiche sono costituite da un'associazione di facies riferibile a processi gravitativi di massa con blocchi fino a decametrici, correlabile alle RLG (*Resedimented Lower Gypsum*) (MANZI *et alii* ,2005) e da gessi selenitici primari di 2° ciclo (COSTA, comunicazione personale) riferibili alle *Upper Evaporites* (CIANFLONE & DOMINICI, 2011).

Le facies evaporitiche primarie e risedimentate sono state analizzate mediante l'integrazione di dati stratigrafici sedimentologici associati all'osservazione in sezione sottile e al SEM con analisi chimica puntuale EDX .

I blocchi dell'unità clastica evaporitica sono costituiti dalle seguenti facies primarie evaporitiche.

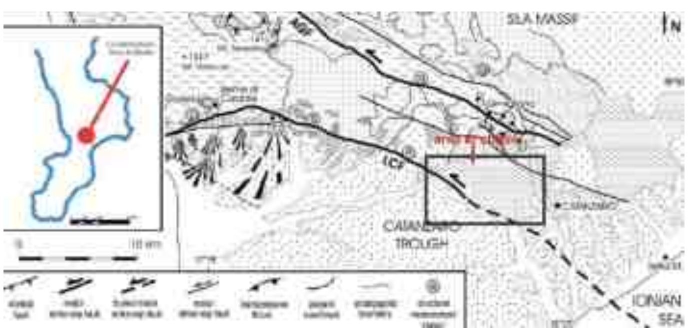

Fig. 1 – Localizzazione dell'area di studio (modificata da TANSI *et alii*, 2006)

<u>*Massive and Giant Selenite*</u> (LUGLI *et alii* ,2010) – Nell'area di studio è caratterizzata da cristalli fino ad 1m di altezza e 50cm di spessore con tipica geminazione a ferro di lancia talora associati a formare il tipico *nucleation cone*. All'interno dei cristalli si osserva la presenza di un nucleo più scuro dovuto all'intrappolamento di filamenti di cianobatteri (*spaghetti facies*, VAI & RICCI LUCCHI, 1977). All'interno dei grandi cristalli di selenite si osservano delle superfici di arresto e successiva ripresa della crescita in continuità ottica probabilmente legate ad una ciclicità stagionale e caratterizzate talora da piccoli granuli di gesso prodotti da fenomeni di dissoluzione o da attività batterica. L'osservazione al SEM con associate analisi EDX ha messo in evidenza all'interno dei cristalli la presenza di inclusioni fluide, coccoliti, piccoli cristalli di halite e cavità riempite da celestina.

<u>*Banded Selenite*</u> - È caratterizzata da cristalli centimetrico-

Fig. 2 – Cristallo della facies *Massive Selenite*

decimetrici di selenite sviluppatisi in direzione verticale e organizzati spazialmente a formare una struttura a palizzata. Ogni intervallo termina superiormente con una superficie di non precipitazione o molto spesso di dissoluzione su cui si sviluppa superiormente un nuovo strato. Anche i cristalli di questa facies presentano un nucleo più scuro dovuto all'intrappolamento nell'angolo rientrante del geminato di filamenti di cianobatteri come per la facies *Massive Selenite.* L'analisi morfologica al SEM ha mostrato la presenza all'interno dei cristalli di inclusioni

fluide, coccoliti e minerali argillosi. In alcuni intervalli di questa facies i cristalli presentano l'asse di geminazione inclinato lungo un asse Est-Ovest a causa dell'incurvamento degli apici dei cristalli verso la direzione di provenienza della salamoia (BABEL, 2005).

Branchig Selenite (LUGLI *et alii*, 2010) – Questa facies, fino

Fig. 3 – Cristalli della facies *Banded Selenite* organizzati in livelli con struttura a palizzata.

a poco tempo fa considerata di origine diagenitica, è costituita da piccoli cristalli non geminati che crescono lateralmente formando dei "rami" che si dipartano da una comune zona di nucleazione.Questa facies è peculiare delle PLG (*Primary Lower Gypsum*) e compare a partire dal 6°ciclo. Nell'area di studio questa facies è stata osservata solo sotto forma di grandi blocchi arrotondati.

Cumuliti - Sono costituite da piccoli cristalli aciculari che si

Fig. 4 – Particolare di un blocco della facies *Branching Selenite* all'interno del Conglomerato del Riato (CIANFLONE & DOMINICI, 2011)

formano in superficie o all'interno della colonna idrica ma raggiunta una certa dimensione decantano e si accumulano sul fondo. La formazione di questo tipo di deposito può avvenire a diverse profondità e in ambienti come quelli anossici dove è invece inibita la formazione delle seleniti.

Sui depositi evaporitici clastici si sviluppano dei gessi primari di secondo ciclo che raggiungono uno spessore massimo osservato di circa 15 m e sono caratterizzati dalla presenza Sui depositi evaporitici clastici si sviluppano dei gessi primari di secondo ciclo che raggiungono uno spessore massimo osservato di circa 15 m e sono caratterizzati dalla presenza delle facies *Massive* e *Banded Selenite* a cui sono associate delle facies gessose risedimentate e delle peliti finemente laminate con intercalazione di sottili livelli sabbiosi.

Nel settore orientale dell'area di studio sono stati riconosciuti dei depositi calcarei correlabili al *Calcare di base*

Fig. 5 – Vecchio fronte di cava (C.da Stella, Marcellinara) dove affiorano le facies gessose correlabili alle *Upper Evaporites*.

(CdB). In particolare sono state riconosciute due associazioni di facies: CdB-1 e CdB-2. La prima, affiorante in corrispondenza dell'alto strutturale di Gagliano, è caratterizzata da corpi tabulari di micrite compatta e massiva con piccoli vacuoli e rari ciottoletti (2-5 mm), occasionali *clay chips* e isolati ciottoli appiattiti (*flat-pebbles*) di calcilutiti. In virtù della sua posizione stratigrafica e dei caratteri tessiturali e sedimentologici si ipotizza un'origine in posto legata all'attività batterica come descritta da GUIDO *et alii*. (2007) per la Formazione del Calcare di Base del Bacino di Rossano.

L'associazione di facies CdB-2 presenta un aspetto vacuolare derivante dalla presenza di *rip-up mud clast*, *clay chips* da centimetrici a decimetrici e piccoli ciottoli sub-arrotondati di origine metamorfica. I singoli corpi di forma lenticolare a geometria concavo-piana e di spessore decimetrico mostrano talora grossolane gradazioni, superfici di amalgamazione e sono delimitati da superfici erosive. Le facies calcaree si alternano a intervalli decimetrici marnoso pelitici laminati che drappeggiano i sottostanti corpi clastici carbonatici.

Il CdB-2 può essere considerato come l'equivalente del

Calcare di Base Type 3 descritto da MANZI *et alii* (2010).

L'analisi di facies delle unità evaporitiche e calcaree clastiche e primarie fornisce una visione completa dei processi sedimentari attivi durante l'evoluzione messiniana del settore nord-orientale del Graben di Catanzaro pemettendo la ricostruzione di un primo modello evolutivo. L'integrazione di dati geochimici e petrografici permetterà di elaborare un modello definitivo e di confrontare l'archiettura deposizionale del Graben di Catanzaro con i modelli oggi proposti (**CIESM**, 2007).

Sedimentary and tectonic evolution of the Pliocene Ariano wedge-top basin (southern Apennines, Italy)

CIARCIA SABATINO (*) & VITALE STEFANO (°)

Key words: *basin evolution, facies analysis, slab break off, southern Italy.*

INTRODUCTION AND GEOLOGICAL SETTING

The southern Apennines are characterized by a tectonic pile formed by the superposition of several basin to platform successions, including NE-directed thrusts (e.g. VITALE *et alii*, 2012) resulted from the fast SE-ward retreat of the Apulian slab within the general framework of the slow convergence between African and European plates. The roll-back of the Apulian lithosphere was synchronous with the opening of the Liguro-Provencal and Tyrrhenian back-arc basins in the Upper Oligocene/Middle Miocene and Upper Miocene/Recent, respectively. This work concerns the study of Pliocene wedge-top basin deposits along the outer sector of the southern Apennines (Fig. 1). Recently ASCIONE *et alii* (2012) envisaged, starting from a detailed stratigraphic paper on these successions, a Pliocene-Pleistocene sedimentary evolution of the wedge-top basins as response to the tectonic subsidence and uplift of the Apennine prism related to deep processes involving the downgoing plate (Apulia). This process is marked, along the chain axis, by a decreasing age of sedimentation (since 3.98 Ma) within each basin.

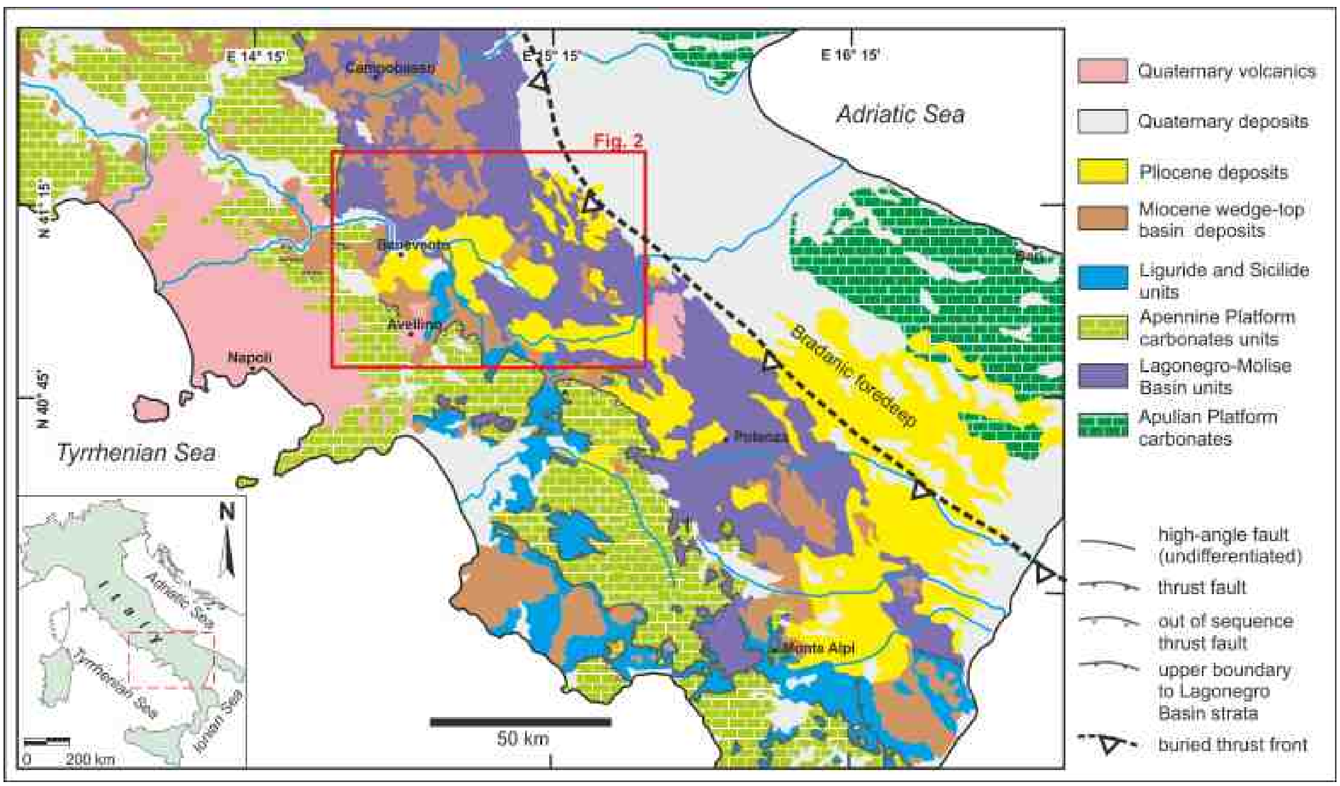

Fig. 1– Geological sketch map of the southern Apennines (from Ascione et al., 2012, modified).

The study area is located in the external sector of the southern Apennines (Fig. 1) where Lagonegro-Molise Basin units are tectonically sandwiched between carbonates of the Apennine Platform, located on the top, and the Apulian Platform at the bottom. The allochthonous Lagonegro-Molise Basin units are

unconformably covered by the upper Tortonian wedge-top basin deposits of Ponticello Fm. whereas the upper Tortonian-lower Messinian (Castelvetere Fm.), upper Messinian-lowermost Pliocene (Altavilla Unit) and lower-middle Pliocene (Ariano Unit) wedge-top basin successions seal the whole tectonic pile. Finally Plio-Pleistocene fluvio-lacustrine intramountain basin deposits are widespread in the whole area.

STRATIGRAPHY AND SEDIMENTARY FACIES OF THE PLIOCENE ARIANO BASIN SUCCESSIONS

The Ariano Basin was a wedge-top depocenter within a wide foreland basin system (*sensu* DECELLES & GILES, 1996) connected to the Pliocene Paleo-Adriatic Sea. The analyzed Lower Pliocene deposits, extensively drilled for the oil exploration (e.g. Trevico 1 well log;), are widely exposed in the Benevento Valley, Ariano Irpino area, Baronia Mts. and Daunia Hills, southward of the SW-NE Benevento-Buonalbergo fault, running from Caudina Valley to Torrente Sannoro, unconformably covering Lagonegro-Molise Basin allochthonous successions.

The late Zanclean Ariano Basin succession (biozone MPl4a, MNN14-15/MNN16a *partim*, CN11b-CN12a *partim*; AMORE *et alii*, 1998), characterized by a maximum thickness of 2000 m and by a transgressive trend in the lower part and a regressive trend in the upper part, has been subdivided in five informal members by CIARCIA *et alii*, (2003) here named from BF1 to BF5.

Four main groups of facies associations have been recognized in the Baronia Fm.: (A) Alluvial; (B) Beach; (AB) Delta; (C) Inner-shelf/Offshore (Fig. 2). In order to provide the paleocurrent pattern, in each coarse grained facies, at least 40 measurements of pebble clusters and embricated pebbles have been collected. The gathered data have been integrated with those reported in literature (AIELLO *et alii*, 2005; AMORE *et alii*, 1998; ASCIONE *et alii*, 2012; BARRA *et alii*, 1998; CIARCIA *et alii*, 1998, 2003, 2006).

BASIN EVOLUTION

The sedimentary, paleoenvironmental and paleogeographic evolution of the Ariano Basin has been characterized by a complex interplay between several features where the tectonics largely overcome the effects of eustatic sea-level fluctuations. Major tectonic events, related to thrusting within allochthonous successions seem to have controlled mainly the basin shape also during its filling (CIARCIA *et alii*, 1998, 2003, 2006). According to age and facies analysis of sediments deposited in the Ariano Basin we envisage that the analyzed area was again emerged in the early Lower Pliocene and only in the upper part of the Zanclean stage has been reached by the Paleo-Adriatic marine ingression with the deposition of shelf marine clays (lowermost

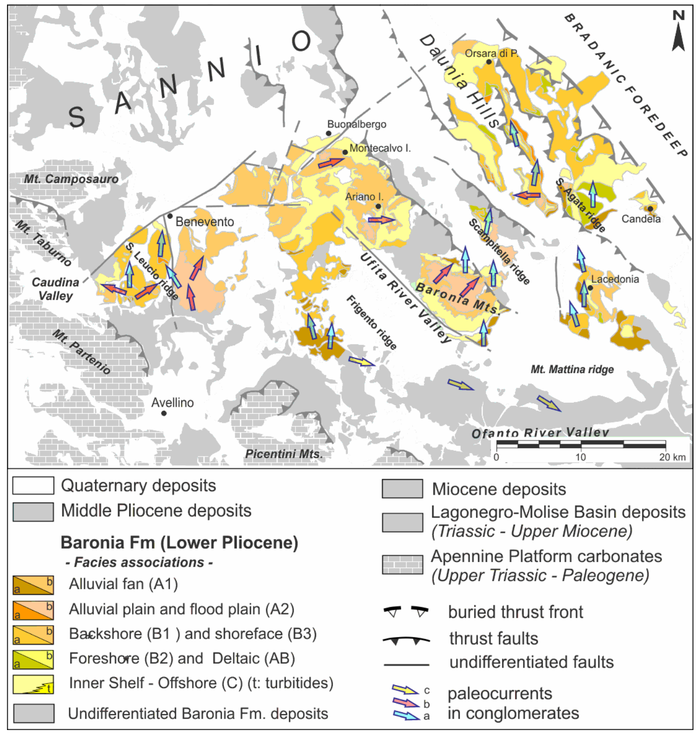

Fig. 2 – . Geological map showing facies associations, paleoenvironments and paleocurrents in the Baronia Fm. a- fining upward succession; b-coarsening upward succession; c-undifferentiated paleocurrents referred to Ofanto River Valley deposits.

deposits of Ariano Basin) onto the pre-Pliocene substratum (i.e. Lagonegro-Molise Basin successions). The facies distribution within the Ariano Basin permits to imagine a paleomorphology characterized by an asymmetric geometry, with the main depocenters located in the northwestern sector, close to the Benevento-Buonalbergo fault, and the E-W directed Mt. Mattina ridge separating the Ariano Basin from the southward Ofanto Basin (Fig. 3).

The regional drowning of this sector, allowing the ingression of the Paleo-Adriatic Sea in the Ariano Basin, and the successive retreat, as consequence of progressive uplift from SW to NE of different sectors passing from marine to continental environments, could be related to geodynamic processes occurred both in the underlying Apulian slab and allochthonous successions. As suggested by ASCIONE *et alii* (2012) the general subsidence and the successive uplift are associated to the SE migration of the downgoing plate break off.

Structural analysis and stratigraphy of Internal units (Calabria-Lucania boundary, Southern Italy)

SABATINO CIARCIA (°), FRANCESCO D'ASSISI TRAMPARULO (*), STEFANO VITALE (*)

Key words: *Ligurian Accretionary Complex, southern Apennines, stratigraphic units, structural geology.*

INTRODUCTION AND GEOLOGICAL SETTING

The Ligurian Accretionary Complex cropping out in the southern Apennines consists of several tectonic units (Fig. 1) encompassing the ophiolite-bearing Frido Unit (BONARDI *et alii*, 1988), and three units (Fig. 1) formed by sedimentary successions probably deposited on thinned continental/transitional crust (VITALE *et alii*, 2011; CIARCIA *et alii*, 2012): Nord-Calabrese, Parasicilide and Sicilide units (BONARDI *et alii*, 1988; CIARCIA *et alii*, 2009; OGNIBEN, 1969). The Frido Unit shows relics of high-pressure (HP) metamorphism, suggesting it was accreted to the Ligurian accretionary complex by underplating and rapidly exhumed in Miocene times whereas, the Nord-Calabrese, Parasicilide and Sicilide units generally do not show metamorphism and are interpreted as resulting from frontal accretion (VITALE *et alii*, 2011; CIARCIA *et alii*, 2012).

Miocene wedge-top basin deposits of the Cilento Group, Perosa and Oriolo Fms unconformably overlie the Ligurian units. In the study area the Ligurian accretionary complex tectonically covers other units resulting from the deformation of sedimentary cover successions belonging to the Apulian continental margin, comprising shallow-water and slope carbonates (Lungro-Verbicaro and Pollino-Ciagola units, VITALE & MAZZOLI, 2008) as well as pelagic basin (Lagonegro Basin) successions. The Frido Unit is overlain by the Nord-Calabrese and Parasicilide units in the Lauria area located to the NW, whereas overlie the Nord-Calabrese Unit in the SE sector (between the Terranova del Pollino and San Severino Lucano villages).

STRATIGRAPHY

The preorogenic successions, of the Ligurian Accretionary Wedge of the Calabria-Lucania boundary, include the Frido, Nord-Calabrese, Parasicilide and Sicilide units.

The Frido Unit is characterized by a metamorphic and highly deformed succession formed by large bodies of both oceanic crust and upper mantle and continental crust. The crystalline rocks are covered by a deep basin metasedimentary succession formed by metaradiolarites, calcschists, phyllites, quartzites and metapelites and finally by Upper Oligocene (BONARDI *et alii*, 1988) calcschists.

The Nord-Calabrese Unit is formed, from bottom to top by Timpa delle Murge ophiolites, Timpa delle Murge Fm, Crete Nere Fm and Saraceno Fm (BONARDI *et alii*, 1988). The Early-Middle Jurassic remnants oceanic crust (pillow lavas, pillow breccias gabbros and diabases) of Timpa delle Murge ophiolites is followed by the Timpa delle Murge Fm, characterized by argillites, quartz-arenites, allodapic limestones and jaspers. Upward Crete Nere and Saraceno Fms represent a predominantly siliciclastic and calciclastic succession deposited onto an oceanic crust evolving to a foredeep basin. The age of middle-upper part of Crete Nere Fm is Middle Eocene; however the age of the lower part could reach the Upper Cretaceous as suggested by BONARDI *et alii* (1988). The age of the Saraceno Fm is Late Eocene-?Burdigalian.

The Parasicilide Unit (*sensu* CIARCIA *et alii*, 2009) comprises both pre-orogenic and foredeep basin deposits grouped into four formations (from bottom to top): (i) clay, slates and sandstones of Postiglione Fm; (ii) marls and limestones of Monte Sant'Arcangelo Fm; and (iii) whitish marls and marly limestones of Contursi Fm; (iv) foredeep deposits of the Arenarie di Albanella Fm. The age of these deposits ranges between the Middle Eocene and the Burdigalian, however, for the lower undated deposits could be a Late Cretaceous in analogy to Crete Nere Fm.

The Sicilide Unit (OGNIBEN, 1969), analogously to the Parasicilide Unit, is formed by orogenic and foredeep basin deposits grouped into four formations (from bottom to top): (i) clay and slates of Argille Varicolori Inferiori Fm; (ii) marls and limestones of Monte Sant'Arcangelo Fm; and (iii) clays and marls, somewhere calcarenites rich in foraminifera, of Argille Varicolori Superiori Fm; (iv) foredeep deposits of the Arenarie di Corleto, Tufiti di Tusa or Numidian Flysch fms. The age of these deposits ranges between the Middle Eocene and the Burdigalian.

The unconformably overlying successions are characterized by Miocene thrust-top basin deposits.

The Cilento Group succession, ranging in age from the Langhian to the lowermost Tortonian, is formed by arenitic and marly deposits of Pollica and San Mauro Fms laterally passing southward to conglomeratic, arenitic and marly deposits of Torrente Bruca Fm. In Basilicata region these formations correspond to the undifferentiated succession of the Albidona Fm.

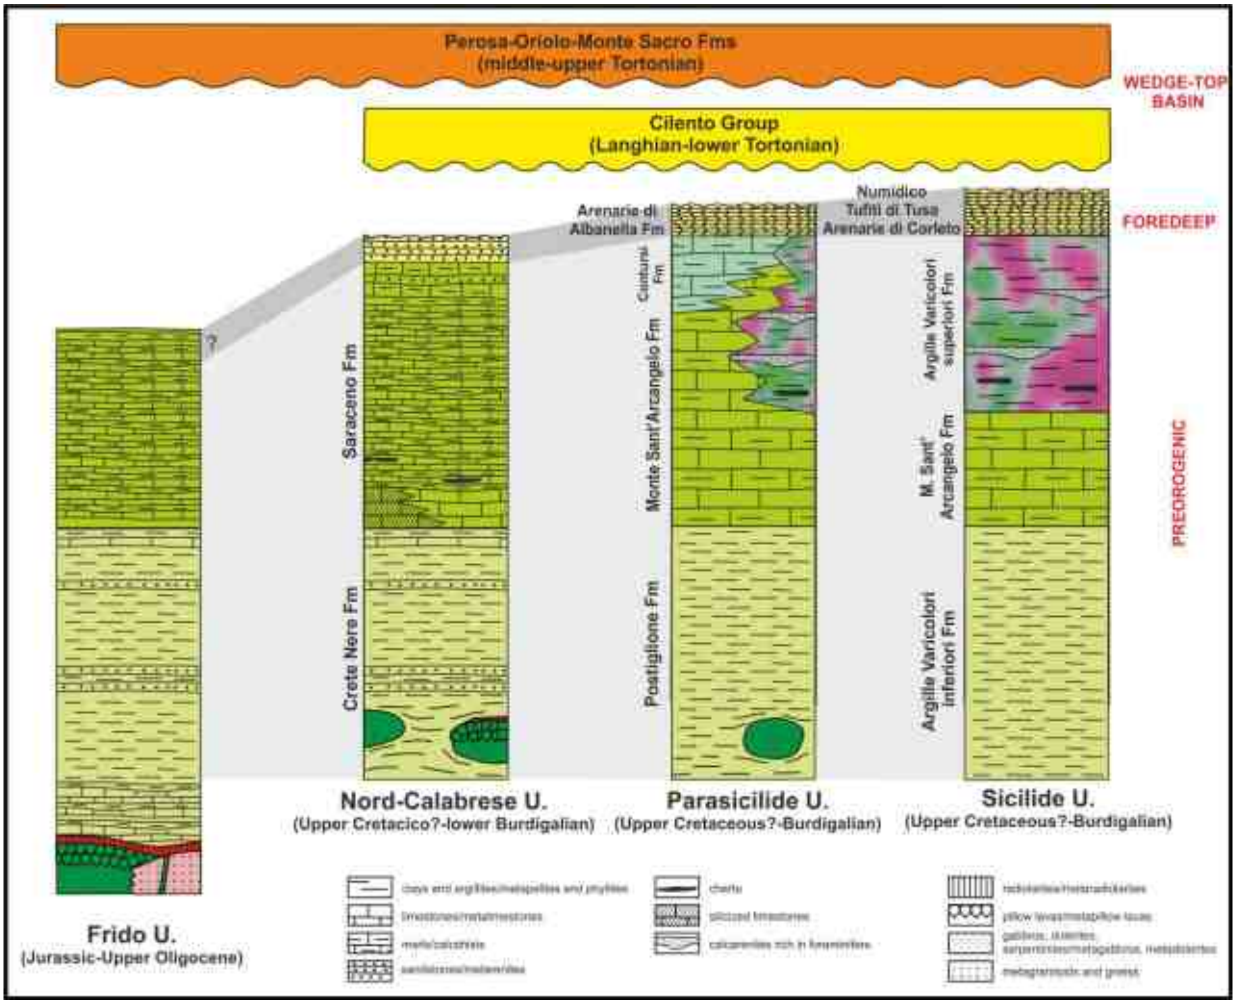

Fig. 1 – Stratigraphic logs of units of the Ligurian Accretionary Wedge of the Calabria-Lucania boundary

The Upper Miocene thrust top basin deposits of (i) Castelvetere Fm; (ii) Monte Sacro Fm and (iii) Oriolo, Serra Manganile and Gorgoglione Fms, cropping out in the Sele Valley, Cilento and Basilicata, respectively are characterized by dominant coarse-grained clastic deposits.

STRUCTURAL ANALYSYS

The three units forming the unmetamorphosed part of the Ligurian Accretionary Wedge, are characterized by three superposed fold stages:

1. the first deformation phase in the Nord-Calabrese Unit is remarked by tight to isoclinal folds with an associated slaty cleavage in the pelites and a spaced cleavage in the arenites and limestones. The second phase folds are more open showing a kink geometry. The interference pattern between the first and second folding ranges between the 2 and 3 types of the Ramsay classification. The third deformation stage is characterized by decametric folds associated to thrust faults affecting the whole tectonic pile (also the Parasicilide and Sicilide units);
2. The Parasicilide and Sicilide units, showing a similar stratigraphic succession and probably occupying the same paleogeographic position, are characterized by the same deformation pattern described for the Nord-Calabrese Unit, however both successions appear often as a broken formation due to the incompetent deposits of whichis formed. Fold axes of first, second and third deformation stages, show prevailing (i) E-W or NW-SE, (ii) N-S or NE-SW and (iii) NW-SE trends, respectively. It worth to note as the third phase fold directions are parallel to those of the folds affecting the thrust-top basin deposit of the Albidona Fm and those of the third phase affecting the Lungro-Verbicaro Unit.

Evidence of the Mediterranean early Zanclean flooding in the Adana Basin (southern Turkey)

PAOLA CIPOLLARI (*), DOMENICO COSENTINO (*), GIUDITTA RADEFF (*), TAYLOR F. SCHILDGEN (**), COSTANZA FARANDA (*), ELSA GLIOZZI (*), FRANCESCO GROSSI (*), ALESSANDRA SMEDILE (***), ROCCO GENNARI (****), GÜLDEMIN DARBAŞ (*****), FRANCIS O. DUDAS (******), KEMAL GÜRBÜZ (*******) & ATIKE NAZIK (*******)

Key words: *Messinian salinity crisis, Adana Basin, Zanclean flooding*

ABSTRACT

Following the complete closure of the seaway connection with the Atlantic Ocean via the Gibraltar Strait at the end of the Messinian Salinity Crisis (MSC), the Mediterranean area experienced brackish- and freshwater environments (Lago-Mare event). Starting from about 5.6 Ma, Lago-Mare biofacies consisting of Paratethyan immigrant fauna (ostracods, molluscs and dinocysts) characterized all the sub-basins of the Mediterranean area until the base of the Pliocene (5.332 Ma). At the end of the MSC, rapid inflow of seawater from the Atlantic Ocean (Pliocene flooding) gave rise to the deposition of epibathyal early Zanclean clays just above Lago-Mare late Messinian marls and clays (CITA & GARTNER, 1973; MEULENKAMP, 1979; ROUCHY, 1982, HILGEN, 1987; 1991b; DI STEFANO *et alii,* 1996; IACCARINO *et alii*, 1999a, b; ROUCHY *et alii*, 2007; CRESCENTI *et alii*, 2002; COSENTINO *et alii*, 2005; PIERRE *et alii*, 2006; GENNARI *et alii*, 2008; COSENTINO *et alii*, 2007).

According to the literature, the Adana Basin (Fig. 1) recorded the Pliocene stage with the deposition of shallow marine to fluvial deposits (Handere Fm) (SCHMIDT, 1961; YALÇIN & GÖRÜR, 1984; GÜRBÜZ & KELLING,1993; ÜNLÜGENÇ, 1993; NAZIK, 2004; BURTON-FERGUSON, 2005; DARBAŞ and NAZIK, 2010). Our micropaleontological analyses of samples from the southern margin of the Adana Basin, near Avadan village, reveal late Lago-Mare biofacies in the upper part of the section, with Paratethyan ostracod assemblages pertaining to the *Loxocorniculina djafarovi* zone. South of the Avadan uppermost Messinian Lago Mare deposits, a very short section of grey clays was sampled for a total thickness of 3 m. The continuous occurrence of *Reticulofenestra zancleana* (DI STEFANO and STURIALE, 2010) and the base of the *Reticulofenestra pseudoumbilicus* paracme have been identified in the calcareous nannofossil assemblages of the Avadan section. This latter bioevent occurs diachronously in a time range spanning from the 4th to the 6th precessional cycles of the Pliocene.

These results point to a very early Zanclean age (MNN12a subzone) for the studied section (5.332-5.199 Ma). The planktonic foraminifera assemblages of the section are characterized by Early Pliocene fauna. The occurrence of *Sphaeroidinellopsis* spp., which is common in some samples, the presence of *Neogloboquadrina acostaensis* dx, and the absence of *Globorotalia margaritae* allow us to constrain the sampled section to the basal Zanclean (MPl1). The ostracod assemblage is characterized by the presence of *Krithe compressa* and *Argilloecia acuminata*, pointing to epibathyal and bathyal environments. Similar paleodepth indications with disaerobic conditions come from the benthonic assemblages characterized by *Cibicidoides* sp., *Planulina ariminensis*, *Sphaeroidina bulloides*, *Uvigerina rutila*, and *U. peregrina.*

$^{87}Sr/^{86}Sr$ measurements on ten foraminifera samples gave ratios ranging between 0.709006 and 0.708979, with an average value of 0.708998, for estimated ages falling within the early Zanclean. In particular, taking into account the 3-point running mean through data from the Indian Ocean (ODP site 758; FARRELL *et alii*, 1995) the average $^{87}Sr/^{86}Sr$ value from the Avadan samples point to the following estimated ages: 5.0, 5.2, and 5.3 Ma. Although the Messinian/Zanclean boundary doesn't crop out in the Adana Basin, the occurrence in the Avadan section of epibathyal to bathyal early Zanclean microfossil association (MNN12a and MPl1) close to the outcrop of late Messinian Lago-Mare biofacies suggests that in the Adana Basin, the Messinian/Zanclean transition parallels conditions reported throughout the whole Mediterranean Basin.

The Messinian/Zanclean transition was drilled by the T-191 borehole at around 220 m depth, with the transition between late Messinian Lago-Mare biofacies, containing *Cyprideis agrigentina*, and fully marine clays with abundant planktonic foraminifera assemblages.

We further use the ages and paleodepths of the marine

sediments together with their modern elevations to determine uplift rates of the Adana Basin of 0.06 to 0.13 mm/yr since 5.2-5.3 Ma (total uplift of 350 to 650 m) from surface data, and 0.02 to 0.13 mm/yr since ca. 1.8 Ma (total uplift of 30 to 230 m) from sub-surface data (T-191 borehole; CIPOLLARI *et alii*, in press). Faster uplift rates over the same time interval along the SE margin of the Central Anatolian plateau (COSENTINO *et alii*, 2010a, b; COSENTINO *et alii*, 2012; SCHILDGEN *et alii*, 2012), which borders the Adana Basin to the NW, imply that differential uplift of the plateau margin relative to the basin continued even after the basin started to be uplifted.

Evidences of recent tectonics in the Northern Adriatic sea?

FEDERICA DONDA (*), DARIO CIVILE (*), EDY FORLIN (*), VALENTINA VOLPI (*), MASSIMO ZECCHIN (*), EMILIANO GORDINI (*), BARBARA MERSON (*) & LAURA DE SANTIS (*)

Key words: *Northern Adriatic Sea, gas leakages, multichannel seismic data*

The Northern Adriatic sea lies at the northern boundary of the Adria microplate foreland, shared by three chain systems, i.e. the Southalpine, Dinaric and Apennines. The tectonic evolution of the Adria plate can be divided in two main steps: Mesozoic extension and Cenozic compression. The extensional stage started in the late Permian and reached its maximum development during the mid-late Jurassic and Early Cretaceous rift phase, when the Trento Plateau, the Belluno Basin and the Friulian Carbonate Platform formed (MASSARI *et alii*, 1986; FANTONI *et alii*, 2002; FANTONI & FRANCIOSI, 2010).

The Cenozoic compression took place in the foreland at different times and with variable directions of tectonic deformation, leading to a diachronous evolution of the whole area: 1) the Dinaric chain has been deformed from Late Cretaceous in a dominant E-W direction; 2) the eastern Southalpine was active from Middle Miocene, under a predominant N-S compression; 3) in the Apennine system, where the deformation took place in a NNE-SSW direction, the compression was active from Oligocene. Recent hypotheses on behalf the evolution of these systems suggest that the deformation involves not only the Late Mesozoic to early Neogene successions, but it would propagate in the Plio-Pleistocene sequences also (FANTONI & FRANCIOSI, 2010; GHIELMI *et alii*, 2010). This seems to be confirmed by seismostratigraphic and structural analyses performed on multichannel seismic lines collected by OGS in the framework of the STENAP (Seismostratigraphic and Tectonic Evolution of the Northern Adriatic in the Plio-Quaternary) survey in 2009, where about 820 km of multichannel seismic and Chirp profiles have been collected (Fig. 1).

From the stratigraphical point of view, the Late Mesozoic to Paleocene carbonate sequence, consisting of the Soccher Limestones, Maiolica and Scaglia Formations, is overlain by an Eocene to Miocene sequence mostly composed of marly hemipelagic mudstones (BARBIERI *et alii*, 2007). The late Oligocene and Miocene part of this succession, represented by the Gallare Marls Formation, consists of a southward prograding sedimentary body feeded from the uplifting Alpine chain (MASSARI *et alii*, 1986). A marked erosional unconformity, showing deep incisions some hundreds of meters deep, caps the Miocene succession and is the result of the high-magnitude base-level drop and subaerial exposure occurred during the Messinian salinity crisis (GHIELMI *et alii*, 2010). The unconformity is usually typified by a high-amplitude reflector that truncates the underlying Miocene succession, trough veruy prominent V- to U-shaped incisions, especially in the northern sector of the study area. (Fig. 2). Here, the Pliocene succession is represented by a southward prograding unit composed of slope, shelf and shoreface clastic sediments, passing into basinal sediments to the south. Within the Pleistocene sequence, the NE-ward paleo Po delta progradation is recognizable as gently-dipping clinoforms downlapping on a basal surface. The uppermost part of the succession consists of cyclic shallow-marine to continental deposits controlled by late Quaternary glacio-eustatic changes.

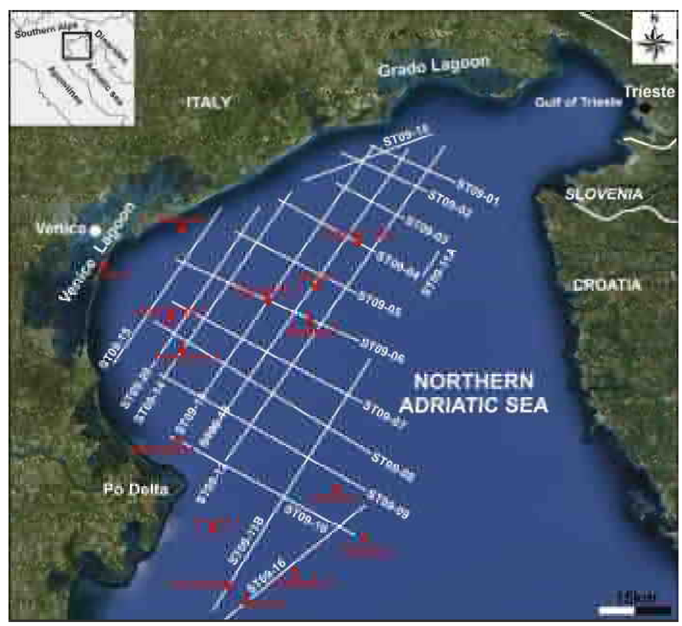

Fig. 1 – Location map of the multichannel seismic profiles and Chirp data collected in the framework of the OGS/STENAP geophysical survey. The position of the boreholes drilled is also shown (from DONDA *et alii*, submitted).

Borgo Grotta Gigante, 42/c – 34010 Sgonico (TS), Italy

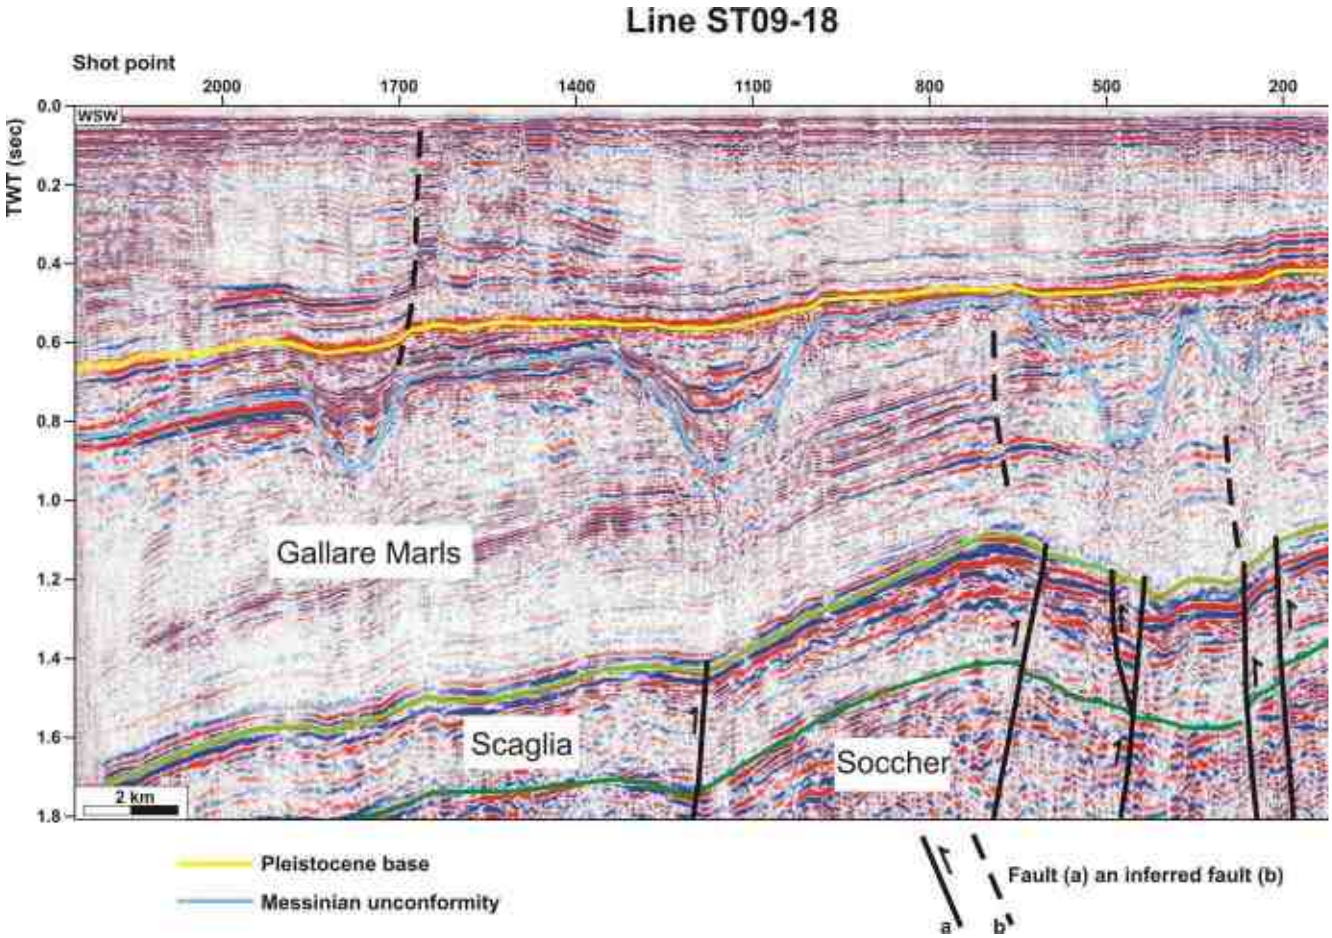

Fig. 2 – Seismic line collected in the northern sector of the study area (from DONDA *et alii*, submitted)

In the Neogene sequence, the reflectors show frequent lateral variations in amplitude, continuity and frequency. Vertical dim and wipe-out zones (LØSETH *et alii*, 2009), commonly associated to both pull-up and push-down reflector configurations have been also identified. They can be 2-3 km wide, but most frequently these features are sub-vertical, narrow pipe-like zones (Fig. 3). On the Chirp data, the uppermost stratigraphic levels reveal an almost transparent facies, that, locally, reaches the seafloor. Commonly, the wipe-out zones affect the whole Plio-Quaternary sequence down to the Messinian unconformity, although in places they can be traced down to the Eocene-Oligocene sequence. All these seismic anomalies could be ascribed to gas leakages. We suggest that the wipe-out zones represent sub-vertical chimneys, possibly developed along faults or fractures zones, which act as preferential paths for fluid migration toward to the surface. Gas seepages have been identified in the study area, where they appear to be locally associated with the formation of methane-derived carbonates, also known as “Trezze” (GORDINI *et alii*, 2012) or “Tegnue” (GIOVANARDI *et alii*, 2003). The origin of gas is still under debate, although the widespread occurrence of the wipe-out zone would led to favor the hypothesis that it migrates from the Neogene sequences.

The correlation of these sub-vertical features among the seismic profiles reveals the occurrence of two main alignments, i.e. a NW-SE trend offshore the Venice Lagoon and a NE-SW trend in the northernmost part of the study area. Offshore the Venice Lagoon, the identified trend would be consistent with the main direction of fault systems recognized onshore by MASSARI *et alii* (1986) and parallel to the “Schio-Vicenza fault system”. It is an inherited Mesozoic-Paleocene extensional feature, which would be reactivated during the Neogene (RICCIATO *et alii*, 2011) and is considered as still active. Instead, the orientation of the wipe-out zones in the northern sector of the study area could be associated to the NE-trending anti-Dinaric lineaments, interpreted as Cretaceous-Paleogene strike-slip fault systems (PLACER *et alii*, 2010; BUSETTI *et alii*, 2010; CARULLI, 2010). Although most of the deformation appears to be sealed by the Late Miocene succession, there are evidences that, in places, the deformation affects also the Plio-Quaternary sequences (DONDA *et alii*, submitted).

Calcarenites in the upper Miocene terrigenous units of Central Apennines: composition, age and paleogeographic significance

SIMONE FABBI (*), FABRIZIO GALLUZZO (**), RITA MARIA PICHEZZI (**) & MASSIMO SANTANTONIO (*)

Key words: *Central Apennines, Miocene, Stratigraphy.*

INTRODUCTION

Resedimented calcarenites and hybrid arenites are commonly found interbedded with various upper Miocene terrigenous units across the Simbruini Mts. and neighbouring areas of Central Apennines. Their distribution provides evidence for a complex paleogeography across a region that was experiencing a carbonate ramp to foredeep transition during the Tortonian and Messinian. Thin-section analysis of >120 samples revealed that the resedimented levels are mainly composed by bioclastic calcarenites. Bio-chronostratigraphic analysis was performed using benthic and planktonic foraminifera, and calcareous nannoplankton.

DATA AND STRATIGRAPHY

Above the carbonate ramp deposits of the Bryozoan limestone, three major units form the upper Miocene terrigenous succession in the study area: "unità argilloso-marnosa " (UAM), "brecce della Renga fm." (BDR) and "complesso torbiditico altomiocenico laziale-abruzzese" (CTLA) (Fig. 1).

The calcareous substrate is overlain by a hemipelagic unit (UAM - "Marne a *Orbulina*" *auctt.*) ~30m thick. The vertical change is abrupt, marked by a phosphatic hard-ground (BRANDANO *et alii*, 2009 and references therein). Biostratigraphic analysis (PAMPALONI *et alii*, 1994; COMPAGNONI *et alii*, 2005) gives an early Tortonian–early Messinian age for the UAM (modified after the ratification of the Serravallian-Tortonian boundary and the consequent revision of the calcareous nannofossil biostratigraphy; RAFFI *et alii*, 2003; 2006). The UAM is constituted by shales and marls, commonly bioturbated, with planktonic foraminifers, echinoderms, fish teeth and ostracods, followed by a shale/marl alternation, with thin levels of siltstones and fine-grained sandstones. The age of the calcarenites found in this

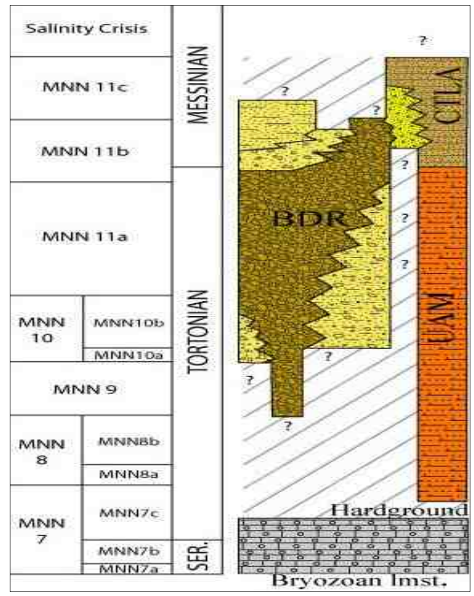

Fig. 1 – Cronostratigraphic sketch of the upper Miocene terrigenous units outcropping in the study area, with Calcareous nannoplankton biozones.

unit is early Tortonian (GALLUZZO & SANTANTONIO, 1995).

Near Tagliacozzo and Pescorocchiano (Fig. 2) several calcarenite beds are observed within the UAM, often amalgamated, with "water escape" and "cut and fill" structures. Clay-chips are common at the base of beds, which are granule- to gravel size. Calcarenite beds show normal grading, with common fragments of echinoids, bryozoans, bivalves, balanids, *Ditrupa* sp., red algae, benthic foraminifera (*Heterostegina* sp., *Planorbulina, Elphidium* sp., *Anomalinidae, Textularidae, Nodosariidae*) and are often made of dominant planktonic foraminifera (*Globorotalia* sp., *Globigerinoides* sp.) in their upper subdivisions.

Calcarenite intercalations within the UAM have been also found in several other localities across the study area (Fig. 2), bearing fragments of echinoids, benthic foraminifera (*Nodosariidae, Bolivinitidae, Textulariidae*, *Planulina* sp., *Heterolepa* sp.) and small planktonic foraminifera (*Orbulina universa*, *Globorotalia* gr. *scitula, Gl.* sp. *Globigerinoides* gr. *Trilobus*).

The BDR (DEVOTO, 1967) cover >100 km², along the NE side of the Simbruini range. This unit, represented by a rudite-arenite-pelite facies association, rests unconformably on the

(*) Università degli Studi di Roma "La Sapienza" - Dipartimento di Scienze della Terra

(**) ISPRA-Servizio Geologico d'Italia

Meso-Cenozoic carbonate substrate, documenting the dismantling of a faulted carbonate platform. COMPAGNONI *et alii* (1990; 1992; 2005) identified three lithofacies and various sublithofacies within the BDR, covering an age ranging from the early Tortonian to the early Messinian. The granule to boulder lithoclasts of the rudites are mainly derived from the local Meso-Cenozoic carbonate succession. The rudite-calcarenite-pelite lithofacies 1 and 2 are early Tortonian to early Messinian in age. The rudites/arenites of Lithofacies 3 are early Messinian and are associated with the siliciclastic turbidites of the RovetoValley. The calcarenites form discrete beds or represent the matrix of the rudites. The resedimented beds associated with lithofacies 1 and 2 are composed by fragments of bivalves, echinoids, balanids, bryozoans, red algae, benthic foraminifera (*Planorbulina, Amphistegina* sp., *Elphidium* sp., *Anomalinidae, Cibicididae, Textularidae)* and planktonics (*Orbulina universa, Globigerinoides* sp., *Globorotalia* sp.) whose relative abundance varies. Lithoclasts of Miocene and Cretaceous limestone (age depending on local substrate) are common, as are clay-chips of planktonic-rich marls. The siliciclastics include quartz and muscovite, while authigenic minerals are dolomite and glauconite. The calcarenites interbedded within lithofacies 3 are composed by fragments of echinoids, balanids, bryozoans, bivalves, coralline algae and benthic foraminifera (*Amphistegina* sp., *Elphidium* sp., *Anomalinidae, Cibicididae, Rotaliidae, Textulariidae*). Miocene and Cretaceous limestone lithoclasts are abundant.

The CTLA is a thick siliciclastic turbiditic foredeep deposit (MILLI & MOSCATELLI, 2000). The sparse occurrence of calcarenite intercalations is remarkable and their spatial distribution is also intriguing. While such calcarenites are completely missing in the Val di Varri sector, calcarenite beds are common near Collalto Sabino, associated with carbonate conglomerates and large olistoliths of Bryozoan limestone. The calcarenites bear common bivalves, bryozoans, echinoids, balanids, red algae and benthic foraminifera (*Amphistegina* sp., *Elphidium* sp., *Anomalinidae, Cibicididae*) and rare planktonic foraminifera.

DISCUSSION

The sedimentology and composition of the calcarenites indicate turbidity flow as the dominant transport mechanism, and sourcing from sites of heterozoan carbonate production locally lying at photic depths. Positioning these carbonate factories is partly speculative, as Neogene thrusting and Quaternary erosion have deeply modified the original depositional system. The resedimented material could therefore represent the sole present-day evidence for an original existence of ephemeral sedimentary environments, which are no longer preserved in outcrop.

The local abundance of *Heterostegina sp.* both at Tagliacozzo and Pescorocchiano is remarkable, as this taxon is not found *in situ* in the Bryozoan limestone of the study area, nor in the other studied intercalations; their source area probably lay east, on the undeformed foreland. In contrast, evidence from field mapping, their common association with Cretaceous and Miocene carbonate lithoclasts, and the age of the encasing units, all suggest that the calcarenites in the BDR and in the "complesso torbiditico altomiocenico laziale-abruzzese" could have a different source;

The BDR were sedimented on a faulted substrate. The presence of a carbonate ridge, bordered by normal faults exposing the Cretaceous substrate corresponding today to a sector of the Simbruini range, is proven by mappable submarine paleoescarpment tracts onlapped by clastics and hemipelagites. This ridge fed surrounding deeper areas with a mixture of loose bioclastic material and lithoclasts, produced through erosion of exposed bedrock. The close association of calcarenites with the rudites in this formation suggests in fact that the dismantling of escarpments was accompanied by active carbonate production. Since this production most likely occurred on and around the tops of morpho-structural highs, the breccias and the calcarenites conceivably shared the same source area. Resedimented deposits are missing in the upper Tortonian-lower Messinian "UAM" of the Carseolani Mts. The calcarenites found west or south-west of this resediment-free zone, could not therefore have been sourced by the foreland existing to the east, as this would imply that flows were bypassing the Carseolani area leaving no trace. Provenance from the Simbruini sector is consequently much more likely. On the other hand, the distribution of the calcarenites interbedded in the CTLA (more frequent near Collalto Sabino and Carsoli, and rare or absent in the Roveto Valley and Val di Varri) suggests that their primary source was the Sabina domain.

Late Miocene extension in the Central Apennines: field evidence from the Simbruini Mts.

SIMONE FABBI (*)

Key words: *Miocene, Central Apennines, extension.*

INTRODUCTION

Evidence of pre-orogenic Tertiary deformation across the Simbruini Mts. (Latium-Abruzzi domain, Central Italy) is much more common than previously believed. Several authors identified pre-orogenic tectonic phases both at regional and local scale. In particular, they inferred active extension during the Cretaceous, Paleogene and/or the early Miocene (DAMIANI, 1992; CIPOLLARI & COSENTINO, 1995; CENTAMORE & ROSSI, 2009). New field data suggest that in this area the Messinian compressive phase was predated by a pervasive middle-late Miocene extensional phase, as inferred by COMPAGNONI *et alii* (1992) and by BIGI *et alii* (2003) in a neighbouring area.

GEOLOGICAL SETTING

In the northeastern Simbruini Mts., the "Brecce della Renga fm." (BDR) (DEVOTO, 1967), a dominantly ruditic unit, crops out, resting unconformably on the Meso-Cenozoic platform succession, and is partly lateral to the late Miocene Latium-Abruzzi siliciclastic turbidites (fig. 1). This unit has an early Tortonian-early Messinian age, based on calcareous nannoplankton biostratigraphy. The breccias play a key role for identifying ancient faults, for several reasons: 1. Faults in the substrate producing up to ~ 0.5 km displacement in the substrate are sealed by unfaulted breccias; 2. Surfaces truncating bedding of the substrate with a high cut-off angle, are covered unconformably by upper Tortonian breccias and associated pelites; these surfaces can be interpreted as normal fault paleoescarpments; 3. Geological mapping provides clear evidence that the three-dimensional development of the BDR was ruled over by synsedimentary faulting. This paper gives an overview and brief description of the key outcrops documenting the syntectonic significance of the BDR (see map in figure 2 for outcrop locations).

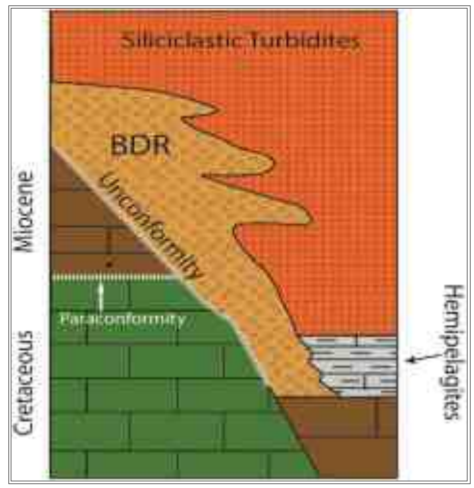

Fig. 1 – Stratigraphic sketch (not in scale)

Paleoescarpment outcrops

By analogy with their Jurassic counterparts in the Umbria-Marche and Sabina domains (GALLUZZO & SANTANTONIO, 2002; CARMINATI & SANTANTONIO, 2005), paleoescarpments are separated here from genuine faults, in that they are seen in the field as sites of unconformable stratigraphic contacts rather than as actual shear zones. That said, paleoescarpments have their roots as paleofaults. Between Mt. Fontecellese and Villaromana, the base of BDR is an angular unconformity along a steep SW-dipping surface truncating the Miocene substrate. The paleosurface is thoroughly mineralized, with abundant phosphatic, and rare siliceous nodules; the phosphatization is taken as an evidence for submarine exposure during the Miocene (BRANDANO *et alii*, 2009). The epi-escarpment deposits, represented by ponded BDR and scattered outcrops of hemipelagites, apparently occupy ancient rockfall detachment surfaces. Near Fonte Lubro a small SW-dipping surface cutting the Miocene carbonate substrate is encrusted by phosphates; yellow Messinian pelites lay unconformably on this paleoescarpment. Along the NE side of Macchialunga, an articulated surface marks the boundary between BDR and their Cretaceous substrate. A Quaternary SW-dipping fault seems to reutilize the paleofault weakness zone. The described unconformity crops out both at the hangingwall and at the footwall of the Quaternary fault. This surface is not mineralized. Along the SW slopes of Mt. Midia

(Piccionara) the BDR overlie a paleosurface truncating Cretaceous beds, with geometries typical of normal fault paleoescarpments. A similar situation is observed south of Monna Rosa.

Miocene normal faults

Four tectonic lineages have been identified indicating pre-thrusting Miocene extension. The *Marsia-Fao Rotondo fault* cuts the Cretaceous succession with a WNW-ESE strike and is sealed by undisplaced BDR. The *Mt. Midia fault* is a WNW-ESE trending tectonic element that cuts the Cretaceous-to-middle Miocene succession with a displacement of some tens of meters, sealed by unfaulted BDR. The *Acquaramata fault zone* interpretation is controversial: the amount of displacement in the substrate increases from south to north, and near Acquaramata the fault seems to cut the upper Cretaceous limestones and the BDR. Southwards the breccias are apparently undisplaced. The fourth element falls within a complex zone at Colle La Fossa, where the Cretaceous substrate shows a displacement of some hundred meters, in contrast with the sealing breccias that seem laterally continuous. The fault zone is generally buried by BDR, but the substrate has locally been exhumed by modern erosion, revealing the trend of at least two tectonic elements. The BDR (lower Tortonian) show a thickening in the hangingwall of this fault zone, suggesting a syntectonic growth.

DISCUSSION AND CONCLUSIONS

Both the Fontecellese and Fonte Lubro paleosurfaces should have a post Serravallian-pre Messinian age, as constrained by the ages of the faulted substrate and the epiescarpment deposits. Most likely their age could be early Tortonian, and the diffuse phosphatization would represent an evidence of the early Tortonian phosphogenic event (10-9,8 My; FÖLLMI et al. 2008). The Piccionara and the Macchialunga escarpments could be their along-strike continuation, but the lack of mineralization suggests either a younger age (after the phosphogenic phase) or that these were deeper paleoescarment tracts that were rapidly buried by the breccias, before any phosphatization could take place. The *Marsia-Fao Rotondo fault* is difficult to date precisely, as its activity could be placed in a time window ranging from the late Cretaceous (age of faulted substrate) to the late Tortonian (BDR seal age). The activity of the *Mt. Midia fault* is likely to be Tortonian, because it cuts middle Miocene limestones and is buried by upper Tortonian BDR, and is probably linked with the early Tortonian Piccionara escarpment. *The Acquaramata*

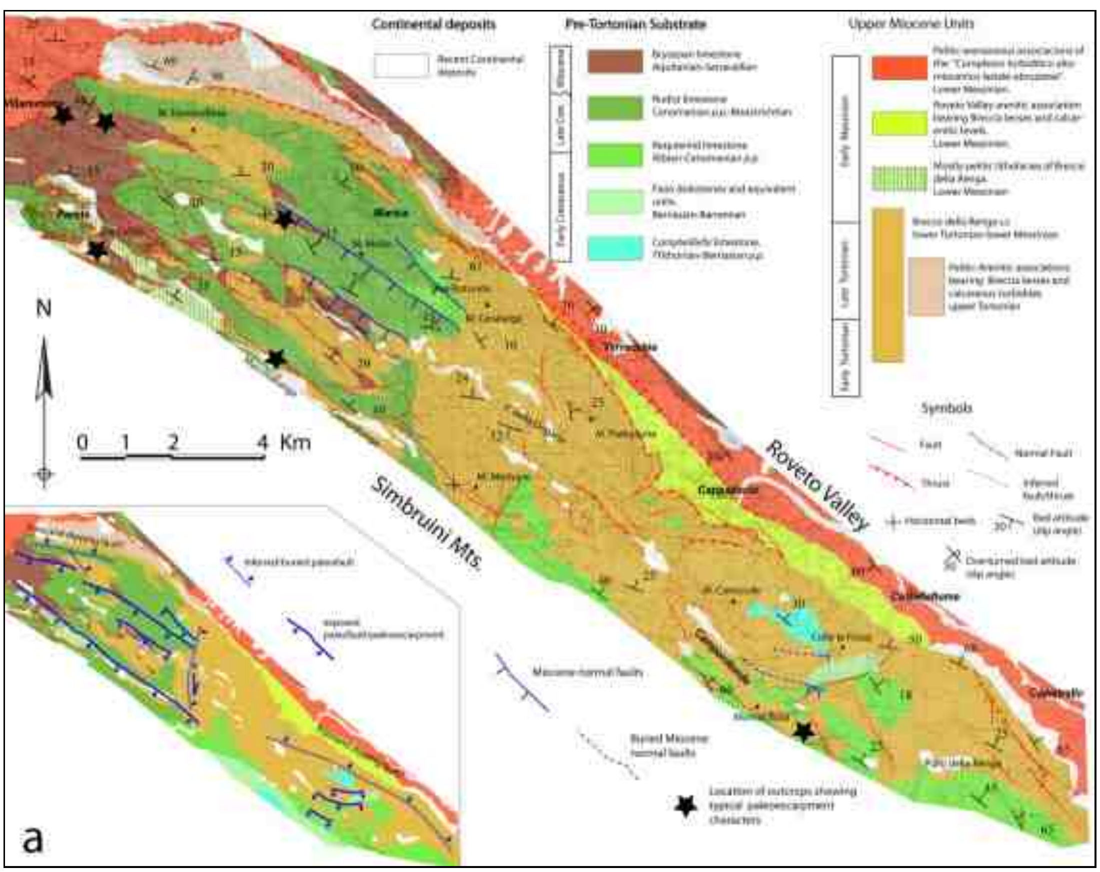

Fig. 2- Geological map of the NE Simbruini Mts. a) Geological sketch: the main identified upper Miocene faults are shown.

fault zone is conceivably a Miocene fault that underwent local reactivation. A Miocene activity of the *Colle la Fossa fault zone* is testified by thickening of the BDR at the hangingwall, with abundant Miocene clasts, despite the present-day lack of Miocene outcrops. This fact testifies a deep erosion of the substrate during the late Miocene.

Based on the above data, it is possible to envisage a complex post-Serravallian paleogeography as a result of synsedimentary extension (see sketch map in fig. 2a). The northern sector is characterized by two major SW-dipping early Tortonian extensional faults. One tract connects Villaromana with the Mt. Fontecellese and Piccionara escarpments, separating a footwall almost free of resedimented deposits, from an hangingwall where breccias outcrop extensively. The Fonte Lubro-Macchialunga fault cuts the hangingwall of the former master fault (similarly to the Acquaramata fault). Its hangingwall hosts an elongated pelite-dominated basin.

The central sector, southeast of the N-S trending Fao Rotondo-Morbano alignment, is the major depocenter of the BDR, that cover almost continuously an area of several square kilometers. The mentioned N-S alignment could represent the expression of a buried transfer fault escarpment.

In the southern sector the oldest substrate crops out, faulted by at least three extensional SW dipping normal faults, buried by unfaulted BDR. Two faults cut the early Cretaceous substrate near Colle la Fossa. Their outcrop expression is not obvious, but biostratigraphic analysis reveals that the total displacement exceeds 500 m. The third element crops out at Monna Rosa, and is the most internal evidence of Miocene extension in the study area. The early Tortonian structural high was located roughly in today's Colle la Fossa position, cut by SW dipping faults that are partly rotated by subsequent compression.

The present-day dip angle of paleoescarpments and paleofaults (< 20° to ~ 60°) is obviously the result of the interaction between Miocene extension and subsequent compression-related tilting.

The above data suggest a Tortonian phase of extension predating the Messinian thrusting. In the study area it is possible to find evidence for a number of synsedimentary faults that ruled over the sedimentation of the BDR. Some of these faults were reactivated by Quaternary tectonics, also with strike-slip kinematics, besides being rotated by Messinian compression. It is possible to identify two structural high sectors separated by a large embayment that represents the depocenter of the BDR and which likely was bounded by a transfer fault. This tectonic activity marked the initial flexure of the foreland under the advancing chain. In this model, foreland- dipping paleofaults should also exist, being possibly buried by BDR or overthrust by foreland verging structures.

Stratigraphic and Tectonic evolution of Crati basin: extension along strike of northern part of Calabrian Arc

FAMIANI F. (*), PIERANTONI P. (*), MACCHIAVELLI C. (*), BALDANZA A. (**) & TURCO E. (*)

Key words: *Tectonic, Stratigraphy, Extension, Crati, Calabrian Arc*

The study area is located in the northern portion of the Calabrian Arc, a fault-bounded terrain sited between Southern Apennine and Sicily (a "wedge" of Europe into Adria promontory). The migration of the Calabrian Arc was contemporaneous to the spreading of the Tyrrhenian back-arc basin, which started between Langhian and Tortonian times (MATTEI et al., 2002). This process generated by a passive subduction of the Ionian lithosphere along a steeply inclined Benioff Plane (MALINVERNO & RYAN, 1986) led to a segmentation of the arc, with consequent differential movements of blocks along strike-slip faults (DEWEY et al., 1989; KNOTT & TURCO, 1991; VAN DIJK & SCHEEPERS, 1995). In current literature there are two models that attempt to explain the origin of the CB.

The former consist in NW–SE oriented left-lateral strike-slip faults exerted a major control on the tectonic evolution of northern-central Calabria, from Middle Miocene to Lower Pleistocene times. Such faults, arranged in an en-échelon geometry and dissecting the pre-existing Late Oligocene–Early Miocene orogenic belt. The latter predicts that the basin Crati is related to the extension of the Tyrrhenian Sea, with a NS-oriented normal faults that are present along the coastal range on western side of Crati valley.

Stratigraphic and structural data are a supplement to a new interpretative model of CB which is being built using Field data and seismic reflection profiles of various resolutions (V.I.D.E.P.I. database), calibrated by deep well logs, have been used to unpick the tectonic evolution of CB. Regional lineaments are recognized through a GIS analysis using a DTM 30m, geological maps 1:25000 of Calabria Region and orthophotos. Three regional alignments are enhanced by morphstructures located in Crati area and the main of this is oriented N-S. These regional lineaments are known in their outcrop features but the timing of activity and their kinematics are still debated.

The CB is filled by Upper Miocene to Holocene clastic marine and fluvial deposits. Although the main depocentre is located in the northernmost sector of the basin (Sibari Plain), the thickness of the deposits increases from the Coastal Range (COLELLA, 1988). Basin fill consists of two main depositional sequencesbounded by a regional angular unconformity. The first sequence, Late Miocene to Early Pliocene in age (bounded by discontinuities and depositional hiatuses) is characterized in the structural highs by a Messinian unconformity, while the second one, spanning from the Middle-Late Pliocene to the Pleistocene.

In this work we present the stratigraphic and sedimentological data collected in a field trip carried out for analyze new sections in Crati Basin (CB). Stratigraphic analyses allow to say that sections studied in Firmo – Terranova da Sibari and Cassano allo Ionio area provide new biostratigraphic data for the study area due to the presence of markers of the early Pleistocene (Calabrian).

The sections analyzed can be attributed to a depositional environment of Fan-Delta (distal facies), in particular morphology characterized by a slightly steeper slope and an organization similar to the model-shelf type of ETHRIDGE & WESCOTT (1984) and modified by MASSARI & COLELLA (1988) and COLELLA (1988).

Our stratigraphic and structural data can be related to a N-S extensional tectonic framework wich involved during the Pliocene time Crati Basin, Sibari Plain, Corigliano basin, Paola basin and probably the whole of Northern Calabria.

Tectono-sedimentary evolution of Miocene – Pliocene wedge-top basins in the North-Western Sicilian Maghrebides (Italy)

C. GUGLIOTTA (°), G. AVELLONE (*), M. GASPARO MORTICELLI (*), M. AGATE (*) & M. R. BARCHI (°)

Key words: *Middle-late Miocene, Early Pliocene, Sicily, Transpression, Wedge-top basin*

INTRODUCTION

The Sicilian fold-and-thrust belt (**SFTB**) represents an interesting case study since its multi-phase deformation was accompanied by large (up to 120°) clockwise rotations accommodated by the tectonic units during their emplacement. The tectonic stack in the North-Western SFTB resulted for the underthrusting of the external carbonate platform units below inner deep-water units; deformation resulted from two main tectonic events developed at different structural levels and ages: (1) early-middle Miocene *shallow-seated* **Event I** and (2) late Miocene – Early Pliocene *deep-seated* **Event II** (AVELLONE *et alii*, 2010). The deep-seated event was accompanied by extensive back-thrusting into the lowermost structural levels and by development of deep-seated transpressional structures. The non-coaxial superposition of tectonics events can be recognized in the field through the analysis of both *structural* and *depositional* interferences (GUGLIOTTA & GASPARO MORTICELLI, 2012). Particularly, these latter are quite diffuse in syn-tectonic successions deposited filling wedge-top basins which developed between the middle Miocene to Early Pliocene. Remnants of such basins are preserved in North-Western Sicily, in correspondence of wide to quite narrow structural depressions, which are, from the easternmost (Fig. 1): (i) the Early Pliocene Lascari Basin (**LB**, northern Sicily); (ii) the late Serravallian - late Tortonian Scillato Basin (**SB**); (iii) the late Serravallian – Early Pliocene Ciminna-Bosco Basin (**CBB)** and (iv) the late Serravallian – early Messinian Camporeale Basin (**CMB**). The upper Serravallian – Lower Pliocene syntectonic deposits outcropping in the study basins are represented by: upper Serravallian-lower Tortonian hemipelagites and sandstones (Castellana Sicula Fm., SIC); upper Tortonian-lower Messinian continental to transitional conglomerates, sandstones and clays (Terravecchia Fm., TRV); Messinian shallow-marine carbonates and evaporites (MEV) and lower Pliocene marine limestones and marls (Trubi Fm., TRB). The above listed successions outcrop overlaying a deformed substrate made up of Sicilide and/or Numidian flysch units. The detailed study of sedimentology, facies tracts, deformative pattern of the Mio-Pliocene deposits, as well as, the relationships in respect to the underlying deformed substrate units allowed us to suggest in this paper a possible model of the tectonic and depositional evolution of the fold-and-thrust belt and the associated foreland basin system, also in regards of non coaxially superimposed wedge-top basins.

IMPLICATION FOR THE TECTONO-SEDIMENTARY EVOLUTION AND TIMING OF TECTONIC EVENTS

After the deformation of the Oligo-Miocene foreland basin with the tectonic emplacement of the Sicilide units (post middle Langhian) above the Numidian flysch, this latter, together with its carbonate substrate (Imerese deep-water units) begun to be deformed and progressively detached from their substrate, forming a thrust-sheets wedge (Fig. 2). Since that time a new foreland basin system begun to develop. Between the Serravallian and early Tortonian, deposition in this new basin occurred in a overall submerged setting; it was recorded by sedimentation of two almost time equivalent units, represented in turn by distal hemipelagites (San Cipirrello Marls Fm., CIP) passing mountainward into coarser slope to shelf deposits (SIC). The CIP was accommodated away from the thrust belt front (foredeep depozone), spanning in continuity of sedimentation the whole Serravallian and the early Tortonian. Otherwise, the SIC was unconformably deposited above the orogenic wedge, filling wide and laterally connected wedge-top basins, lacking part of the Serravallian. The angular unconformity which marks the base of the SIC retains about 1.3My (at least the early Serravallian) recording the growth of the thrust wedge. Thus, the early Serravallian approximates the earliest stage of compressional Event I. Since the late Tortonian a new phase of advancement of the thrust belt occurred. The advancing tectonic wedge, consisting of: embricated thin deep-water units (Sicilide and Imerese units), deformed foredeep deposits (Numidian Flysch units) and the overlaying wedge-top deposits (SIC), overridden the thicker carbonate platform units above the CIP deposits thus, reasonably, since the late Tortonian. This relative age approximates the later stage of the compressional Event I in the study region. Deposition in the new foreland basin system occurred in open marine (foredeep depozone, present day South and South-West), transitional to continental settings (wedge-top

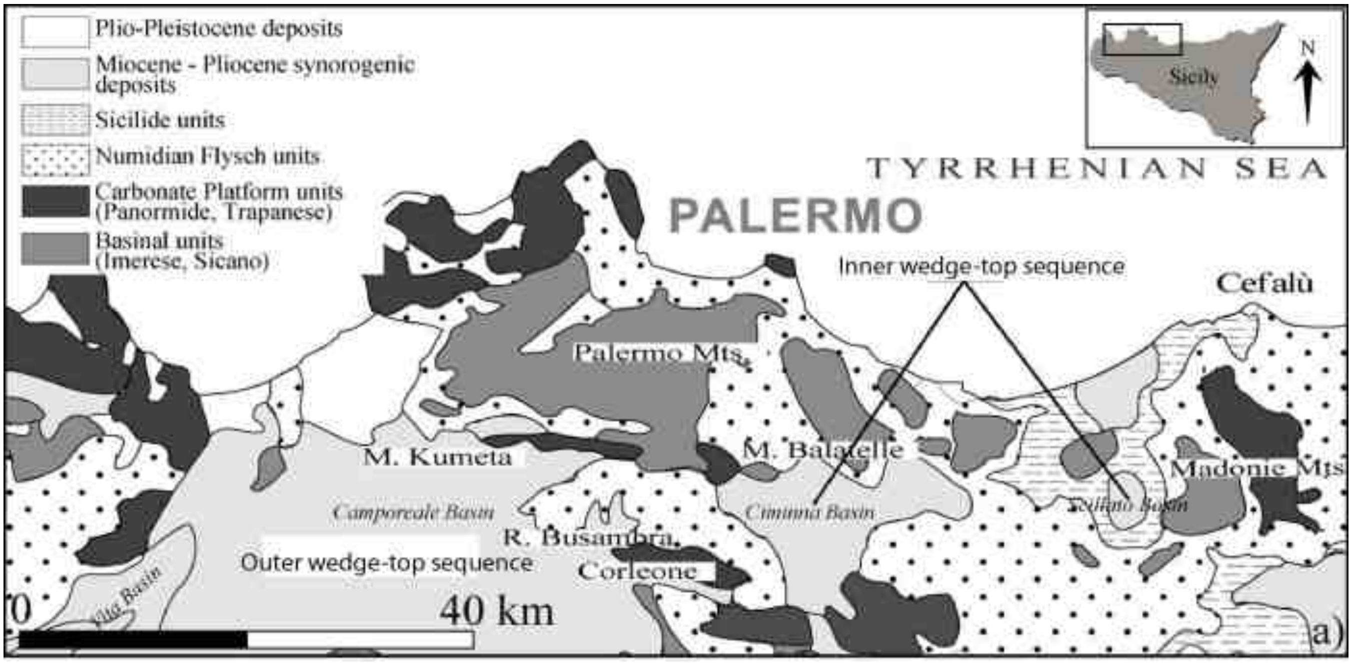

Fig. 1 – Geological sketch of NW Sicily with location of the studied basins.

depozone, study area). The angular unconformity observed at the base of the TRV is at least late Tortonian in age and marks the first episode of subaerial exposure of some portion of the thrust belt. This phase of emersion was probably forced by interaction of tectonic uplift and eustatic fall. A comparison among the different TRV successions outcropping in the study area allowed us to differentiate an inner and an outer wedge-top depozone during the late Tortonian-early Messinian (GUGLIOTTA, 2012). The inner wedge-top depozone (present day East, Scillato and Ciminna-Bosco basins) was characterized by quite narrow, continental to shallow-marine basins, enclosed among localized structural highs, probably sheltered from the main marine areas. The evolution of these syn-tectonic basins was strongly controlled by deep-seated tranpressional faulting at least since the latest Tortonian. Contemporaneously, the outer wedge-top depozone (present day West, Camporeale Basin) was characterized by relatively wide and mainly marine basins, probably connected (toward the south and south-west) to major marine areas. It could be suggested that during the latest Tortonian the tectonic evolution of the wedge-top depozone was influenced by both compressional structures of the Event I and the deep-seated transpressional structures of the Event II (already active in the inner wedge-top depozone). This data allowed us to approximate the transition between these two tectonic events in this portion of Sicily around the late(st) Tortonian. The transition could have occurred during the time span (more then 4My) recorded by the TRV deposition (Fig. 2). Moving longitudinally (from the present day East to West) across the thrust belt, both the stratigraphic and deformative differences in the SIC and TRV deposits account for the reconstruction of a regional palaeoslope dipping towards the present day SW. This palaeoslope connected the inner wedge-top depozone with the outer wedge-top depozone between the late Serravallian to earliest Messinian. A such dipping palaeoslope is coherent with the mean tectonic transport calculated for the tectonic units emplaced during the Event I in this sectors of Sicily (SW-ward-verging thrusts and NW-SE-trending folds, AVELLONE *et alii*, 2010). Moreover, it substantially differs from the present-day regional slope (S- and SE-dipping) and appears present day preserved along a roughly E-W belt due both to the syn-kinematics clockwise rotation of the thrust-sheets and the occurrence of post-Tortonian major strike-slip faults. Since the Messinian and onward during the Early Pliocene the role of the deep-seated structures seems to increased and double verging transpressional structures affected a large portion of the wedge-top depozone, controlling both the evolution and location of sedimentary basins as recorded by the Messinian evaporites (Ciminna and Bosco basins) and Early Pliocene deposits (Lascari Basin). Another implication for the Sicilian thrust belt evolution is that, since the latest Tortonian, the N-ward verging deep-seated faults (deep-seated back-thrusts) played a progressively more meaningful role both in the evolution and internal architecture of several latest Miocene-early Pliocene syntectonic basins. According both to ALBANESE & SULLI (2011) and AVELLONE *et alii*, (2010), the development of extensive back-thrusting may be explained taking into account the presence of inherited Mesozoic structural highs, affecting the carbonate platform units, that acted as structural buttress for the advancement of the deformation towards the late Miocene – early Pliocene foreland region.

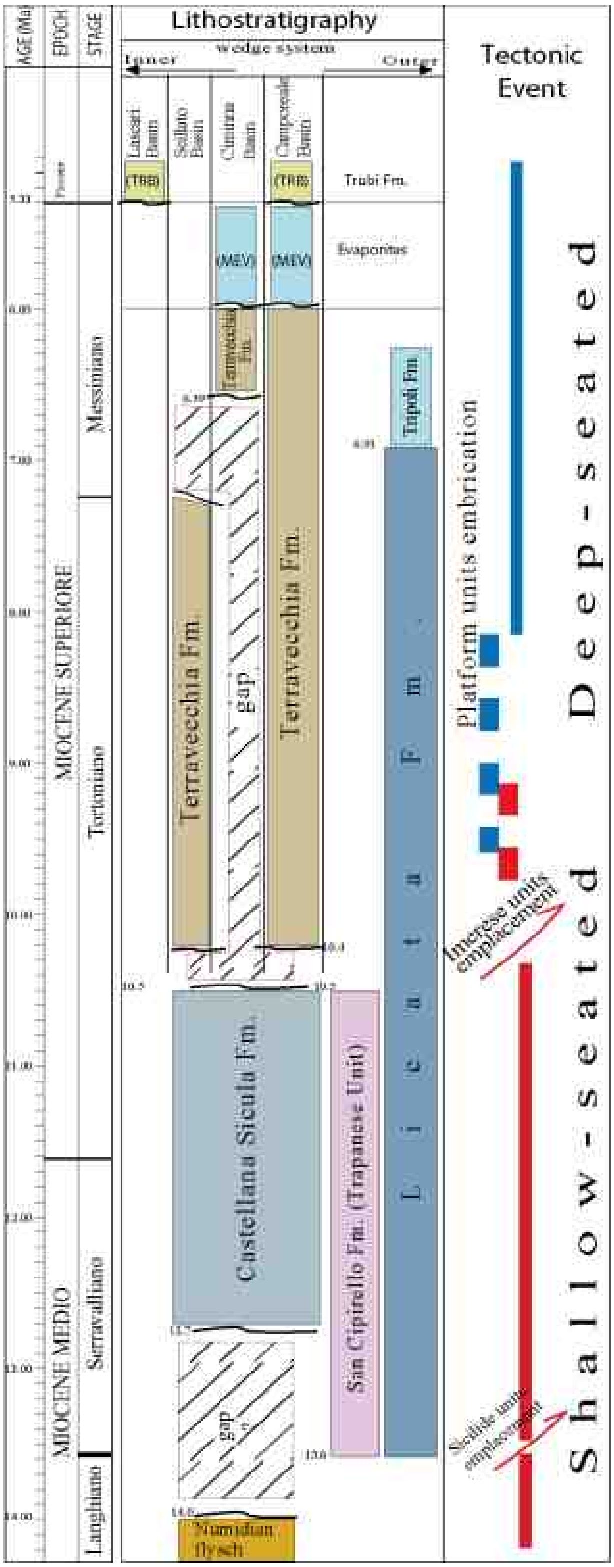

Fig. 2– Timing of tectono-sedimentary evolution.

CONCLUSION

In North-Western Sicily the transition between shallow and deep seated tectonics is recognizable throughout both superposed interfering tectonic structures and stratigraphic analysis of wedge-top basins successions.

The main conclusions of this study are concerning both some aspects of the tectonic evolution of the thrust belt and associate wedge-top depozone, as well as, an accurate timing of the tectonic events.

- Tectonic evolution and timing of different tectonic events: since late Serravallian to late Tortonian times both location, shape and sedimentary evolution of syn-tectonic basins were controlled by shallow-seated structures developed during compressional Event I. The transition to the deep-seated tectonic Event II occurred at least since the late(st) Tortonian time. Since that time and onward during the Messinian and the Early Pliocene the syn-tectonic successions were accommodated filling progressively narrower, localized and laterally discontinuous depocentres, controlled by transpressional, often double verging structures. These structures increased their importance in time affecting a considerable part the whole of the Messinian – Early Pliocene wedge-top depozone.

- Rotation of the orogenic wedge and superimp osed wedge-top basins: remnants of late Serravallian – earliest Messinian wedge-top basins are preserved in the study area suggesting a SW-dipping orogenic wedge palaeoslope. Unlike to what happens in other fold and thrust belts, the reconstructed palaeoslope is not coherent with the present-day regional slope (S- to SE-dipping) and suffered of a clockwise rotation. This peculiar difference is probably due both to the intervening large scale clockwise syn-kinematics rotation of the thrust-sheets and the lateral displacement produced by major transcurrent faults.

Tectonic evolution of southern Matese Mounts (Southern Apennine)

BRUNO MASSA (*), ROBERTO GRAZIANO (°) & MASSIMO D'ONOFRIO (*)

Key words: *facies analysis, remote sensing, stratigraphy, tectonics.*

INTRODUCTION

A tectono-stratigraphic analysis was carried out on a southern Apennine sector (Matese-Monaco di Gioia Mts. area) with the aim of reconstructing the orogenic and post-orogenic history of the south-eastern sector of the Matese Mts. Massiff.

In the study area Mesozoic carbonate successions, widely cropping out and belong to Apennine platform tectonic units, thrusted over "Lagonegro-Molise-Sannio" Basin units an then on the Inner apulia platform buried units.

METHODS

A detailed stratigraphical and structural survey at 1:5000 scale, supported by remote-sensed data analysis at 1:25000 scale, allowed to recognise that the general structural setting of the area is strongly imprinted by the east-verging Neogene thrusting, responsible for the superposition of the mesozoic carbonate units over the late Miocene terrigenous ones. This major motif is overprinted by NW-SE and E-W strike-slip fault systems, probably coeval to thrusting, and SW- and SE-dipping normal fault systems active in Early-Middle Pleistocene times.

DISCUSSION

The analysis of strike-slip and dip-slip fault systems involving the Jurassic-Cretaceous carbonatic succession highlighted that the main strike-slip faults are frequently associated to secondary transpressive and transtensile structures, that locally determined the development of push-up ridges in Monaco di Gioia Mt. area. Aerial-photo interpretation allowed to recognise that the geomorphological landscape is strongly imprinted by Pleistocene dip-slip faults.

Sedimentological and litho-biostratigraphical analyses, on the field and by microscope, were also performed and enable the evaluation of the separation magnitude of several faults.

This stratigraphical and structural study is devoted to contributing to improve the knowledge of the late Cenozoic geological evolution of Matese Mts.

Tectono-stratigraphic relations along a transect between the Neogene Ionian foreland and Tyrrhenian backarc basins (Northern Calabria)

FRANCESCO MUTO (*), SALVATORE CRITELLI (*) & VINCENZO TRIPODI (*)

Key words: *Calabrian Arc, foreland basins, orogenic belt, strike-slip faults.*

INTRODUCTION

The Neogene to Quaternary history of the orogenic edifice is mainly controlled by the activity of NW-SE trending sinistral shear zones (CATALANO *et alii*, 1993; Van DIJK *et alii* 2000), driving the differential south-eastwards migration of the Calabrian Arc.
The subduction plane, have migrated eastward/southeastward causing the roll-back of the subduction plane (e.g. MALINVERNO & RYAN, 1986).
The modern physiography and geology of Calabria are the results of post-30Ma geodynamic processes in which synchronous accretionary processes were active along the eastern flank (Ionian Sea), and rifting processes along the western flank (Eastern Tyrrhenian Margin).

GEOLOGICAL SETTING

The northern Calabrian Arc is made up of a thrust sheet of Palaeozoic basement units, belonging to the former European-Iblean margin, overthrusting, since Oligocene, ophiolite bearing units of the Neo-Tethys domain (OGNIBEN, 1973; AMODIO MORELLI *et alii*, 1976; DEWEY *et alii*, 1989; MESSINA *et alii*, 1994; ROSSETTI *et alii*, 2001). As such tectonic edifice tectonically covered Mesozoic carbonate rocks of the Apenninic Maghrebide chain, since the Middle Miocene (AMODIO MORELLI *et alii*, 1976).

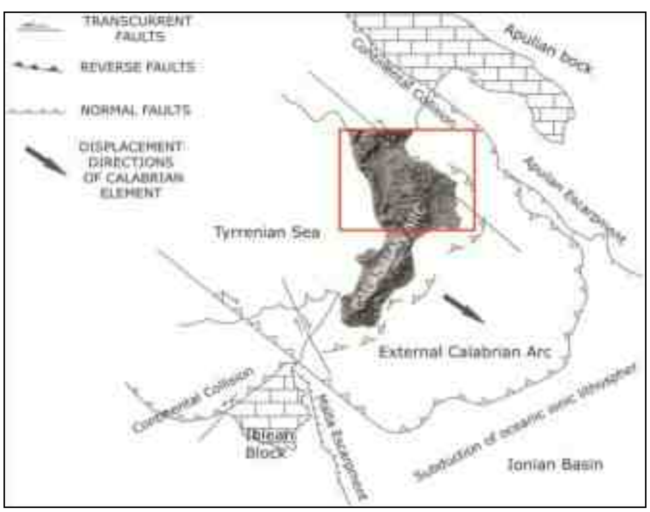

Fig. 1-Structural map of Calabrian Arc; modified from Van Dijk et al, 2000.

The modern basin configuration on the thrust belt includes to the northeast, the wedge-top depozone (Corigliano-Amendolara basins), the marine and subaerial foredeep depozone (Gulf of Taranto and the Bradano river basin, respectively), the forebulge (the Gallipoli Basin) and the back-bulge (southern Adriatic Sea; e.g. CRITELLI, 1999). Several Pliocene-Pleistocene basins cross-cut the southern Apennines and northern Calabria thrust pile, the most important of which are the Mercure Basin and the Crati Basin (e.g. TURCO *et alii*, 1990).
On the back-arc area similar fault-controlled Pliocene-Pleistocene basins (Tortorici *et alii*, 1995), as such as the submarine Paola Basin, represent the syn-rift troughs of the eastern Tyrrhenian margin (e.g., SAVELLI & WEZEL, 1980).

TECTONO SEDIMENTARY EVOLUTION

Since Middle Miocene, overthrusting – combined with the progressive migration of the CA towards southeast – was associated with the opening of the Tyrrhenian basin (Malinverno and Ryan, 1986). The migration occurred along a NW-SE to WNW-ESE-trending regional strike-slip fault system characterized by left- and right-lateral movements in the northern and in the southern sector of the CA, respectively (GHISETTI & VEZZANI, 1981). Since Late Miocene, the ancient reverse contacts responsible for the building of the Calabrian Nappe complex were reactived by extensional tectonics (ROSSETTI *et alii*, 2001).
Middle Pliocene to Middle Pleistocene deposits, represent the basin-fill deposits of the main tectonic depressions (Crati Basin, Catanzaro Trough). In the SW sector, Late Pleistocene fluvial terraced deposits, marine terraces (up to the seventh order, WESTAWAY, 1993), and Late Pleistocene-Holocene alluvial fans crop out.
The northeastern Ionian margin of Calabria is characterized by Neogene-Quaternary basins belonging to the wedge-top. Neogene strata directly cover the Paleozoic plutonic and metamorphic rocks of the Sila Massif and the Jurassic to early

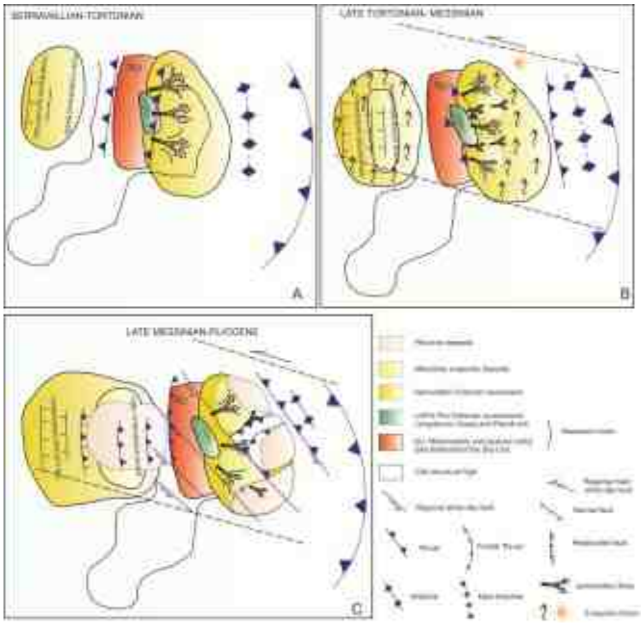

Fig. 2 - Schematic tectonic evolution of the outer front of the Neogene Calabrian belt. The figure shows that thrusts can be associated with NW-SE striking strike-slip regional fault zones(modified from Barone *et alii*2008).

Miocene sedimentary successions. Neogene sedimentary succession crop out along the piedmont of the Sila Massif, filling three distinctive depocenters within the wedge-top depozone of the foreland-basin system. During late Tortonian-early Messinian, these basins experiences huge volumes of Sicilide-derived olistostroma, composed of variegated clay matrix and large blocks (olistholiths) of limestone and sandstones. Those gravity flow deposits are related to out of sequence thrust accomodation or back-thrusting of the Sicilide units.

The Rossano and Crotone basins include a basal transgressive sedimentary fill of Serravallian–Tortonian age that unconformably overlies basement rocks throughout the region. In both basins, these deposits are overlain by an interval of olistostrome bodies of varicolored clays and olistholiths of various limestone types, marl, chert and quartzose sandstone, equivalent to the typical successions of the Sicilide Complex of southern Apennines (e.g., CRITELLI 1999). The Serravallian–Tortonian stratigraphy of the Crotone Basin is similar to that of the Rossano Basin, at least until deposition of Tripoli Formation, after which some stratigraphic differences occur. The sedimentary succession of the Crotone and Rossano basins can be subdivided into two main sedimentary cycles bounded by unconformity surfaces, a first cycle of Serravallian to early Messinian age and a second cycle of early to late Messinian age. The sequences are characterized by progressive pinching unconformity as results of progressive the Sila margin thrusting and flexuring (BARONE *et alii*, 2008).

In the central area (Cirò Basin) a thick siliciclastic succession, known as "Cariati Nappe", overthrusted on the Upper Tortonian-Messinian sequences. The succession was involved in oblique back thrusting related to regional oblique tectonic arrangement. The "Cariati Nappe" includes two thinning and fining upward units, unconformably covering the Oligocene siliciclastic strata of the Paludi Formation (RODA, 1967; ROVERI *et alii*, 1992; CRITELLI *et alii*, 2011). The NW-SE striking shear zone led, during the Neogene, to the configuration of intrabasinal structural highs and wedge-top partitioning (VAN DIJK *et alii*, 2000; BARONE *et alii*, 2008).

In the basins the second sequences overlies the first with an angular unconformity, due to the fall of sea level and synsedimentary activity of normal faults. During the deposition of upper part of second unit in the late Tortonian, the basin was subjected to contractional deformation with the development of fault related folds. The sedimentation and the architecture of the basin were abruptly influenced by this tectonic change. As a result, sedimentary sequences developed numerous unconformities, related with the growth of anticlinal folds. During Tortonian-Messinian the accrectionary prosesses in the foreland domain are accompanied by transtensional depozones, developed in a complex strike-slip setting, in the back-arc domain (CRITELLI, 1999). In the two areas the Pliocene-Pleistocene sedimentary successions record hinterland folds and thrust propagation (Amantea, Paola slope and Crotone Basins). In the western margin of Calabria these structures are related to the transpressional deformation (VAN DIJK *et alii*, 2000; TANSI *et alii*, 2007) or represents the response to the different velocity of the slab retreating. Pulsating tectonic phases are testified in the Neogene-Quaternary successions of eastern and western basins of the northern Calabrian Arc and local inversion tectonics occurred during contractional and extensional stages.

CONCLUSION

In this paper we focus on the discrimination of the different tectonic stiles and basin architectures in the two sectors of the Calabrian Arc. We pointed out a Thyrrenian extensional basin to the west, this basin show also, in the northern sector, compressional structures that inverted the syn-rift extensional faults. The foreland basin to the east show different kinds of basinal successions and different tectonic evolutions. Pulsating tectonic phases are testified in the Neogene-Quaternary successions of eastern and western basins of the northern Calabrian Arc and hinterland thrust propagation occurred during the contractional stages.

Interpretation of a 3D seismic survey of an anticline in the Po Plain subsurface: Seismic Geomorphology analysis and reconstruction of the Plio-Pleistocene syn-tectonic depositional systems

VINCENZO POZZOVIVO (*,°), MAURO GALBIATI (**), MASSIMILIANO R. BARCHI (*),
PATRIZIA ROCCHINI (**) & ENRICO CAIRO (***)

Key words: *Foreland basin, Po Plain, Seismic geomorphology*.

The aim of this work is to reconstruct the evolution of syn-tectonic depositional systems from the late Messinian to present, based on detailed seismic-geomorphologic analysis. The study area is located in the subsurface of the Po Plain, a structurally complex region, comprised between the opposite-verging South-Alpine and Northern Apennines thrust belts. The study is focussed on a 3D seismic dataset acquired a few kilometres N of Cremona, imaging the Pliocene-Quaternary turbiditic succession of the Po Plain foreland basin (Fig. 1).

The integration between seismic geomorphology and seismic stratigraphy provided a significant improvement in understanding the evolution of the depositional environments. The depths investigated in TWT (two-way traveltime) vary from 0 to 2000 milliseconds (ms). Specific software (Petrel TM, Paleoscan TM) has been used, allowing the elaboration and displaying of the 3D seismic volumes. In particular, we made the processing, extraction and mapping of seismic attributes (e.g. horizon slices of Amplitude and Continuity, Fig. 2) on about 300 surfaces within the analyzed sequence.

The seismic-geomorphology analysis performed on these maps has allowed the definition of 5 major sequences, reflecting the main stages of the basin evolution. Considering their relationships with the growth of a major anticline located in the central portion of the seismic volume, these sequences have been characterized as pre-tectonic, syntectonic and post tectonic.

In order to do this, we used a mix of sedimentological, structural and geomorphological criteria.

For example, syntectonic sequences show the following peculiar features:

- the sequences show strong lateral variations in thickness, i.e. they are thinner at the top of the growing anticline;
- some portions of the sequences pinch-out towards the flanks of the anticline, where drag folds are also observed (Fig. 3);
- the channels show sharp deviations in correspondence of the anticline (Fig. 2) and progressively migrate apart from the flanks of the structure (scroll bars in Fig. 3).

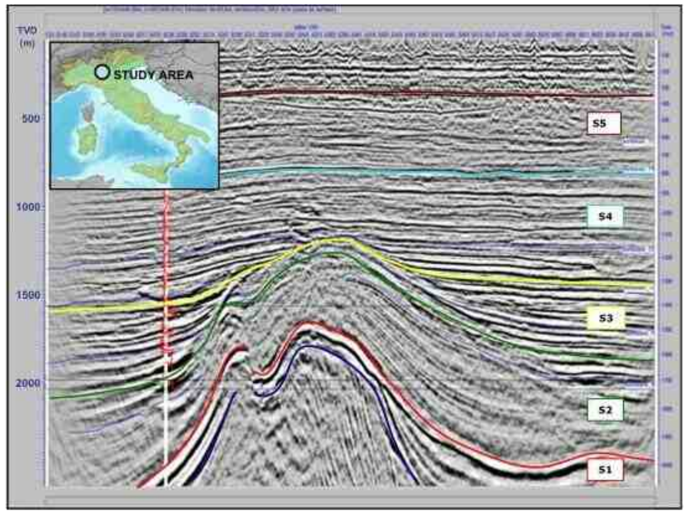

Fig. 1 – A representative vertical section trough the analyzed seismic volume, imaging the 5 major stratigraphic sequences.

The post-tectonic sequences also show thickness variations, possibly related to differential compaction of the previous sediments. Differential compaction may also affect the trajectory of the channels.

In the following, we briefly describe the five detected sequences, from bottom to top.

The first sequence is the pre-tectonic one. Here, the depositional environment is an unconfined basin. The second one is a syntectonic sequence, where the seismic reflectors are actively deformed by the growth of the structural high, influencing the sedimentary/geomorphologic features. The third sequence corresponds to a decrease of the tectonic activity, which slightly influences the sedimentary and geomorphic features. The depositional environment of both the second and the third sequences is a confined basin. The fourth

sequence is post-tectonic. The depositional trends are influenced only by differential compaction on the flanks of the structural high. In this case the deposition environment is an unconfined basin, influenced by the approaching of a prograding complex. The last sequence is made of the prograding complex itself: on the base of depositional features, it can be divided into two minor sequences, distal and proximal respectively.

The studied succession provides a very good example in order to analyze turbidites depositional processes and their seismic image, also favoured by the relatively simple tectonic setting. The results obtained through this work can be taken as a reference in similar depositional environments.

Uplift of the SE margin of the Central Anatolian plateau: Temporal constraints from the Adana Basin, southern Turkey

GIUDITTA RADEFF (* °), DOMENICO COSENTINO (* °°), PAOLA CIPOLLARI (*°°), TAYLOR F. SCHILDGEN (°), MANFRED R. STRECKER (°), GULDEMIN DARBAŞ (***) & KEMAL GÜRBÜZ (****)

Key words: *Southern Turkey, Adana Basin, Messinian Salinity Crisis , Seismic stratigraphy, Plateau uplift*

ABSTRACT

The Adana Basin (Southern Turkey) is located beside the Central Anatolian Plateau southeastern margin, very close to the Arabian-Eurasian collision zone. The sedimentary record of the Adana Basin spans from Late Oligocene to Quaternary (SCHMIDT, 1961; YETIŞ, 1988; ÜNLÜGENÇ ET AL., 1991; 1993; GÜRBÜZ & KELLING, 1993; NAZIK & GÜRBÜZ, 1992; NAZIK, 2004, DARBAŞ & NAZIK, 2010). Due to its position and the age of its stratigraphic record, the Adana Basin is a key area to define the main Neogene geodynamic events that occurred in the easternmost Mediterranean area.

The new stratigraphy of the Adana Basin recently proposed by COSENTINO *et alii* (2010) and CIPOLLARI *et alii* (in press), based on a more accurate facies analysis and new age constraints, allows us to re-interpret some of the seismic profiles acquired in the basin by the Turkish Petroleum Corporation (TPAO). We interpreted 17 seismic profiles, distinguishing different seismic units (MS2, MS3, MS4a, MS4b, and MS5), and identifying some regional erosional surfaces (U1, U2, MES1, and MES2) as recently reported in the literature for the Adana Basin (WILLIAMS *et alii*, 1995; COSENTINO *et alii*, 2010; CIPOLLARI *et alii*, in press) (Fig.1).

In all the interpreted seismic profiles, the oldest erosional surface (U1) separates the Central Tauride basement rocks from the first seismic unit (MS2), constituting the lowermost portion of the Adana Basin filling (Late Oligocene–Serravallian; SCHMIDT, 1961; NAZIK, 2004). A younger erosional surface (U2) divides MS2 and MS3. The latter is a seismic unit corresponding to Tortonian-lower Messinian deposits (Kuzgun Fm). At the NW margin of the basin, the top of MS3 is characterized by a few equally-spaced and high-amplitude reflectors, which, according to COSENTINO *et alii* (2010), correspond to the *Primary Lower*

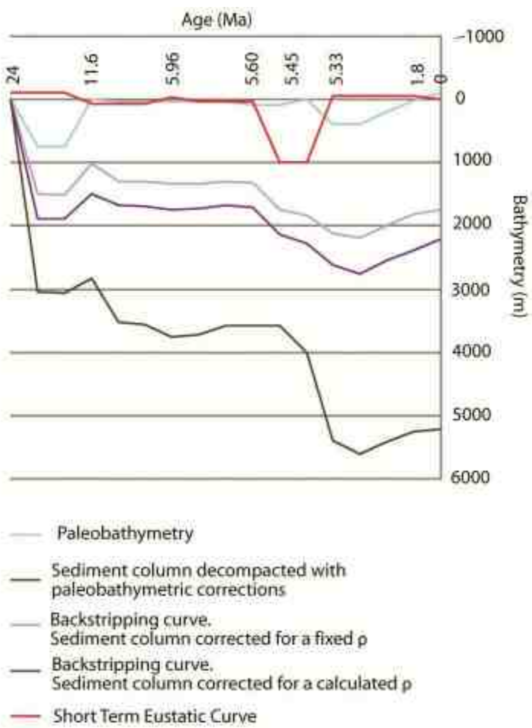

Fig. 2 –Subsidence curve of the Adana Basin. The brown line shows the total subsidence experienced by the basin. The backstripping curves were obtained using the method reported by ALLEN & ALLEN (1984); they show the tectonic subsidence only. The different trends observable in the total subsidence curve are discussed in the text.

Gypsum (5.96-5.60 Ma; CIESM, 2008) of the Messinian salinity crisis (Hsu et al., 1973).

, Within the subsurface Messinian deposits of the Adana Basin, two different erosional surfaces have been distinguished (MES1 and MES2) (Fig. 1). These erosional surfaces were also recognized in the field (COSENTINO *et alii*, 2010). The first intra-Messinian unconformity (MES1) cuts down to MS3. Above the MES1, a peculiar seismic facies characterized by high amplitude and discontinuous reflectors is present (MS4a). This seismic unit that is tentatively correlated (COSENTINO *et alii*, 2010; Cipollari et al., in press) with the *Resedimented Lower Gypsum* of the Messinian salinity crisis (CIESM, 2008), which in the Adana Basin could span from 5.59 to 5.45 Ma. Afterwards, the second intra-Messinian unconformity (MES2) developed, cutting down to the Late Miocene Kuzgun Fm. The seismic facies overlying the MES2 (MS4b unit) is part of the Handere Formation (YALÇIN & GÖRÜR, 1984; YETIŞ, 1988; ÖĞRÜNÇ *et alii*, 1999; GÜRBÜZ, 1999), and is characterized by more continuous reflectors, which correspond to fluvial coarse-grained deposits interbedded with marls (Messinian Lago-Mare event, COSENTINO *et alii*, 2010). At the top of MS4b, a flooding surface (P) developed at 5.33 Ma, and is followed by a seismic facies with continuous and high frequency reflectors, corresponding to the Pliocene clays of the Avadan Formation (CIPOLLARI *et alii*, in press).

To make a time vs depth convertion for the seismic facies, we calculated the Vp velocities for each seismic unit, starting from the interval velocities provided by the seismic lines, and considering the intervals we defined with our new seismic stratigraphy. The values we obtained are consistent with the velocities reported in literature (AKSU *et alii*, 2005). We also cross-checked the correctness of the velocity values on 8 wells kindly provided by TPAO. Using our velocity values, we estimate the MS4b unit to be up to 1.6 km thick. It was deposited in a relatively short amount of time (~120 kyr).

In order to reconstruct the surfaces of the different units, we first digitized the seismic profiles using Petrel®. Next, we used the software MatLab® to estimate the minimum volume of the Handere conglomerates from which we can calculate its sedimentation rates.

The lithofacies analysis of the Handere conglomerates, combined with S- to SE-oriented paleoflow directions, reveals that those deposits are derived mainly from sedimentary, volcanic, magmatic, and crystalline rocks of the Taurides. A clear change from upper Messinian to Recent deposits is evident comparing the clast composition of the Handere conglomerates with those of two other recent fluvial terraces. In particular, we observe an increase in the percentage of carbonates and other sedimentary rocks coupled with a decrease in the volcanic component; these variations probably record a change in the provenance area of the fluvial conglomerates pebbles, which could result from changes to the drainage basin geometry in response to uplift of the Taurides.

The geohistory of the Adana Basin, derived through the reconstruction of its subsidence curve, shows the main events that occurred in the area (Fig. 2). At the Middle Miocene/Late Miocene transition (late Serravallian, 12 Ma), the stratigraphy of the Adana Basin records an erosional surface (U2). This early Tortonian unconformity can be related to the uplift and increased exhumation that affected the Bitlis-Zagros zone as a consequence of the collision between Arabian and Eurasian plates at ca. 12 Ma (OKAY ET AL., 2010). An increase in the subsidence rate is shown at about 5.59 Ma during the deposition of the *Resedimented Lower Gypsum* (MS4a). It corresponds to a period of increased sedimentation rate right after the drawdown of the Mediterranean base level and the formation of the first Messinian erosional surface (MES1). A major increase in subsidence rate is recorded at about 5.45 Ma, above a younger intra-Messinian unconformity (MES2), with the deposition of up to 1.6 km of fluvial deposits (conglomerates and marls of the Handere Fm). The Paratethyan ostracods from the *Loxocorniculina djafarovi* Zone (Cipollari et al., in press) found within the marls of the Handere Fm indicate that they were deposited during the latest Messinian Lago-Mare event (5.45-5.33 Ma; COSENTINO *et alii*, 2010).

Afterwards, the Messinian/Pliocene boundary (P in Fig. 1) corresponds to a strong decrease in sedimentation rate and the onset of a deeper marine depositional environment.

By integrating our provenance analysis on the Handere Fm conglomerates, which support the notion of an evolving source area within the Taurides, together with our new interpretations of seismic data, which reveal a major increase in sedimentation rates at 5.45 Ma, we conclude that the Tortonian-Messinian geohistory of the Adana Basin and the >1.6 km thick fluvial conglomerates of the Handere Fm support the notion of the onset of uplift of the SE margin of the Central Anatolian plateau just before 5.45 Ma.

The evaporitic succession of Monte Castello (Savignano Irpino, Campania). Stratigraphy and facies analysis

MARIA ROSARIA SENATORE (*), MODESTINO BOSCAINO (*), ANNIBALE ROBERTO (*), FELICE PINTO (*)

Key words: E*vaporitic succession, stratigraphy, facies analysis, Evaporiti di Monte Castello, Messinian*

INTRODUCTION

The evaporitic succession in consideration crops out in Monte Castello to the south-west of Savignano Irpino (AV). In this area there are two gypsum quarries (Monte Castello and Ripa dei Corvi) which are not working nowadays. Their digging fronts, reachable at different heights, allowed to perform the stratigraphical reconstruction and a detailed facies analysis.

The examined area is part of the Daunia Mounts, which extend among Molise, Campania and Puglia and represents the outer end of the Southern Apennine Chain, passing eastwards to the bradanic foredeep.

The evaporitic deposits have been known for a long time in literature and they were called "Evaporiti di Monte Castello" (EMC) by Crostella & Vezzani (1964).

According to these authors, this succession, Messinian in age, passes laterally and in the upper part to the formation of Anzano.

Afterwards, Dazzano et alii (1988) suggest a reconstruction of sedimentation environment of the evaporites cropping out on the border between Campania and Puglia, on the basis of their stratigraphical, sedimentological, mineralogical and geochemical characteristics. Recently Matano (2007), on the basis of a review of the works of Crostella & Vezzani (1964) and Dazzaro et alii (1988), suggests an evolutionary pattern of the EMC inserted in the evolution of the south Apennine Chain during the Messinian Age.

The gypsum quarry of Monte Castello was opened in the early 1950s. The blocks of gypsum were carried by cable cars, connected through steel ropes to a telpher line, which carried them up to the rail station of Montaguto – Panni. Here the quarried material was loaded into goods trains and then carried to several factories with kilns, where the manufacturing process took place. In the early 1970s the mining industry went through a phase of rapid growth which causes a quarrying, estimated up to 3.000.000 quintals a year, that determined a fast moving back of the digging front. The quarrying process took place through a series of terraces. On their sides some holes were made and mines were exploded into them.

The material, in blocks, was crumbled in several sizes depending on the market request, and then it was carried to different factories and mixed and cooked with other first matters (limestone, etc). In this way the production of gypsum-based plasters and different kinds of cement was performed.

Fig..1 – Monte Castello quarry (Savignano Irpino) in the early 1960s

METHODS

A geological field survey at 1:10.000 scale of an area of 20 kmq, for the definition of the geometrical relationships with other outcropping successions and of the structural layout, has been carried out together with the stratigraphical and facies analysis on six sections located into the two quarries.

The aim of the work was the reconstruction of the messinian evaporitic succession and the facies evolution in a space-temporal framework during the Southern Apennine Chain structuring.

RESULTS

Structure

The field geological survey allowed to define a system of folds with an axis trending North-North East South-South West and sloping towards North-North East with an angle of 50° on the horizontal plane, displaced by anti-Apennine normal faults. The evaporitic deposits lie in unconformity on Dauna Unit; the

(*) Dipartimento di Scienze per la Biologia, la Geologia e l'Ambiente – Università degli Studi del Sannio, Benevento

evaporitic deposits have been even subject to several deforming events both ductile and fragile.

Stratigraphy

The stratigraphical analysis has been carried out on six sections of which one is located in the Monte Castello quarry (MC) and five in the Ripa dei Corvi quarry (A, B, C, D, Y). On the basis of the litofacies a lower part (A, Y), composed of primary deposits (*algal laminate* limestone, sandy clay, hybrid laminated sand, gravel with siltstone matrix and *euxinic clay*, *algal laminate gypsum)* and a higher part (B, D, C and MC) composed of resedimented evaporitic deposits (coarse *gypsrudites* , middle-fine *gypsrudites, laminated gypsarenites*, *banded gypsarenites, fine-grained laminated gypsum,* clay with *spheroids* and clay with *gypsarenitic fraction)* have been identified

In the Ripa dei Corvi quarry two sub-successions have been reconstructed linked to the succession base. The first (A) starts with *algal laminate* limestone which are founded on a palaeosol, developed on Dauna Unit (Senatore, 1988) already deformed. Some more or less marly, hybrid sandstones follow, sometimes with whitish-coloured *oncolites,* and then *euxinic clay* which pass on the upper part to *algal laminate* gypsum, with a variable percentage of sandy fraction and full of organic matter.

This sub-succession represents the gradual beginning of sedimentation, in areas previously above sea level, with *intertidal* facies (*algal laminate* limestone with desiccating structures) which pass to *subtidal* facies, above all of submerged beaches (hybrid sandstones) with well oxygenated waters, substituted by delta plain clay *euxitic* sandstones in which black-coloured *algal laminate* gypsum with an sandy fraction are found.

The second sub-succession (Y) is composed of dark grey-coloured gravel in lenticular layers which contain vegetable remains (broken branches of forest trees).

Upwards and laterally the gravels pass to dark grey-coloured *euxinic clay*.

This sub-succession represents an alluvial environment passing upwards to an *intertidal* environment.

The upper part of the succession starts with an irregular and sharp surface over the *algal laminate* gypsum. On the sharp surface a layer which is 12 meters thick is founded, composed of *gypsrudites* at its base. Its metric-sized clasts are represented by *algal laminate* gypsum. In the middle part of the layer the clasts are prevalent. They are represented by decimetric sized gypsum crystals, in a *gypsarenitic* matrix. In the upper part of this layer a gradual passage to *gypsarenites* with parallel lamination has been observed. This layer has been interpreted as a debris flow that sensibly erodes the layers below, incorporating some portions of them.

The thickness of this layer, its lateral continuity, the sedimentary structures show a deepening of the sedimentation environment probably connected to tectonic instability.

Following these alternations of layers composed of *gypsarenites,* in which large gypsum crystals oriented in different ways can be observed, clay with *gypsarenitic* fraction, and laminated *gypsarenites* are present. The *gypsrudite* layers are not more than 10 m thick and at their base is always present an erosive surface which cuts and erodes the clay and the laminated *gypsarenites*, up to amalgamate with the other layers below. This part of the succession is interpreted as deposited by turbidty flows, and is referred to a proximal underwater fan (inner fan, Normark, 1965).

On this stratigraphical level, we observe a drastic reduction of the layers thickness and of clasts size from middle-fine *gypsrudites,* with an increasing thicknesses of the *banded gypsarenites*.

This part of the succession crops out with continuity both in the Ripa dei Corvi quarry, where it is about 200 m thick, and in the Monte Castello quarry, where it reaches about 100 m in thickness. It shows a trend of the sedimentation environment that became even deeper, and it is interpreted as distal part of an underwater fan (middle fan, Normark, 1965).

CONCLUSIONS

The stratigraphic analysis of this evaporitic succession allowed to identify a transgressive phase that starts with the precipitation of primary gypsum, followed by, a sudden, fast, relative raising of the sea level, due to tectonic movements of subsidence and raising respectively in the outer and the inner part of the basin

The subsidence allowed to create the accommodation space for evaporitic sediments, composed of resedimented gypsum, deriving from primary evaporitic deposits, eroded from the raising areas subject to erosion.

The transgressive trend, from a transition environment to a deep sea environment, has been observed in the Vena del Gesso succession (Vai & Ricci Lucchi, 1977) and in Sicily (Manzi et alii, 2009). In the latter, a similar paleo-environmental reconstruction is made with a similar phenomenon of “cannibalization” of primary evaporitic deposits, precipitated on the edges of the basin.

Finally the structural relationships allowed to insert the studied succession in a thrust-top (piggyback) basin, laying on the deformed Dauna Unit.

Tectono-stratigraphic evolution of the Siderno Basin, southern Calabrian Arc, Italy

VINCENZO TRIPODI (*), FRANCESCO MUTO (*), SALVATORE CRITELLI (*).

Keywords*: calabrian arc; fault zone; forearc; ionian basin; orogenic belt; strike-slip faults.*

INTRODUCTION

In the Calabrian Arc, NW–SE oriented left lateral strike-slip faults and associated jog-related features (i.e. folds, reverse/normal faults), have controlled the evolution of the mountain belt since Late Miocene times (KNOTT & TURCO, 1991; VAN DIJK *et alii*, 2000, and references therein).

Segmentation in strike- and oblique-slip fault systems has been the subject of detailed research (e.g. Tchalenko,1970; TCHALENKO & AMBRASEYS, 1970; WALLACE, 1973; AYDIN & NUR, 1982, 1985; AYDIN & PAGE, 1984; BILHAM & WILLIAMS, 1985; SYLVESTER, 1988; VAN DIJK *et alii*, 2000).

In the southern Calabrian Arc, oblique slip fault systems, displacement generates important topographic gradients with associated uplift and subsidence forming both uplifted ranges and sedimentary depocentres (Sylvester, 1988).

All these data allow us to propose a detailed tectonic evolution for the Siderno strait from its initial formation during the Serravallian until the present-day, as well as to evaluate the influence of strike-slip fault and reverse fault present .

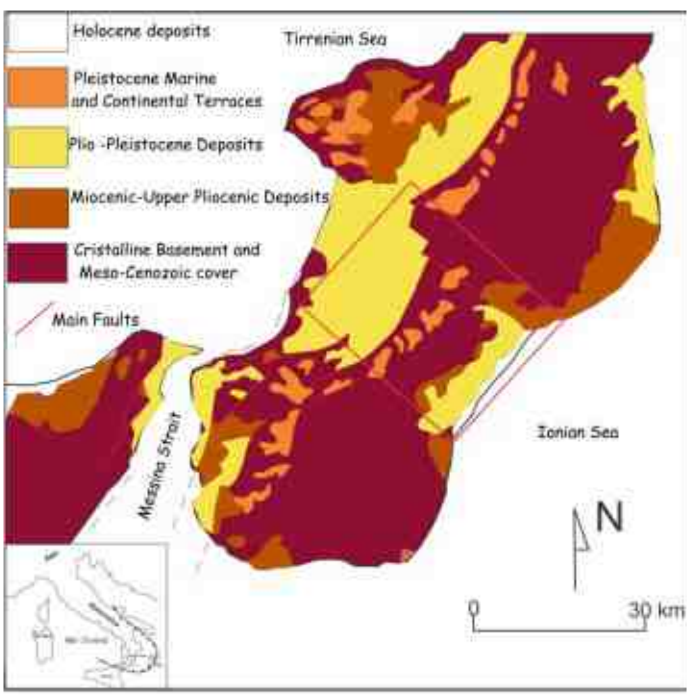

Fig.1-Geological map of Southern Calabria, modified from Monaco *et alii* 96.

GEOLOGICAL SETTING

The study area is located in southern portions of the Calabrian Arc, along a transect including the Ionian face and part of the Tyrrhenian margin(fig.1).

In the Mediterranean area, the convergence between the African and European plates generally expresses itself in the form of subduction and partial obduction of the Tethyan oceanic crust, although in the Ionian Basin and the eastern Mediterranean, residual oceanic crust can still be found (CAVAZZA *et alii* 2004).

The Calabria–Peloritani Orogen (CPO) is a composite fragment of the circum-Mediterranean orogenic system.

This is mostly comprised of poly-orogenic multi-stage metamorphic rocks, merged with several Hercynian (PEZZINO, 1982; ATZORI *et alii*, 1984) or possibly older (FERLA, 2000; MICHELETTI *et alii*, 2007) sub-terranes.

These rocks were locally overprinted during the different stages of the Alpine metamorphic cycle, which also affected part of the Mesozoic oceanic derived units and sedimentary sequences (LIBERI *et alii*, 2006; CIRRINCIONE *et alii*, 2008; FAZIO *et alii*, 2008). These basement rocks were definitively stacked by the Alpine–Apennine thin-skinned thrusting tectonics which occurred in the central Mediterranean area (ORTOLANO *et alii*, 2005). Oligocene-to-Quaternary deposits with a thickness of more than 2000m, directly covering pre-

Fig. 2 - Erosional truncations and thickness variations of the stratigraphic succession

Tertiary rocks, represent the basin infill of the forearc region (CAVAZZA & INGERSOLL, 2005).

TECTONO STRATIGRAPHIC FEATURES

The stratigraphic units distinguish from the bottom to the top are:

The Stilo Unit that includes a Paleozoic basement of low grade metamorphic rocks and a Mesozoic carbonate cover.

The Oligocene-Miocene formations represented by:

The Palizzi formation, the Pignolo formation, the Stilo - Capo d'Orlando Formation (BONARDI et al, 2002. Variegated clays separate the Oligocene-Miocene lower successions from younger ones. Serravallian-Tortonian siliciclastic unit, Tripoli Formation, evaporitic limestone (Calcare di Base Formation) Messinian conglomerates, the Trubi Formation(Zanclean), Monte Narbone formation(Calabrian) and pleistocenic sandstones and conglomerates.

Since the Oligocene, the area has experienced complex multihistory tectonics due to associated NW-SE oriented pull apart basins. The succession has an eastward dipping monoclinal geometry and growing tectonic structures increasing from the top to the bottom.

Erosional truncations and thickness variations are widely present(fig.2). NW-SE and NE-SW fault systems are dominant, the first exhibiting strike slip and normal kinematics and being evident in the Nicotera-Gioiosa and Molochio-Antonimina fault zones. These faults were active during the infilling of the Neogene basin.

The NE-SW system shows two tectonic kinematics: a compressive stage, with a shortening NW-SE oriented axis and a extensional responsible for deepening of the basin.

CONCLUSION

The orogenic belt is considered to be the results of the continuous northward subduction processes of the Ionian oceanic lithosphere since the Cretaceous. Since the Oligocene, the area has experienced complex multihistory tectonics due to associated NW-SE oriented pull apart basins. In oblique slip fault systems, displacement generates important topographic gradients with associated uplift and subsidence, forming both uplifted ranges and sedimentary depocentres (SYLVESTER, 1988).

All these data allow us to propose a detailed tectonic evolution for the Siderno strait from its initial formation during the Serravallian until the present-day, as well as to evaluate the influence of strike-slip fault and reverse fault.

Erosional truncations and thickness variations(fig.2) suggest a different evolution for the Siderno basin, which, in comparison with northern and southern parts of the Ionian accretionary wedge, evolved differently during the Serravallian – Tortonian stages. NW-SE and NE-SW fault systems are dominant, the first exhibiting strike slip and normal kinematics and being evident in the Nicotera-Gioiosa and Molochio-Antonimina fault zones, the major morphostructural expression of this structure is the Valley of the T. Torbido.

These fault sistem were active during the infilling of the Neogene basin and represent a complex transfer zone. The NE-SW system shows two tectonic kinematics: exstensional and a compressive stage, with a shortening NW-SE oriented axis, responsible of the inversion tectonics documented by east verging folds, thrusts and back-thrusts; the emplacement of Variegated Clay, in the Langhian age, is related to the back-thrust propagation. The strike slip tectonics accommodate the stress generated in the accretionary prism in response to the subduction of the Ionian lithosphere and the progradation of the accretionary front of the Calabrian Forearc.

The Plio-Pleistocene evolution of the Crotone Basin (southern Italy)

MASSIMO ZECCHIN (*), MAURO CAFFAU (*), DARIO CIVILE (*), SALVATORE CRITELLI (**), AGATA DI STEFANO (***), ROSANNA MANISCALCO (***), FRANCESCO MUTO (**), GIOVANNI STURIALE (***), CESARE RODA (****)

Key words: *Crotone Basin, Pliocene-Pleistocene, tectonics and sedimentation, eustasy, Calabrian Arc.*

The Crotone Basin is the exposed part of a larger Neogene forearc basin developed in the Ionian Sea in the frame of the SE-ward migration of the Calabrian Arc, which led to the subduction of the Ionian lithosphere and the spreading of the Tyrrhenian back-arc Basin (central Mediterranean) (MALINVERNO & RYAN, 1986; SARTORI, 2003).

Taking into account the geologic context that accompanied its accumulation, the Plio-Pleistocene part of the Crotone Basin succession is exceptionally well preserved, and consists of a suite of continental, paralic, shallow-marine and deep-marine deposits organized to form unconformity bounded stratal units that, in turn, compose two main tectono-stratigraphic cycles (RODA, 1964; VAN DIJK, 1990; ZECCHIN *et alii*, 2004a, 2006; MASSARI *et alii*, 2010). The unconformities separating these units are well recognizable along the basin margin and tend to vanish basinwards. Additionally, they record phases of basin reorganization linked to large-scale tectonics.

In particular, the basin evolution was characterized by a cyclic pattern consisting of an alternation between longer subsidence phases, that favoured the accumulation of stratal units, and uplift phases that led to base-level falls and the generation of unconformities. These phases were strictly related to an alternation between active subduction of the Ionian lithosphere below the Calabrian Arc, accompanied by the spreading of the Tyrrhenian back-arc Basin and by extension and subsidence in the forearc basin, and regional-scale compressional and transpressional events, during which the Arc migration temporarily stopped.

The younger uplift of the basin, started during middle Pleistocene and still active (ZECCHIN *et alii*, 2011), was characterized by extensional tectonics, and its interplay with glacio-eustasy controlled the formation of marine terraces (COSENTINO *et alii*, 1989; ZECCHIN *et alii*, 2004b).

The tectonic episodes, affecting the Calabrian Arc since Plio-Pleistocene times during its SE-ward migration, are precisely recorded in the Crotone Basin. The tectonic control on the basin fill and its time constrain are critical helping to draw a clearer picture on the complex evolution of the central Mediterranean.

Effects of incremental growth of granite plutons on the thermal evolution of the continental crust exposed in Calabria

ALFREDO CAGGIANELLI (*), VINCENZO FESTA (*), ANTONIO LANGONE (**)(°) & GIACOMO PROSSER (***)

Key words: *Low-P metamorphism, Hercynian granitoids, numerical modelling.*

ABSTRACT

Granitoids represent a considerable proportion of the Hercynian crustal sections exposed in Calabria. In the Sila and Serre massif the granitoids are stacked to make a pile of tabular intrusions with a cumulative thickness of 9 to 13 km. Composition typically ranges from tonalite to granite, but minor dioritic and gabbroic bodies are also present. Magma emplacement took place between 300 and 290 ± 10 Ma during the extensional tectonic stage, following collapse of the Hercynian belt. The heat advected by granitoids was considered responsible both for contact metamorphism in the upper crust and regional low-P metamorphism in the lower to intermediate crust. This was satisfactorily reproduced by static and dynamical numerical models. However, a limit of the models is the assumption concerning the instantaneous emplacement of the magmas, following the general consensus on the idea that large magma chambers can be filled through dykes in a short time interval (< 100 kyr in PETFORD *et alii*, 2000).

In recent years, radiometric datings obtained from different levels of the magmatic bodies indicate that pluton growth can be completed in a significantly longer time (>1 Myr, *e.g.* GLAZNER *et alii*, 2004; MATZEL *et alii*, 2006) as an effect of the discontinuous melt feeding. Consequently, the way the pluton grows (downward or upward) needs to be examined since this affects the intensity of thermal perturbation above and below the magmatic body (ANNEN, 2011).

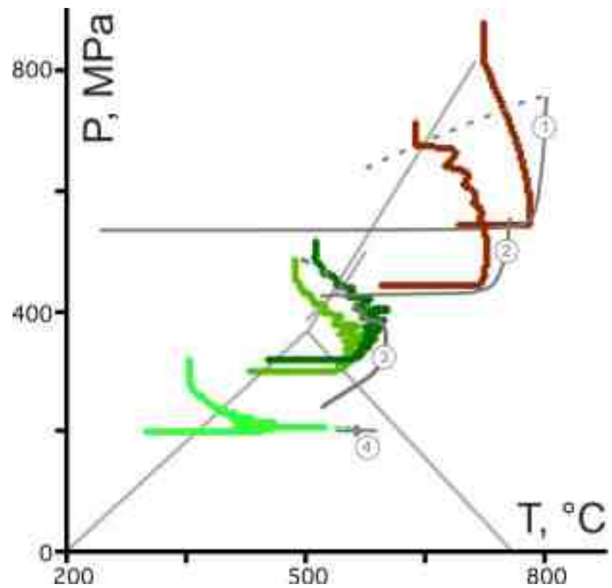

Fig. 1 – A comparison among simulated (coloured lines) and estimated (numbered grey lines) P-T paths for the Sila and Serre crustal sections. The model paths are based on over accretion of the pluton taking place in 5 Myr during extension with a strain rate of 4×10^{-15} s^{-1}. The sinuous paths reflect incremental growth of the pluton. Petrologically determined P-T paths are from: lower crust (1 - SCHENK, 1989; 2 - GRAESSNER & SCHENK, 2001); intermediate crust (3 - LANGONE *et alii*, 2010); upper crust (4 - unpublished

On the basis of these arguments we have set up a new 2D thermal model, applied to the Calabria crustal sections, that takes into account the incremental growth of the pluton. We analysed the effects of the end-member processes of pluton accretion at different growth rates.

In case of under-accretion, contact metamorphism in the upper crust occurs before regional low-P metamorphism in the intermediate to lower crust. Model indicates that pluton growth must be completed in a short time (< 200 kyr) to reproduce peak temperatures (540-590 °C) in the contact aureole observed in the upper crust. A slower growth rate would result in weaker thermal effects. Consequently, deformation structures related to pluton growth and overprinted by peak temperatures porphyroblasts, must be formed in an even shorter time interval.

In case of over-accretion, a reverse time sequence of regional low-P and contact metamorphism is produced and observed peak temperatures can be generated even when pluton construction is completed in 5 Myr (Fig. 1).

In comparing data of the Calabria crustal sections with results of under- and over-accretion models, the second option is mandatory (Fig. 1). Model results suggest also that the smooth transition from regional low-P to contact metamorphism may reflect upward pluton growth and concurrent exhumation by extensional tectonics.

Petrogenetic meaning of zircon growth stages in metasediments

VALERIA CAIRONI (*)

ABSTRACT

The Cenerigneisses, amphibolite facies metasediments from Serie dei Laghi (Southern Alps), contain heterogeneous zircon populations which gave ages spanning from around 430 to more than 1000 Ma. A detailed chemical study of zircons, supported by careful evaluation of cathodoluminescence images, shows that it is possible to recognize and characterize different growth stages and to relate them to petrogenetic processes.

KEY WORDS: *cathodoluminescence images, growth stages, metasediments, zircon chemistry.*

INTRODUCTION

The Cenerigneiss, the main component of the Strona Ceneri Zone (Serie dei Laghi – Southern Alps), is a medium- to very coarse-grained gneiss with Variscan amphibolite facies metamorphism. The main mineral assemblage is Qtz + Pl + Bt + Ms, accompanied by minor Grt, St and Ky; in addiction, the coarser grained varieties contain variable amounts of K-feldspar, sometimes as large augens with typical magmatic features (perthites, Carlsbad twinning, synneusis with small Pl crystals). The amount of Kfs increases with increasing grain size of the rock and with decreasing distance from orthogneiss lenses, which represent granitoid intrusions of Ordovician age (466 $\pm$ 5 Ma, w.r. Rb/Sr isochron; BORIANI *et alii*, 1982-83).

All varieties of Cenerigneiss contain a heterogeneous zircon population of detrital origin, splitted into two groups (CAIRONI, 1995): very abraded to subrounded crystals (probably recycled zircons) and slightly abraded crystals (probably first – cycle detrital zircons); the same two groups occur in Gneiss Minuti, a fine-grained paragneiss often interfingered with Cenerigneiss. Only the Kfs Cenerigneiss contain euhedral zircon crystals with sharp edges, typologically similar to the zircons of the Ordovician granitoids (CAIRONI, 1994).

Recent U-Pb SHRIMP age determinations on zircons (PINARELLI *et alii*, 2008) gave a wide range of ages, with clusters at > 1000 Ma, around 600-700 Ma and around 460, which may well correspond to the above - mentioned three main age components. Such results, together with plenty of data on the petrography, geochemistry and field relations of Cenerigneisses (CAIRONI *et alii*, 2004), support their interpretation as mass flow turbidites derived from a dissected continental arc, locally infiltrated by residual melts related to the Ordovician intrusions (PINARELLI *et alii*, 2008).

In the last years a systematic study on the chemistry of the different zircon groups has been performed, aimed to obtain more details about the complex history of Cenerigneiss.

RESULTS

EMPA analyses were performed on: A) slightly abraded detrital crystals, probably directly derived from an eroded magmatic source, and B) euhedral non-detrital crystals attributed to the granitic melt infiltration. Comparison between photographs of the crystals before abrasion and their cathodoluminescence images after abrasion allowed to evaluate the level of exposure of the inner portions and to recognise and correlate different growth stages.

A) Detrital zircons: most crystals show evident relic cores; in the remaining crystals, cores are probably not exposed due to insufficient abrasion. Two main types have been identified.

Type 1 cores show truncated zones; they are generally characterized by very low Y_2O_3 contents and HfO_2 contents between 0.75 and 1.35 % (slightly increasing outwards); such values are typical of zircons from mafic rocks of dominant mantle origin (PUPIN, 1992). UO_2 is < 0.05 % in the bright zones, but it is in the range 0.05 - 0.20 % in the dark ones.

Type 2 cores show curved boundaries and are invaded by bright (in cathodoluminescence) unzoned areas; they have a limited enrichment in HfO_2 (up to 1.5 %), suggesting crystallization in a slightly more evolved magma. The bright areas also have HfO_2 between 1.1 and 1.5, but Y_2O_3 does not exceed 0.2 %; UO_2 is always < 0.05 % and ThO_2 almost absent; they could represent “recrystallization fronts” formed during high grade metamorphic conditions.

The following stage on both types of cores is represented by a very dark “ring” of variable thickness, with HfO_2 in the range 1.5 - 2.5 and UO_2 up to 0.38 %; Y_2O_3 is generally very low. Such compositions suggest growth in a rather evolved magma, which could represent a product of limited partial melting of the source.

All the analysed crystal share a final growth stage of variable

(*) Dipartimento di Scienze della Terra A.Desio, Università degli Studi, Milano

thickness, characterized by typical magmatic oscillatory zoning. HfO_2 content is mainly between 1-1.35 % in the bright zones, slightly higher (up to 2.1 %) in the dark zones, which are also relatively enriched in UO_2 (0.1-0.38 %); Y_2O_3 is negatively correlated with HfO_2 , decreasing from 0.48 to 0. Such distribution in the Y_2O_3 – HfO_2 diagram (PUPIN, 2000) is compatible with crystallization in an intermediate magma with calcalkaline affinity (diorite – tonalite).

B) Euhedral, non detrital crystals: despite their rather homogeneous external aspect, cathodoluminescence images reveal extremely complex internal structures. Depending on the degree of abrasion, some crystals show relic cores, whereas others do not. The composition of the analysed cores is very similar to that of type 1 cores of the detrital crystals. A second growth stage surrounds such cores, or represents the innermost portion in crystals where cores are not visible. The range of HfO_2 and Y_2O_3 contents determined in those areas mainly overlaps the last crystallization stage observed on the detrital crystals. The last growth stage, occurring on all analysed euhedral crystals, is weakly zoned and sometimes develops a different typology with respect to the internal portions. The HfO_2 content is always > 1.35 % (the value that divides subcrustal from crustal zircons; Pupin, 1992) and Y_2O_3 is mainly comprised between 0.1 and 0.5 %. The average composition on the Y_2O_3 – HfO_2 diagram plots in the area of zircons from granodiorites - granites of mainly crustal origin (Pupin, 1992, 2000), suggesting that such growth phase could be related to the granitization process.

CONCLUSIONS

All the studied detrital zircons share a final growth stage, whose chemical characters suggest that they derive from intermediate calcalkaline rocks (diorite – tonalite). This is in good agreement with the observed zircon typology (CAIRONI, 1995) and with the geochemistry of Cenerigneiss (CAIRONI *et alii*, 2004). Most crystals preserve cores with compositions compatible with those of zircons from mafic rocks of dominant subcrustal origin, which probably produced the dioritic – tonalitic magma through partial melting. The first stages of anatexis are sometimes recorded by a thin dark zone enriched in Hf and U, directly surrounding the relic cores or preceded by limited recrystallization in some crystals. Such crystals correspond to “Type 1 zircons” of PINARELLI *et alii* (2008), which gave ages around 630-670 Ma (ten points) and 1000 Ma (two points).

The analysed euhedral zircons have a weakly zoned rim of variable thickness, whose chemical characters suggest crystallization from a granitic melt. According to fig. 5 in PINARELLI *et alii* (2008), the reported ages around 430-480 Ma (weighted mean 465 $\pm$ 14) were obtained on such rims. However, most of the euhedral zircons preserve older growth stages chemically similar to those observed in the detrital crystals. This suggests that the granitic melt infiltration mostly produced euhedral “overgrowths” on pre-existing zircons rather than entirely new crystals.

The present study demonstrates that zircons can survive several episodes of crystallization, erosion, recrystallization or limited partial melting, new magmatic crystallization and so on. Therefore a careful study of internal structures coupled with geochemical and geochronological determinations is a powerful tool in recostructing the evolution of a rock.

Geodynamic evolution of the central and western Mediterranean: Tectonics vs. igneous petrology constraints

EUGENIO CARMINATI (*°), MICHELE LUSTRINO (*°) & CARLO DOGLIONI (*°)

Key words: *Magmatism, Mediterranean geodynamics, Petrology, Subduction flip, Tertiary.*

INTRODUCTION

We present a geodynamic reconstruction of the Central–Western Mediterranean and neighboring areas during the last 50 Myr, including magmatological and tectonic observations. This area (Fig. 1) was interested by different styles of evolution and polarity of subduction zones influenced by the fragmented Mesozoic and Early Cenozoic paleogeography between Africa and Eurasia. Both oceanic and continental lithospheric plates were diachronously consumed along plate boundaries. The hinge of subducting slabs converged toward the upper plate in the double-vergent thick-skinned Alps–Betics and Dinarides, characterized by two slowly-subsiding foredeeps. The hinge diverged from the upper plate in the single-vergent thin-skinned Apennines–Maghrebides and Carpathians orogens, characterized by a single fast-subsiding foredeep. The retreating lithosphere deficit was compensated by asthenosphere upwelling and by the opening of several back-arc basins (the Ligurian–Provençal, Valencia Trough, Northern Algerian, Tyrrhenian and Pannonian basins). In our reconstruction, the W-directed Apennines–Maghrebides and Carpathians subductions nucleated along the retro-belt of the Alps and the Dinarides, respectively. The wide chemical composition of the igneous rocks emplaced during this tectonic evolution confirms a strong heterogeneity of the Mediterranean upper mantle and of the subducting plates. In the Apennine–Maghrebide and Carpathian systems the subduction-related igneous activity (mostly medium- to high-K calcalkaline melts) is commonly followed in time by mildly sodic alkaline and tholeiitic melts. The magmatic evolution of the Mediterranean area cannot be easily reconciled with simple magmatological models proposed for the Pacific subductions. This is most probably due to synchronous occurrence of several subduction zones that strongly perturbed the chemical composition of the upper mantle in the Mediterranean region and, above all, to the presence of ancient modifications related to past orogeneses. The classical approach of using the geochemical composition of igneous rocks to infer the coeval tectonic setting characteristics cannot be used in geologically complex systems like the Mediterranean area.

The kinematic representation of the Central–Western Mediterranean geodynamics presented here is clearly biased by a number of still unconstrained boundary conditions. Regardless the missing accuracy, it shows a number of regional and general indications. The first robust result is that the subduction zones shaping the Cenozoic of the Mediterranean follow geometrically the inherited Mesozoic lateral variations of thickness and composition of the lithosphere.

Since the wavelength of these lateral variations is relatively short, the Mediterranean basin seems to be more complicated than other areas of the world (e.g., LUSTRINO *et alii*, 2011, and references therein). However, the subduction zones that characterize this region follow the same rules that have been recognized worldwide, being the geographic polarity one of the primary controlling factors (CARMINATI *et alii*, 2004, 2010; DOGLIONI *et alii*, 1999). In this context, the subduction zones with the subduction hinge moving towards the upper plate (i.e., Alps–Betics and Dinarides–Hellenides) are characterized by Alpine-type belts, i.e., doubly vergent, higher elevation, deeper decollements, etc. On the other hand, the subduction zones where the subduction hinge migrates away from the upper plate (i.e., Apennines and Carpathians) have an Apennine-style, single vergence, low elevation, shallower decollements, and back-arc basin formation. Moreover, following the example of the Atlantic subduction zones, the Apennines are here interpreted as formed along the retro-belt of the Alps where oceanic or thinned continental lithosphere was occurring.

The movie presented here is the main result of the research, where, albeit a number of acknowledged limitations, we present our simplified interpretation of the geodynamic evolution of the Central–Western Mediterranean. It is shown that the evolution of this area is characterized by flips in subduction polarity that led to the development of the Apennines and Carpathian subductions. Geometry, kinematics and magmatism of the Apennine-related subduction flip were strongly influenced by the inherited tectonic history. The complex magmatic evolution of the Mediterranean area cannot easily reconciled with simple magmatological models proposed for the Pacific subductions. This is most probably due to the

occurrence of several subduction zones in the area that strongly perturbed the chemical composition of the mantle in the Mediterranean region.

Crustal melting in the Corsica-Sardinia Batholith: where the heat came from?

INTRODUCTION

Crustal melting is a common process in orogenic belts and within active continental margins. Melt-producing reactions usually consume muscovite at low temperature (<700°C), producing trondhjemitic melts. At higher temperature, dehydration of biotite and amphibole occurs (c.a. 750°C and > 800°C, respectively) yielding to granodioritic or monzogranitic melts comparatively enriched in the K_2O and TiO_2 components. Temperatures above 800°C can be reached in regions of thickened crust because of: i) selective enrichment in U-Th-K isotopes and other lithophile elements, ii) increasing heat flowing out from the Moho, iii) advection of lower crustal or mantle-derived mafic melts, and iv) dissipation of viscous shear heating. All these processes are potentially important in active orogens, however their effective contribution to the petrogenesis of granites remains controversial. The observed enrichment in heat-producing elements, in fact, may account for the heat required to generate trondhjemitic leucosomes and the small volumes of biotite-poor rocks such as the Himalayan and Black Hills leucogranites.

Models based on selective enrichment of heat-producing elements however have difficulty to explain the high temperatures required to generate large anatectic batholiths composed of monzogranitic and granodioritic rocks, such as the Corsica-Sardinia Batholith (C-SB).

The beginning of anatexis in the Variscan crust of Sardinia has been precisely constrained at c.a. 345 Ma from the age of trondhjemitic leucosomes in metatexites (layered migmatites, FERRARA *et alii,* 1978). Petrology indicates that these early melts formed by muscovite dehydration melting between 1.2 – 0.9 GPa and 750 – 690 °C. Younger granodioritic plutons around 320 Ma formed *in situ* around 0.42 – 0.37 GPa and 750 – 820°C by biotite dehydration melting of an heterogeneous crust (CASINI *et alii,* 2012), therefore two major melting stages occurred during continuous decompression.

The major shortcomings in applying this model to the C-SB are represented by the preservation of muscovite-bearing rocks in the melts source region, and by the enrichment of U-Th in leucogranites rather than in the rocks where the melts came from. Both observations argue against a process of progressive enrichment of heat-producing elements, therefore crossing the 750° - 800°C thermal boundary would requires some additional heat source such as increased Mantle heat flow, advection of mafic melts or dissipation of shear heating.

THERMAL MODELLING

The potential of these components is firstly evaluated here by a simple numerical model which solves the conventional Fourier equation in 1D space.

The thermal structure of the Variscan crust of north Sardinia is evaluated using a modified version of the code described in CASINI (2011), in order to account for the temperature dependence of thermal conductivity. We used a simplified three-layer crustal section with total thickness of 46 km and typical composition for the upper crust, middle crust and lower crust.

Mafic lower crustal or mantle-derived plutons appears very late during the C-SB history, therefore advection of hot melts was not implemented in the code. Shear heating is modeled by adding up to 1 $\mu W\ m^{-3}$ to the geotherm for depths relevant to ductile deformation (BURG & GERYA, 2005). The Moho heat flow was changed between 13 and 18 mWm^{-2}, to simulate near-equilibrium conditions.

CONCLUSIONS

The relation between HT-ductile shear zones and the early granodioritic plutons of the C-SB around 320 Ma (CASINI *et*

(*) Università di Sassari, DiSNT, via Piandanna n°4, 07100 Sassari (Italy), mail: casini@uniss.it

alii, 2012) suggests that shear heating may be a viable mechanism to explain focused anatexis and congruent melting.

Assuming the ductile shear zone is 1 to 3 km thick, compatible with the observed thickness of the Barrabisa shear zone, viscous deformation would have raised the temperature of some 40 - 120°C at a depth of about 16 km. The suggested increment of temperature can account for the onset of biotite breakdown during nearly isothermal decompression.

This localized increment of temperature can account for the generation of granodioritic K_2O-rich melts during nearly isothermal decompression from about 1.1 to 0.4 GPa.

INTRODUCTION

Palinspastic reconstruction of the past geodynamic realms is one of the most challenged aims of the Earth scientist. The development of the multidisciplinary investigation techniques is increasingly allowing elaboration of detailed and reliable models, in particular for those geological scenarios characterized by superposition of different orogenic cycles involving microplate frameworks, such as the Mediterranean realm. In this view, geothermo-barometry via PT pseudosection assisted by image processing of X-Ray Map has been performed to better constrain the PT history of a remnant of the southern European Variscan chain, now incorporated in the southernmost termination (i.e. Peloritani Mountains) of the Calabria-Peloritani Orogen (CPO) (Fig.1a).

The present-day nappe-like edifice of the Peloritani Mountains is characterized by an overturned framework where the higher grade metamorphic units occupy the uppermost levels of the nappe-edifice and where each unit is characterized by an average increment of the metamorphic grade from bottom to the upper present-day levels.

In this contribution we reconstruct the PT history of the medium-grade metapelites from the intermediately stacked Mandanici Unit, thanks to the information preserved in garnet micaschists outcropping in three different areas (Savoca, Montagna di Vernà, Briga) and representative of the highest metamorphic grade levels of the Unit (Fig.1a).

PT EVOLUTION OF THE MANDANICI UNIT: PETROLOGICAL AND MINEROCHEMICAL CONSTRAINTS

The three selected sample collection areas have preserved three different stages of the Mandanici unit tectono-metamorphic evolution, characterized by a Barrovian-type clockwise PT trajectory followed, during the latest stages of the retrograde path, by a quasi-static thermal increase. Thermodynamic modeling, combined with microstructural analyses and minerochemistry data assisted by image processing elaboration of X-ray maps (Fig.1b), has been performed to reconstruct PT trajectories for the studied metapelites of each area (Fig.1c).

P-T pseudosections, calculated by means of Perple_X software package (Connolly and Petrini, 2002) in the TiMnNCKFMASH system, have been used to estimate peak P-T conditions considering XRF bulk-rock chemistry as equilibrium volume compositions. In particular, garnet porphyroblast core compositions of the Montagna di Vernà and Briga metapelites permitted to obtain reliable isopleths intersections in the pseudosections PT space at T of ≈515 °C for P of ≈0.93 GPa, which are likely to be related to an early crustal thickening stage. This was followed by a weak thermal increase, with T of ≈537 °C at lower P of ≈0.80 GPa, constrained by means of garnet isopleths thermobarometry of garnet outer core compositions, probably linked with the initial stages of decompression (Fig.1c).

Retrograde constraints were obtained calculating an effective bulk chemistry taking into account garnet-ilmenite fractionation effects, quantitatively computed by means of statistical data handling of representative X-Ray maps of suitable mineral phases from the Montagna di Vernà sample (Fig.2a), which permitted to determine a new chemical equilibrium volume in NCKFMASH system. According to Fiannacca et al., (2012) New computed pseudosection provided reliable intersections between anorthite and phengite isopleths, indicating temperature of 420-460°C and pressure of 0.30-0.60 GPa (Fig.2a). This retrograde phase can be related to the development of mylonitic foliation in the metapelites from Montagna di Vernà area.

Quasi-static effects at T≈550 °C and P≥0. 5 GPa were determined by means of pseudosection-derived PT estimates in TiMnNCKFMASH system integrated with paragenetic considerations, based on the presence of late- to post-kinematic blastesis of staurolite and chloritoid observed in Savoca metapelites (Fig.1c).

CONCLUSION

The detailed PT path obtained allow to better constrain the tectono-metamorphic evolution of a crustal sector of the southern European Variscides, in the view of especially achieving a deeper knowledge of the early metamorphic evolutionary stages, often re-equlibrated during the following prograde and retrograde stages.

(*)Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università degli Studi di Catania, Corso Italia, 57, 95129 Catania, Italia

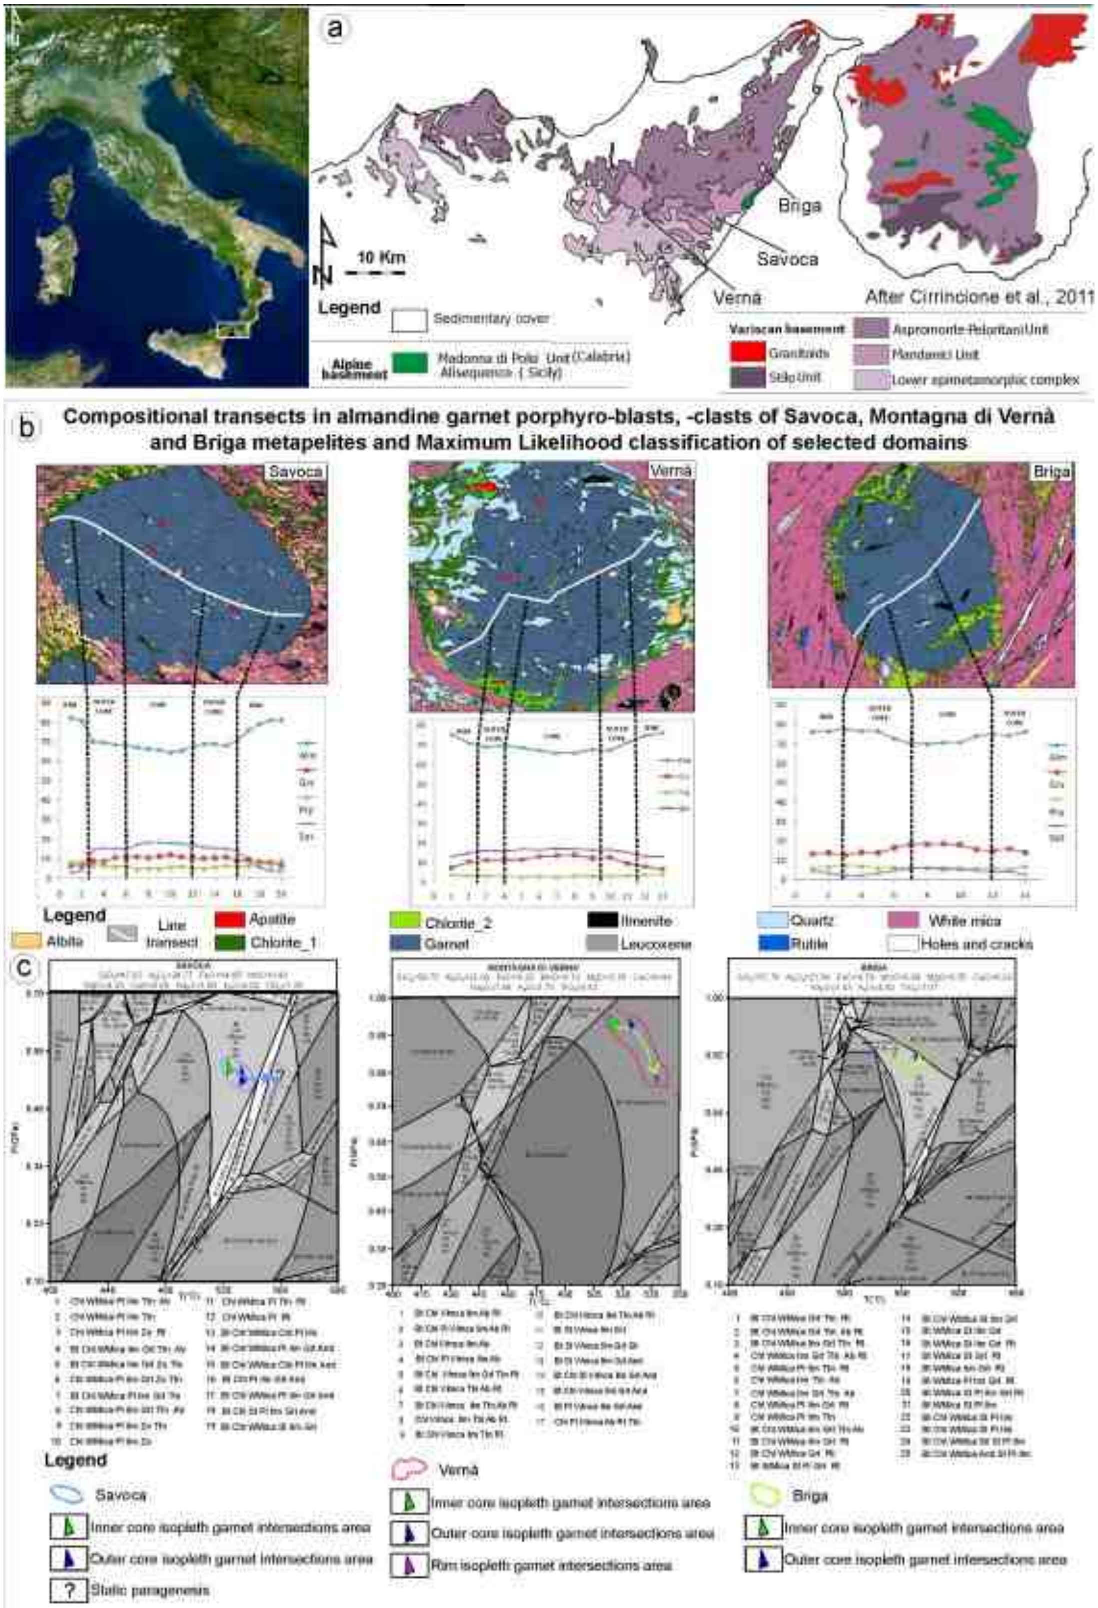

Fig. 1 – a) Geological Sketch map of the southern sector of the Calabrian Peloritani Orogen with location of the three selected collection sample areas; b) Compositional transect profile and maximum likelihood classification of selected garnet porphyro-blast, -clast of three selected sample domains from the three areas; c) PT pseudosection representative for the assemblages produced during the peak and early retrograde metamorphic stages.

Information preserved in the garnet cores of Montagna di Vernà metapelites has for example allowed to highlight the occurrence of relatively high-pressure metamorphic processes, previously unknown for the greenschist facies basement of the Peloritani Mountains.

Complete PT path elaboration tells, indeed, that the Mandanici Unit was involved in a Barrovian-type clockwise path characterized by a baric peak with T conditions of ≈500 °C at relatively high pressure of ≈0.90 GPa, followed by a dynamic metamorphic peak associated with thermal relaxation at temperature of 540 °C for pressure of 0.80 GPa (Fig.2c).

Subsequent retrograde PT constraints suggest development of a shearing stage (T≈440 °C and P≈0.40 GPa) during which late- to post-tectonic evolution producing a final thermal increase at T≈550 °C for P≈0.50 GPa took place (Fig.2c).

Quartz annealing microstructures in sheared rocks from the Serre Massif (Calabria, Italy)

INTRODUCTION

One of the microstructural features of deformed minerals is the development of lattice preferred orientation (LPO) by intracrystalline deformation mechanisms. The latter make active several slip systems of different orientation depending on both the metamorphic grade and deformation conditions. Active slip systems reflect the temperature, strain rate conditions and kinematics of deformation (PARK *et alii*, 2001).

Among fabric studies of geological materials, those dealing with quartz c-axis preferred orientation are probably the best known and most useful for strain quantification (SCHMID & CASEY, 1986; WENK, 1994). The interpretations are based on the assumption that the LPO in rocks develop as the result of deformation processes. Situations which contradict this basic assumption are commonly found in circumstances such as post-kinematic contact metamorphism of deformed rocks that had an LPO developed before the thermal metamorphism.

Care needs, therefore, to be exercised when interpreting the LPO, because there is a possibility of modification of LPO during static recrystallization. On the other hand, REE & PARK (1997), suggested that the LPO in annealed artificial material (octa-chloropropane) has a good memory of former deformation occurred prior than annealing, in agreement with experimental results obtained by HEILBRONNER & TULLIS (2002) for deformed quartzite samples subsequently affected by thermal annealing. .

The present study deals with mylonitic rocks outcropping in the southern sector of the Serre Massif (southern Calabria) where an extensional shear zone developed under amphibolite to greenschist facies conditions (P=0.03 GPa; T=470 °C) has been identified (ANGÌ *et alii*, 2010). The shear zone affected the crystalline basement of the so called Paragneiss Mammola Complex (PMC) (COLONNA *et alii*, 1973), intruded by Late Variscan granitoids (ROTTURA *et alii*, 1990).

(*) Dpt of Biological, Geological and Environmental Sciences, University of Catania (Italy)

GEOLOGICAL SETTING

The Serre Massif is a crustal sector of the southern Calabria-Peloritani Orogen bordered by the Catanzaro trough to the north and the Aspromonte Massif to the south, consisting of lower to upper crustal metamorphic rocks intruded, in between, by the late Variscan plutonic bodies of the Serre Batholith.

According to GRAESSNER *et alii* (2000 and references therein) the extensive the emplacement of the late-Variscan diorite to granite magmas in the intermediate levels of the Serre crustal section, coincided with the peak metamorphic conditions in the lower and upper crust portions, dated at 295 Ma (SCHENK, 1980; GRAESSNER *et alii*, 2000).

In the study area, two metamorphic Variscan Complexes characterized by different evolution (ATZORI *et alii*, 1977) and come into contact before the intrusion of the late-Variscan granitoids crop out: a) the lowermost Mammola Paragneiss Complex (MPC), constituted by paragneisses, leucocratic gneisses and amphibolites and b) the uppermost Stilo-Pazzano Complex (SPC), which includes low greenschist facies metapelites, metalimestones, quarzites and metavolcanics. At the top of the SPC, a composite sedimentary cover lies unconformably over the crystalline basement.

The tectono-polymetamorphic evolution of the Mammola-Paragneiss Complex, consisting of polyphase Variscan regional metamorphism, locally overprinted by pervasive thermal metamorphism due to emplacement of the late-Variscan intrusive bodies, has been investigated by ANGÌ *et alii* (2010). Undeformed dykes (ROMANO *et alii*, 2011 and references therein) cut the regional mylonitic foliation of the MPC basement rocks and limit its metamorphic history to Variscan times.

PETROGRAPHY

A main foliation defined by alternating fine-grained quartz-feldspar and mica domains characterises the host paragneiss rocks collected near the contact with the intrusive bodies, formed in the study area by dominant granodiorites and minor granites and tonalites. The main assemblage of the paragneisses is given by quartz, feldspar, biotite, and Fe-oxides. Thermal effects due to the contact metamorphism have substantially modified the pre-existing texture producing widespread recrystallisation making recognisable different generations of minerals (i.e. quartz and biotite) constituting polygonal microstructure composed by equant, polygonal quartz grain, exhibiting different grain size (10 to 150 microns). Quartz boundaries often meet at right angles the basal plane of mica flakes aligned parallel to the foliation.

Two quartz typologies have been recognized on the basis of their different size: the first is represented by small (ca 50 microns) equant strain-free grains with only minor undulose extinction and with straight grain boundaries defining a foam texture, whereas the other is constituted by quartz grains (ca. 400 microns) with lobate boundaries and with extensive bulging phenomena well preserved in relic mylonitic domains. Plagioclase grains also contribute to form this polygonal texture. Bulging and grain boundary migration recrystallization microstructures are frequently observed. Formation of quartz subgrains is incipient. Coesistence of different quartz fabrics as well as textural re-equilibration of the other minerals is the result of annealing by thermal effects after dynamic recrystallization.

Two generations of biotite occur too. The former is represented by laths parallel to the main foliation, which have often toothed edges indented with quartz subgrains growing at their margin (bulging texture). The latter constitutes decussate plates overgrowing the first mica generation and, at places, mimetically replacing sigmoid shaped crystals (early mica-fish). Both of them are partially to totally retrogressed to chlorite.

Epidote overgrows clusters of static biotite. Patchy relics of cordierite are replaced by white mica, quartz and chlorite. Sporadic sillimanite relics are surrounded by biotite laths. Porphyroclastic plagioclase crystals have amoeboid shape. Apatite occurs as porphyroclast. It is characterized by abundant tiny microinclusions, especially in the outer edge, forming a corona-type structure.

Samples collected about 2 km far from the granitoids are less affected by thermal metamorphism and have preserved the mylonitic features such as fine grain size and ribbon quartz grains. The quartz c-axis pattern, obtained from these sample using an image-assisted analysis computer program, show an asymmetric cross girdle quartz c-axes fabric indicating that mylonitic deformation occurred at upper greenschist facies conditions. These samples show sometimes a greater grain size (up to 300 microns) compared to those close to the intrusive contact. They show wavy grain boundaries, bulging and formation of sub-grain boudaries indicative of grain boundary migration recrystallization (GBMR) and exhibit a weakened c-axis quartz pattern probably partly affected by thermal metamorphism.

QUARTZ MICROSTRUCTURES

A variety of quartz microstructures is present in quartz-feldspar mylonites from the Mammola village area (Serre Massif), which show varying degrees of recrystallization: bulging and GBMR are frequently observed. In addition, adjacent to quartz layers elongated parallel to the main foliation, mica domains occur, consisting of aligned mica flakes, whose basal plane meet at right angles the quartz boundaries.

Two generations of quartz occur: the first is represented by equant strain-free grains of quartz with minor undulose extinction and with straight grain boundaries defining a foam texture; the other one is constituted by quartz grains with lobate boundaries well preserved in relic mylonitic domains. The coesistence of different quartz fabrics as well as the textural re-equilibration of the other minerals is the result of annealing after dynamic recrystallization by thermal effects associated with the intrusion of granitoids.

The annealed samples all have equant straight-sided, polygonal grains; annealing appears to reduce grain boundary lobateness The static annealing following deformation does not greatly affect the pattern or strength of the CPO, even though it completely changes the grain size and shape.

The AVA technique was applied on a well preserved oblique foliation microstructure of samples, due to the effects of combined sub-grain rotation and grain boundary migration re-crystallisation regime. It allowed to obtain an asymmetric single girdle quartz c-axes fabric, consistent with a top-to-the ENE/NE sense of shear. These c-axes quartz patterns, suggesting that basal <a> slip was more active than prism <a> slip during the shearing phase, are indicative of a shearing temperature ranging from 400 °C to 500 °C (HIRTH & TULLIS, 1992).

CONCLUSIONS

Approaching the contact with plutonic complex, the metapelites display a variation in the minero-textural re-equilibration (i.e. metamorphic annealing) and an increase in the static mineral-growth. Several samples exhibit textural features clearly related to the static re-crystallisation, which are represented by: a) strain-free quartz level aggregates with slightly undulose extinction and straight grain boundaries, b) a network of triple junctions among grains of re-crystallised oligoclase-andesine plagioclase; c) biotite, garnet and feldspar static mineral-growth, overprinting the earlier regional metamorphic assemblage; d) randomly oriented tabular plates porphyroblasts of biotite with irregular rims occur as well as static garnet, represented by subhedral to euhedral inclusions-free almandine-rich rim on previous regional garnet.

The microstructural investigation of a suite of samples collected at different distance from the intrusive contact of the granitoid outcropping in the southern termination of the Serre Massif (near the Mammola village) allowed us to confirm that, although the previous mylonitic features are clearly annealed by thermal effect re-crystallisation in rich-quartz-level domains, a memory of the relic strong quartz c-axes pattern is recorded, consistent with a top-to-the ENE/NE sense of shear in the present-day geographic coordinates, as suggested also by microstructural observations and structural field data.

INTRODUCTION

The relative contributions of pure and simple shear at finite strain are related to the dimensionless Wm ($0 \leq Wm \leq 1$), which is a measure of the rotational quality of a flow type (PASSCHIER, 1987). According to XYPOLIAS (2009) and as shown in figure 1, under progressive simple, pure and general shear, the central girdle segment of quartz c-axis-fabrics develops nearly orthogonal to the flow plane (A1; Fig. 1a). Therefore, the angle, β, between the perpendicular to the central girdle segment of quartz c-axis fabric and the foliation (SA) is equal to the angle between the flow plane (A1) and the flattening plane of finite strain (Fig. 1a). Such a β angle can be used in the following equation to calculate Wm (WALLIS, 1995):

$$Wm = \sin 2(\beta + \delta) \quad (1)$$

where δ is the angle between the oblique-grain-shape fabric (SB) and the main foliation (SA, Fig. 1b).

Calculation of Wm allows to obtain both the percentages of pure and simple shear (LAW *et alii*, 2004), and the amount of thinning (WALLIS *et alii*, 1993).

According to WALLIS *et alii* (1993) the amount of thinning (A) depends on the values of Wm and the finite strain (Rf), and is given by

$$A = 0.5(1 - Wm^2)^{0.5}(((Rf + Rf^{-1} + 2((1 + Wm^2)/(1 - Wm^2)) + (Rf + Rf^{-1} - 2)^{0.5}))) \quad (2)$$

If deformation was steady state Wm can be used with β to calculate Rf; the results can be obtained by the solution of the equation

$$Rf = (-b \pm \sqrt{b^2 - 4ac})/2a \quad (2b)$$

where

$$a = 2Wm^2 - 2Wm^2 \cos 2\beta - \sin^2 2\beta \quad (2b')$$
$$b = -2\sin^2 2\beta \quad (2b'')$$
$$c = 2Wm^2 + 2Wm^2 \cos 2\beta - \sin^2 2\beta \quad (2b''')$$

(WALLIS, 1995).

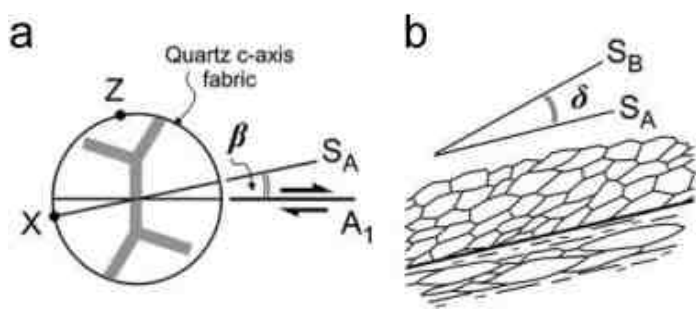

Fig. 1 – a) The angle, β, between the perpendicular to the central girdle segment of quartz c-axis fabric (A1, that corresponds to the flow plane) and the main foliation (SA). b) The angle, δ, between the oblique-grain-shape fabric (SB) and the main foliation (SA; slightly modified after XYPOLIAS, 2009).

Using quartz c-axis analyses from the literature (KRUHL & HUNTEMANN, 1991; ANGÌ *et alii*, 2010) and own unpublished data, our study aims to estimate the amount of thinning of the entire Hercynian continental crust exposed in Calabria. Crustal thinning was accompanied by decompression, which has been detected by several authors at different crustal levels (e.g. ACQUAFREDDA *et alii*, 2008; ANGÌ *et alii*, 2010; LANGONE *et alii*, 2010; FESTA *et alii*, 2012). The decompression stage started at ca. 325 Ma (LANGONE *et alii*, 2010; FESTA *et alii*, 2012) and

protracted up ca. 300 Ma (FESTA *et alii*, 2012) under granulite facies conditions, in the lower crust (e.g. FESTA *et alii*, 2012, and references therein), and greenschist facies conditions, in the shallowest middle crust (e.g. ANGÌ *et alii*, 2010; LANGONE *et alii*, 2010).

RESULTS

The considered literature data are quartz c-axis fabrics determined within samples collected in the Serre Massif of Calabria, comprising quartz-monzodioritic dykes and metapelitic country-rocks belonging to the intermediate level of the lower crust (KRUHL & HUNTEMANN, 1991) and paragneisses from the shallowest middle crust (ANGÌ *et alii*, 2010). In addition, new quartz c-axis analyses acquired within felsic granulites of the deep crust and within metapelites of the shallowest lower crust are also discussed.

According to KRUHL & HUNTEMANN (1991) and FESTA *et alii* (2012) the main metamorphic layering in both quartz-monzodiorites and metapelites developed under granulite facies conditions and dips constantly toward SE, with an average angle of about 40°, whereas the lineation dips from S to SE, with an angle ranging from 20° to 40°. The same attitudes are generally shown by the main foliation and the lineation of the above paragneisses (ANGÌ *et alii*, 2010) and the underlying felsic granulites.

Quartz c-axis fabrics obtained by KRUHL & HUNTEMANN (1991) on metapelite and quartz-monzodiorite samples, belonging to the intermediate level of the lower crust, are characterized by point maxima near the stretching direction, and incomplete small-circle arrangements with opening angles of about 100-120°. The asymmetry shown by these small-circles in relation to the flattening plane suggests a simple shear component of deformation. Similar characteristics are also shown by the new quartz c-axis fabrics obtained on samples of felsic granulites of the deep crust and of metapelites from the shallowest lower crust. The value of β, obtained using all these fabrics, can be assumed to be 10°. A null value can be reasonably assigned to δ, since the maximum elongation of the quartz grains is generally parallel to the main foliation, as observed on thin sections. It follows that solving the equation (1), Wm = 0.35, which suggests that the lower crust thinned and decompressed under dominant pure shear conditions.

Quartz c-axis fabrics obtained by ANGÌ *et alii* (2010) on paragneiss samples belonging to the shallowest middle crust, are characterized by an asymmetric type-I cross-girdle, that also indicates a simple shear component of deformation. A value of 30° has been obtained for β. Similarly to the lower crustal rocks, the value of δ can be reasonably reglected since the maximum elongation of the quartz grains is generally parallel to the main foliation in the paragneiss as well. It follows that solving the equation (1), Wm = 0.87. Although this value indicates a higher simple shear component, it suggests also that the shallowest middle crust underwent a significant pure shear component with consequent thinning and decompression.

Late Cadomian and late Variscan granitoid magmatism in the southern Calabria-Peloritani Orogen (southern Italy)

FIANNACCA P. (*), WILLIAM I.S. (**), CIRRINCIONE R. (*) & PEZZINO A. (*)

Key words: *Augen gneiss, granitoids, poly-orogenic melting, zircon, Calabria-Sicily*

INTRODUCTION

The medium to high-grade basement exposed in the Aspromonte Massif (southern Calabria) and the adjacent Peloritani Mountains (north-eastern Sicily), as well as in other basement sectors of the Calabria-Peloritani Orogen (CPO), is characterized by the widespread occurrence of peraluminous granitoids emplaced during the post-collisional stages of both the Cadomian and Variscan orogenies. Cadomian granitoids emplaced at ~565-540 Ma (MICHELETTI *et alii*, 2007; FIANNACCA *et alii*, in review) and were later affected by amphibolite facies Variscan metamorphism turning them into augen gneisses. Late Variscan granitoids intruded, at ~ 315-300 Ma (GRAESSNER *et alii*, 2000; FIANNACCA *et alii*, 2008), into the amphibolite facies basement, mostly composed by dominant biotite paragneisses deriving from metamorphism of flysch-like greywacke sequences, large augen gneisses bodies and minor amounts of micaschists, amphibolites and marbles. A comparative SHRIMP zircon and geochemical study has been carried out on an augen gneiss from the Peloritani Mountains and a leucogranodiorite from the Aspromonte Massif to shed light on the processes and sources involved in granitoid magma production in a crustal sector affected by poly-orogenic evolution.

RESULTS AND DISCUSSION

The augen gneiss, cropping out in north-eastern Sicily, resulted from Variscan metamorphism of a 545 ± 5 Ma granite protolith while the leucogranodiorite, from the southern Calabrian counterpart of the same tectonic unit (Aspromonte-Peloritani Unit), emplaced at 300 ± 4 Ma. Cathodoluminescence imaging revealed that the zircon grains from both rocks are characterised by a large amount of discordant cores rimmed by a thick igneous overgrowth. U-Pb SHRIMP dating of the zircon cores showed inheritance ranging in age from Early Paleoproterozoic to latest Neoproterozoic, with main clusters at c. 0.55 and c. 0.63 Ga, and minor ones at c. 0.95 and c. 2.5 Ga. These results suggest that both granitoid magmas were generated by partial melting of a source rock containing different zircon populations as typical of sedimentary rocks. Strong similarity in the zircon inheritance patterns of the two rocks point to the same sedimentary magma source for the two granitoid magmas. Another possibility could involve derivation of the late Variscan magma from partial melting of the augen gneisses. Nevertheless, detrital zircon from a biotite paragneiss, host rock of the late Cadomian, studied by WILLIAMS *et alii* (2011), shows exactly the same age pattern as that of the inherited cores in both the late-Cadomian and late-Variscan granites, providing strong evidence that both granites could have originated by partial melting of that, or a closely related, paragneiss. Geochemical investigations, based on new and pre-existing geochemical data on the two granite suites, show that both are dominantly strongly peraluminous and characterised by similar compositions and trends in variation diagrams, as well as similar patterns in multi-element diagrams. Chondrite normalised REE diagrams show also similar, LREE enriched patterns with negative Eu anomalies. REE patterns for the late Paleozoic granites are, however, on the whole more fractionated and with low contents of HREE, suggesting equilibration with a magma source containing residual garnet. Restitic garnet-rich metasedimentary rocks are abundant in the lower crust of southern Calabria, possibly representing the granulite counterpart of the amphibolite facies paragneisses from the shallower crustal portions exposed in the studied area.

Sr and Nd isotopic data recalculated at the emplacement age of the late Variscan granitoids allow to exclude the possibility that the late Variscan magmas could have derived by partial melting of the late Cadomian granitoids. Initial Sr-Nd isotopic compositions for both granite suites indicate that melting of crustal material played a main role in the generation of both granite suites and are on the whole close to those of metasediments from the CPO, including the peloritanian paragneisses, On the other hand, Sr and Nd isotopic data are also consistent with a possible involvement of mantle-related components in the genesis of the granitoids. Comparison between the major element compositions of both the late Precambrian and late Paleozoic granitoids with the compositions of experimental melts produced by partial melting of metasedimentary (pelite and greywacke) and metaigneous (basalt and andesite) rocks has been also carried out, using the diagrams of PATIÑO DOUCE (1999) that also permit to take into account the possible interactions between metasedimentary-derived melts and mantle-derived melts or restitic components. In these

(*) Dipartimento di Scienze Geologiche, Biologiche e Ambientali, Università di Catania

(**) Research School od Earth Sciences, Australian National University

diagrams the compositions of the late Variscan granitoids mostly fall in the fields of melts produced by partial melting of greywacke-pelite sources, but tend, at the same time, to plot along the reaction curves representing hybridization of metagreywacke with basaltic melt at high pressure. The late Cadomian granitoids result to have been derived by partial melting of the same metasedimentary source, but to have possibly had more interaction with a basaltic component, but at low pressure. On the other hand, despite the large amount of inherited zircon in both granitoids, demonstrating the presence of restitic components in the granitic magmas, no clear evidence for unmixing processes involving major mineral phases may be inferred based on these diagrams. The effect of fractional crystallization is not taken into account in the above diagrams, whereas it appears likely that the range of granite compositions may have been produced by a combination of processes including that process, other than processes of mixing-assimilation and/or restite unmixing.

CONCLUSIONS

Studies of zircon from an augen gneiss, the granite protolith of which was emplaced at 545 ± 5 Ma, and a 300 ± 4 Ma leucogranodiorite, both cropping out in the southernmost sector of the Calabria-Peloritani Orogen, indicate that both granitic rocks originated by poly-orogenic partial melting of metasedimentary rocks derived from the same metagreywacke sources. Geochemical investigations of a relevant number of representative samples from both the late-Cadomian and the late-Variscan granites, including the dated samples, support this statement and provide evidence for possible involvement of mantle-derived components in the generation of the granitoid magmas. Integration of the different data lead to infer an origin of both granitoid populations by dominant crustal melting at expense of original flysch-like greywacke sequences, associated with, or followed by a variable combination of processes, involving interaction with mantle-derived melts, crystal fractionation and restite unmixing, finally producing the entire granitoid compositional spectrum. Specific geochemical features, such as REE patterns and variation trends in Patiño Douce diagrams, suggest that crustal melting took place at different depths during similar, post-collisional, stages of the late Cadomian and of the late Variscan orogenies in the southern CPO. Relatively shallow crustal levels were affected by partial melting during the late Precambrian/early Cambrian processes leading to generation of the augen gneiss granitoid protolith, whereas the late Variscan metasedimentary rocks did attain lower crustal conditions before the onset of anatectic processes responsible of generation of the late Variscan strongly peraluminous granitoids.

Key words: *LA-ICP-MS zircon dating, Hercynian amphibolite-facies micaschists, Southern Italy, peri-Gondwanan provenance*

INTRODUCTION

The Calabria-Peloritani terrane (CPT) represents a fragment of the European Hercynian Chain. The Hercynian basement consists mainly of metasediments and orthogneisses, with minor magmatic and metamorphic rocks of mafic composition, which are diffusely intruded by late-Hercynian granitoids. Magmatic and metamorphic rocks belonging to different crustal levels are well exposed due to the Alpine tectonics.

Despite numerous studies on the metamorphic evolution (P-T-t) of the Hercynian basement rocks have been published in the recent years, geochronological inferences about protolith, source and depositional ages are still scarce. Pre-Carboniferous palaeogeographic reconstructions are mainly based on Palaeozoic sequences outcropping along the entire CPT (*e.g.*, ATZORI & FERLA 1992; FERLA *et alii* 1982; ACQUAFREDDA *et alii* 1991; 1994a). Paleontological data from these weakly metamorphosed sedimentary sequences revealed Cambro-Ordovician to Carboniferous ages (Bouillin *et alii* 1984; Majesté-Menjoulas *et alii* 1986; Acquafredda *et alii* 1991; 1994a and references therein; Navas-Parejo *et alii* 2009). Magmatic rocks and orthogneisses related to the Hercynian orogenesis have been largely investigated for geochronologic issues resulting very helpful to detail palaeogeographic reconstructions. Different authors (SCHENK & TODT 1989; SCHENK 1990; MICHELETTI *et alii* 2007, 2008, 2011; FIANNACCA *et alii* 2008; FORNELLI *et alii* 2011; WILLIAMS *et alii* 2011) reported geochronologic data indicating a late Pan-African/Cadomian (600–500 Ma) crust-forming event. Archean to Neoproterozoic inheritance has been also largely documented by in situ analyses of zircon (*e.g.*, MICHELETTI *et alii* 2007, 2011; FIANNACCA *et alii* 2008; WILLIAMS *et alii* 2011). Moreover, Proterozoic ages have been documented by DE GREGORIO *et alii* (2003) for amphiboles (Ar-Ar ages) of amphibolites from the Peloritani mountains. The authors interpreted the Ar-Ar amphibole ages as a mixture between a younger generation formed around 600 Ma and older cores. DE GREGORIO *et alii* (2003) reported even older ages around 1.6–1.8 Ga by dating titanite with U-Pb method.

Source and depositional ages of medium- to high-grade metasedimentary rocks exposed along the CPT are still poorly constrained. In the last 10 years, geochronological study focused on high grade metamorphic rocks, belonging to the lower crust. Both zircon and monazite dating had given mainly Carboniferous to Early-Permian ages related to thermal peak and post-peak metamorphic conditions (*e.g.* GRAESSNER & SCHENK 1999; GRAESSNER *et alii* 2000; MICHELETTI *et alii* 2008; FORNELLI *et alii* 2011). The high-grade metamorphic conditions reached by these lower crustal rocks erased any geochronological information related to source components (MICHELETTI *et alii* 2008). In contrast, metasedimentary rocks of the upper crustal levels, with amphibolite to green-schist-facies metamorphic assemblages, may easily preserve this memory. Monazite dating of amphibolite-facies metasediments, belonging to the Hercynian upper crustal levels, confirmed the thermal metamorphic peak at about 300 Ma, synchronously with granitoid emplacement (GRAESSNER & SCHENK 1999; GRAESSNER *et alii* 2000; LANGONE *et alii* 2010; APPEL *et alii* 2011). Despite zircon could fail as geochronometer for protoliths and source components of high-grade metamorphic rocks it could provide information about the protolith ages of these shallower crustal levels due to its low reactivity under amphibolite- to green-schists facies conditions (e.g. HARLEY *et alii* 2007).

RESULTS AND DISCUSSIONS

New LA-ICP-MS U-Pb zircon dating has been performed on amphibolite-facies micaschists of the Hercynian intermediate-upper crust (Mandatoriccio complex) exposed in the Sila massif (northern Calabria, southern Italy). Micaschists are characterized by low-pressure/high-temperature assemblages with P-T peak conditions of about 0.35 GPa and 590 °C. The studied samples show a P-T-t Hercynian evolution comparable with other basement units exposed in the Serre (ANGÌ *et alii* 2010) and Aspromonte (GRAESSNER & SCHEnk 1999) Massifs; moreover, the Mandatoriccio Complex is tectonically juxtaposed to the low

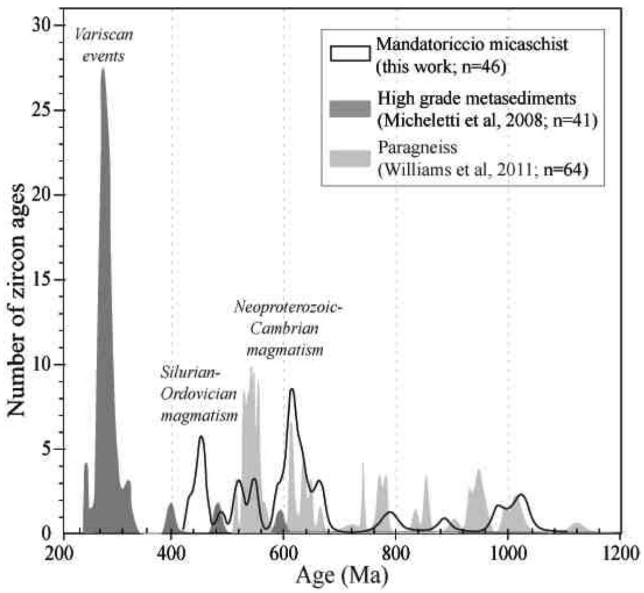

Fig. 1 – Probability density curves for U-Pb concordant data in the interval 200- 1200 Ma of LL61b2 sample (n=46), high grade metasediments dated in Micheletti et alii (2008) (n=41) and a paragneiss dated in Williams et alii 2011 (n=64)

metamorphic grade Palaeozoic sequence (the Bocchigliero complex), dated paleontologically. These two complexes represent a near complete section through the Hercynian upper crust, from amphibolite-facies metamorphic rocks of the intermediate/upper crust to the weakly metamorphosed rocks of the shallowest levels. Noticeably, a similar section is well recognisable in southern Serre, with the Mammola paragneiss unit and the Stilo-Pazzano phyllite unit (COLONNA *et alii* 1973) representing the equivalent of the Mandatoriccio and Bocchigliero complex, respectively.

Zircon shows a variable morphology ranging from euhedral–elongated prisms to sub-rounded grains. Internal structures are dominated by oscillatory zoning. Relic cores have been observed, whereas metamorphic re-crystallised domains are absent. Seventy-three concordant U–Pb ages, ranging from 2562 ± 44 Ma to 428 ± 10 Ma, have been determined on forty-eight crystals. On the basis of textural features and U-Pb ages, the zircon crystals have been interpreted as detrital grains providing information about source material. The Cambrian to Silurian ages have been referred to magmatic domains indicating a direct derivation from intrusive–effusive sequences of this time span (≈550 Ma – ≈430 Ma). U-Pb zircon data indicate that the metasediments derived from a basement containing significant igneous and metamorphic components related to older orogenic cycles (Pan-African/Cadomian) suggesting a northern Gondwana domain provenance. A comparison of the new geochronological data with those from different structural levels of the Hercynian continental crust revealed how amphibolite-facies micaschists of the intermediate/upper crust may provide more information with respect to the granulite-facies metasediments of the lower crustal levels. The new zircon data allowed to locate the volcaniclastic sedimentary sequence of the Mandatoriccio complex within a new palaeogeographic reconstruction coherent with those proposed for the Calabria-Peloritani Terranes and for the other Hercynian fragments of the peri-Mediterranean areas, e.g. Sardinia.

Permo-Triassic grabbroic magmatism whitin the lower Variscan continental crust section of the Northern Calabrian Arc, Southern Italy

FRANCESCA LIBERI (*) & EUGENIO PILUSO (**)

Key words: *Permian, Triassic, magmatism, Northern Calabrian Arc.*

In the Northern Catena Costiera small volumes of gabbros with tholeiitic affinity are exposed, embedded within a deep Variscan continental crust complex. Geochemical, petrological and microstuctural studies display that gabbros derived from crystallization, through cumulitic processes, of an hydrous tholeiitic melt. P-T estimates for gabbro yield a mean crystallization temperature of about 770°C at pressure between 0.58 and 0.67 GPa. Based on the field relationship, it is thought that gabbros intrude at the contact between crustal and mantle-derived rocks. Both the crustal and mantle derived rocks experienced HT metamorphism: the granulite metamorphic peak conditions are estimated at 1.0 GPa and 800°C (PILUSO & MORTEN, 2004). No age determinations regarding this metamorphic event are available in this area. However, an age of circa 300 Ma was obtained for granulites belonging to the same unit from the Sila massif (GRAESSNER *et alii*, 2000), thus referring this high-pressure granulitic event to the late-Variscan stage. After the granulite metamorphic peak the crustal and mantle rocks, in which gabbros are intruded, follow a retrograde path characterized by isothermal decompression in the granulite facies, at physical conditions of about 0.6 GPa, and 800°C for P and T, respectively (PILUSO & MORTEN, 2004). This low-pressure granulitic event was followed by cooling in the amphibolite and greenschist facies conditions. Accordingly, it can be suggested that the physical conditions of gabbro emplacement overlap the P-T retrograde path of the country rocks along the final stage of the isothermal decompression. This fact suggests that the exhumation of the lower continental crust of the original Variscan crustal section of the Sila unit, was contemporaneous with partial melting of the mantle. Combining thermobarometric data obtained for gabbros with the P-T evolution proposed by PILUSO & MORTEN (2004), for the enclosing deep crustal and mantle-derived rocks, allows to conclude that gabbros intruded the deepest portions of the continental crust during a lithospheric thinning event characterized by anomalous high geothermal gradient. The in-situ U-Pb dating of zircon from Mg-Fe gabbros provide the first age data set for the investigated area. Age determination has been performed through zircon in situ U-Pb geochronology, associated to LA-ICP MS analyses:

a) the oldest group of early Permian ages are interpreted as metamorphic inherited cores of crustal origin and corresponds to the peak granulitic metamorphic event;

b) the crystallization age of the gabbros from the Northern Catena Costiera can be considered as middle Triassic, although evidence of a middle-late Permian magmatic episode is preserved.

The origin of this gabbroic magmatism can be ascribed to an important Permo-Triassic thermal episode that leads to Pangea fragmentation. This is consistent with an extensional geodynamic setting in which the magmatic activity at deep crustal levels corresponds to the onset of the Triassic rifting in the upper crustal levels. In the Sila upper crustal levels, the first indication of syn-rift tectonics and sedimentation is attested by the deposition of the late Triassic redbeds, representing the base of the Longobucco syn-rift sedimentary cover, directly above the basement rocks (SANTANTONIO & TEALE, 1988; PERRONE *et alii*, 2006). We provide evidences for the rift-related processes in the deeper portions of this continental fragment. It can be inferred that the gabbros intrude in the deepest levels (about 18 Km) of a continental crust already thinned, escaping the granulitic metamorphic re-equilibration. The age determination of gabbro emplacement, thus, provide an opportunity to better define the geodynamic scenario responsible for the Sila continental domain during the Mesozoic, reconciling the post-Variscan evolution of this continental fragment with those of the Southalpine and Austroalpine domains.

Basic magmatism in the lower crust of the Serre (Calabria): petrographic and geochemical study

ANNALISA MUSCHITIELLO (*), ANNAMARIA FORNELLI (*), FRANCESCA MICHELETTI (*)

Key words: *Calabria, basic rocks, lower crust, geochemistry.*

In the Serre massif (southern Calabria, Italy), a Variscan crust section crops out consisting, from the top to the bottom, of: i) middle–to low–grade metamorphic rocks, ii) a "layer" of granitoids having a thickness of about 13 km and iii) 7-8 km thick lower crust. The lower crust section includes from the bottom: a) layered metagabbros with interbedded meta-peridotites; b) felsic and mafic granulites with interleaved metapelites; c) migmatitic metapelites with interleaved metabasites, rare marbles and felsic orthogneisses.

In order to characterize the geochemistry and the evolution of the Neoproterozoic to Early Cambrian basic magmatism in the Serre, petrographic and geochemical studies were performed on metagabbros and metabasites.

The lower crustal rocks have been affected by Hercynian metamorphism and, locally, by multistage partial melting. Consequently, the rock original compositions and the primary mineralogical assemblage have been modified.

At the base of the deep crust, in the gabbroic portion, different types of basic rocks have been identified on the basis of petrographic and geochemical features: metagabbros, biotite-bearing metagabbros and "hybrid" metagabbros.

According to Streckeisen – Le Maitre diagram (1979), the metagabbros are classified as gabbros and Qtz-gabbros. This rock type is characterized by coarse grained size and isotropic texture and the mineralogical association consists of Pl+Opx+Amph±Cpx±Bt±Qtz±Grt. Biotite is rare, whereas amphibole can form thick layers. On the other hand, leucocratic portions having trondhjemitic composition are interspersed within the main gabbroic body. Some samples of metagabbro contain clinopyroxene nodules surrounded by an Amph+Opx or Opx+Amph±Pl corona and porphyroblastic garnet with symplectitic corona consisting of Amph+Pl+Opx or Amph+Bt+Pl+Opx. Zircon and apatite are accessory phases.

In association with metagabbros, the biotite-bearing metagabbros form layers or lenses. This rock type is characterized by medium grained size and anisotropic texture, it consists of Pl+K–Feld+Opx+Cpx+Bt±Qtz±Grt. Apatite and zircon are accessory phases. Peculiar characteristics of this rock-type are: absence of amphibole, abundance of biotite and presence of centimeter sieno-granitic pockets having magmatic texture. When present, garnet forms porphyroblasts including Amph, Px, Pl, ±Bt and ±Qtz and it is mantled by a corona of Pl+Bt±Opx±Cpx.

Within the most primitive metagabbros, there is a hybrid-metagabbro type consisting mostly of Bt+Amph±Pl±Cpx±Qtz; zircon, apatite and opaque minerals are accessory phases. This rock type has abundant amphibole and clinopyroxene nodules as well as metagabbros; medium grained size, anisotropic texture, biotite abundance and sieno-granitic melt pockets similar to those of biotite-bearing metagabbros.

Lenses or layers (up to 20-30 cm thick) of metabasites are interleaved with migmatitic metapelites and felsic granulites of the upper part of the deep crust. Mineralogical association consists of Pl+Opx+Cpx±Bt±Amph±Qtz±Grt; zircon, apatite and opaque minerals are accessory phases. The content in amphibole and biotite is variable. When present, the porphyroblastic garnet might be rimmed by a corona of Pl+Opx+Bt. They show medium grained size and trondjemitic portions.

In order to characterize the geochemistry of each rock group, mineral phases of selected samples have been performed using Scanning Electron Microprobe.

Plagioclase generally ranges from An_{50} to An_{60} having a labradoritic composition and reverse zoning in more primitive metagabbros whereas an andesinic plagioclase (An_{40-49}) is present in more differentiated types. Plagioclase of symplectitic coronas around garnet or included in garnet has bytownitic composition (An_{70-85}) showing re-equilibration with garnet. Even plagioclase in biotite-bearing metagabbros and in hybrid metagabbros presents labradoritic composition (An_{50-60}).

A bytownitic-anortitic plagioclase (An_{80-90}) is present in more primitive metabasites whereas a calcium-poorer plagioclase with andesinic composition (An_{40-49}), appears in more differentiated metabasites.

K-Feldspar is an Or_{84-90} with homogeneous composition in matrix and sieno-granitic pockets present in biotite-bearing metagabbros and hybrid metagabbros.

In metagabbros, orthopyroxene is En 55-65 (Mg-number 0.62-0.74). Clinopyroxene is a diopside and shows Mg-number 0.83-0.96 (En_{36-39}); its composition is homogeneous in matrix, nodules, and symplectitic corona.

(*) Dipartimento di Scienze della Terra e Geoambientali, University of Bari, via Orabona 4 – 70125, Bari, Italy

Author for correspondence: annalisa.muschitiello@uniba.it

In biotite-bearing metagabbros, the orthopyroxene in matrix and corona of garnet shows Mg-number 0.64-0.74 (En_{56-57}), clinopyroxene is diopside with Mg-number 0.87-0.98 (En_{37-40}).

Diopside with high Mg-number ($Mgn_{0.90}$) is present in matrix and nodules of hybrid metagabbros without orthopyroxene.

In metabasites, the orthopyroxene is generally an enstatite En_{56-58} with Mg-number 0.63-0.72, but some samples record Mg-poorer orthopyroxene ($Mg\text{-}n_{0.51-0.55}$). Clinopyroxene is a diopside with Mg-number 0.75-0.98.

Within the more-primitive metagabbros, two types of amphibole have been distinguished: 1) ferroan-pargasitic hornblende ($Mg/(Mg+Fe_2)$~0.70; K~0.16) and 2) potassian-ferroan-titanian pargasites ($Mg/(Mg+Fe_2)$~0.55; K~0.40), the last is poorer in Mg and richer in K_2O (Fig. 1). In the qtz-metagabbros the amphibole is a potassian-ferroan pargasite with Mg-number of ~0.60 and K ~0.25 (Fig. 1) as that of the hybrid metagabbro (Fig. 1); in biotite-bearing metagabbros amphibole is absent.

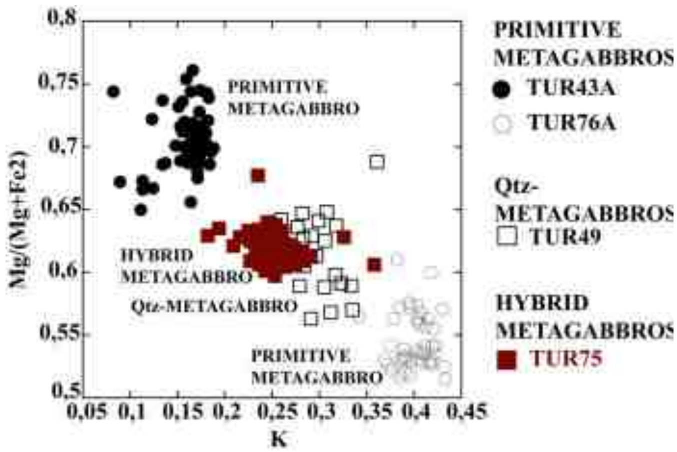

Fig. 1 – $Mg/(Mg+Fe_2)$ vs. K diagram for amphiboles in metagabbros and hybrid metagabbros.

Even in metabasites different amphiboles have been distinguished: 1) magnesium-hornblende (Mg-number 0.57-0.65, K 0.08-0.15); 2) edenitic hornblende (Mg-number 0.54-0.63, K 0.15-0.25); 3) potassian-ferroan-pargasitic hornblende (Mg-number 0.53- 0.64, K 0.25-0.36). In some samples (e.g. *TUR71*), magnesium-hornblende coexists with few crystals of potassian-ferroan-pargasitic hornblende and edenitic hornblende (Fig. 2).

The potassian amphiboles might be post-magmatic, produced by solid-state reactions between primary amphibole and potassic melts or fluids during metasomatic processes.

Biotite shows homogeneous composition in each rock type: it is a phlogopite with Mg-n in the range of 60-65; Ti/22ox varies between 0.6 and 0.7 and Al_{tot} from 2.40 to 2.60.

Porphyroblastic garnet shows similar features in metagabbros, in Bt-bearing metagabbros and in metabasites: it has almandine-pyrope composition (Mg-n ranges from 30 to 50); it records homogeneous core and reabsorbed rim enriched in Fe. Porphyroblastic garnet is absent in hybrid metagabbros.

Major and trace element analyses evidenced that metagabbros and metabasites are subalkaline rocks (Na_2O+K_2O=1-5%) with K_2O<1%wt, whereas Bt-bearing metagabbros and hybrid metagabbros show calc-alkaline characters (Na_2O+K_2O=5-7%) with K_2O around 3%wt.

The other major elements have quite similar abundances in the studied rocks, even if, in metagabbros and metabasites they vary on wider range from cumulitic portions to more differentiated rocks (in metagabbros and metabasites: SiO_2=41-63%; CaO=5-15%; MgO= 3-10%; FeO*=4-15%; Al_2O_3=15-20%. In Bt-bearing metagabbros and hybrid metagabbros: SiO_2=46-51%; CaO=8-9%; MgO=5-8%; FeO*=8-9%; Al_2O_3=15-20%).

The metagabbros and metabasites show lower contents of Ba,

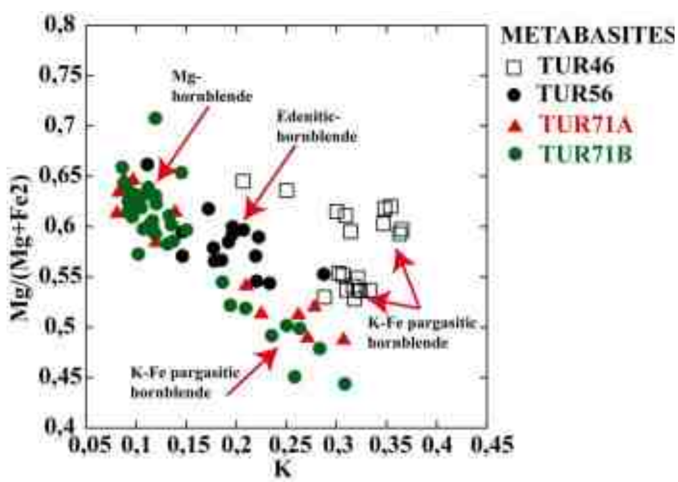

Fig. 2 – $Mg/(Mg+Fe_2)$ vs. K diagram for amphiboles in metabasites.

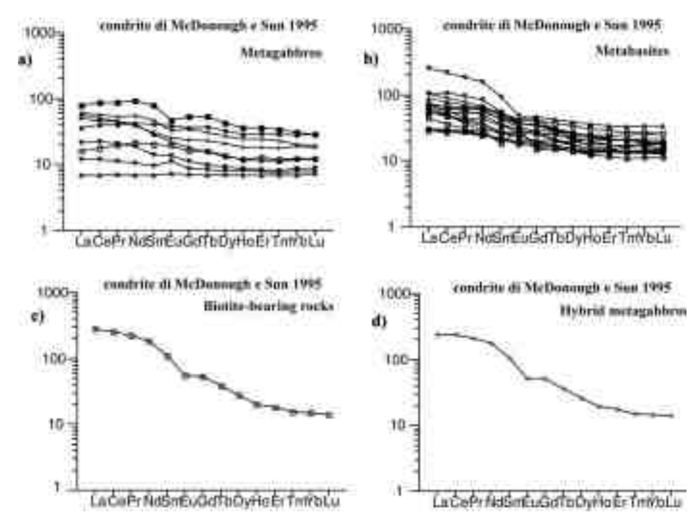

Fig.3 –LREE enrichment from metagabbros (a) and metabasites (b) to Bt-bearing metagabbros (c) and hybrid metagabbros (d).

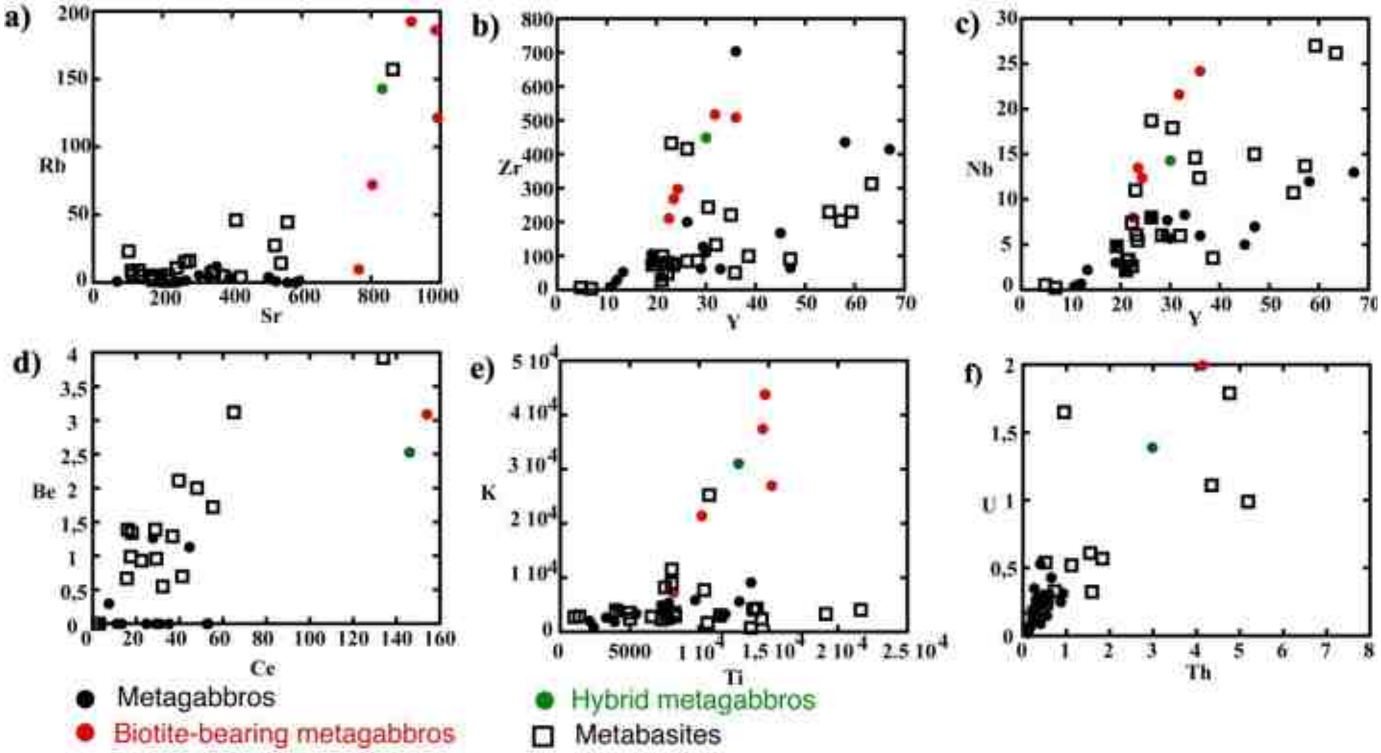

Fig.4 – Trace element diagrams.

Rb, Sr, Zr, Nb, Hf, Cs, Ce, K, Th, U, and LREE with respect to the Bt-bearing metagabbros and hybrid metagabbros **(Fig. 4)**.

The metagabbros and metabasites show generally flat REE patterns. In metabasites the increase of biotite corresponds to an increase of the ΣLREE from 39.31ppm to 145.3ppm. The LREE enrichment is also shown in Bt-bearing metagabbros and hybrid metagabbros (La_N/Sm_N is 1.26 in metagabbros; 1.79 in metabasites; 2.25 in hybrid metagabbros and 2.55 in Bt-bearing metagabbros) (Fig.3).

Mineral chemistry, chemical compositions, ACF and A'KF diagrams and isotopic data indicate a common mantle origin for the protoliths of the studied rocks. Rb-Sr and Sm-Nd isotopic analyses were performed on several samples. The $^{87}Sr/^{86}Sr$ initial ratios were calculated at 570 Ma, the emplacement age of the basic protoliths. In metagabbros, $^{87}Sr/^{86}Sr_{(570\ Ma)}$ ratio ranges from 0.703 to 0.708 with low values of $^{87}Rb/^{86}Sr$ (from 0.001 to 0.024). Biotite-bearing metagabbros and hybrid metagabbros show $^{87}Sr/^{86}Sr_{(570\ Ma)}$ ratio around 0.705 with high $^{87}Rb/^{86}Sr$ (0.544 and 0.489 respectively). These data suggest an interaction with fluids enriched in K, Rb and incompatible elements. Metabasites have higher $^{87}Sr/^{86}Sr_{(570\ Ma)}$ values (0.707-0.710) with low $^{87}Rb/^{86}Sr$ values (from 0.025 to 0.237).

The εNd_{570Ma} becomes progressively more negative when the content of biotite increases: it vary from 4.902 to -0.843 in metagabbros, from 0.741 to -2.388 in metabasites, whereas in Bt-bearing metagabbros and in hybrid metagabbros is -1.078 and -1.2531 respectively confirming the interaction with fluids enriched in K_2O and Rb.

Rb-Sr and Sm-Nd isotopic analysis indicate an involvement of mantle material in the genesis of protoliths of the studied rocks. The alkali enrichment of some samples of metabasite, biotite-bearing metagabbros and hybrid metagabbros, the occurrence of K-rich amphiboles and biotite and, finally, the incompatible trace element enrichment (e.g. Th, U, Ta, Nb, P, Hf, Zr, Cs, Be, K, Ce, Ti, LREE in Bt-bearing metagabbros and in hybrid metagabbros) seem to be linked to permeation of melts or fluid enriched in K_2O and Rb, probably, derived from wall rocks. A severe metasomatic event probably affected the mafic lower crust of the Serre changing the composition of the primary magmatic rocks along preferential directions. The metasomatic event induced partial melting in the mafic portions forming the sieno-granitic pockets, whereas the origin of trondhjemitic portions seem bound to evolution of primary magma. The metasomatic event could be dated around 345 Ma, during granulitic metamorphism as suggested by U-Pb zircon ages in metagabbros with porphyroblastic garnet and biotite-bearing corona.

Memory of the pre-Triassic events in the Calabria Terrane

PICCARRETA GIUSEPPE (*), FORNELLI ANNAMARIA (*), LANGONE ANTONIO (**), MICHELETTI FRANCESCA (*)

Key words: *Calabrian Terrane, U-Pb zircon dating, pre-Triassic events, peri-Gondwanan provenance*

INTRODUCTION

Peri-mediterranean chains keep memories of widespread magmatic and metamorphic events in pre-Cambrian and Paleozoic times. The study of these key sectors of continental crust can provide fundamental information about their geologic evolution in order to delineate more reliable paleo-geodynamic and paleo-tectonic reconstructions. One of the most current subject is the study of the tectonic evolution of the Gondwanaland and its fragments.

Memory of some events attending the evolution of the supercontinent Gondwana is preserved in medium-high grade metaigneous and metasedimentary rocks of the Calabria-peloritani terrains (CPt; southern Italy) reworked by Variscan and Alpine orogeneses (Fig. 1). The CPt has been considered as part of the Alboran microplate located at the northern Gondwana margin in Precambrian times (MICHELETTI *et alii* 2007).

A lot of U-Pb zircon ages determined through isotopic dilution and spot dating are now available. These data, together with the grain structures and the REE-U-Th distribution in the zircon domains help to define or approximate: (1) the ages of the protoliths of metaigneous rocks, (2) the source of acidic and mafic melts and (3) the ages of sedimentation of detritus and (4) the evolution of Variscan metamorphism.

CAMBRIAN-EDIACARIAN MAGMATISM

Evidences of a Neoproterozoic-Cambrian mafic and acidic magmatism affecting an older basement are widespread in the rocks of the CPt. The mafic calc-alkaline plutonism in Calabria was dated at ~570 Ma as that documented in other Cadomian Units along the present Alpine-Mediterranean mountain belts (NEUBAUER 2002 and references therein).

The basic magmatism in Calabria records tholeiitic and calc-alkaline affinities and being associated to a thick pile of metasediments can be connected to orogenic context related to a (mature?) magmatic arc (FORNELLI *et alii* 2011).

(*) Dipartimento Scienze della Terra e Geoambientali, Università di Bari
(**) CNR - Istituto di Geoscienze e Georisorse U.O.S di Pavia

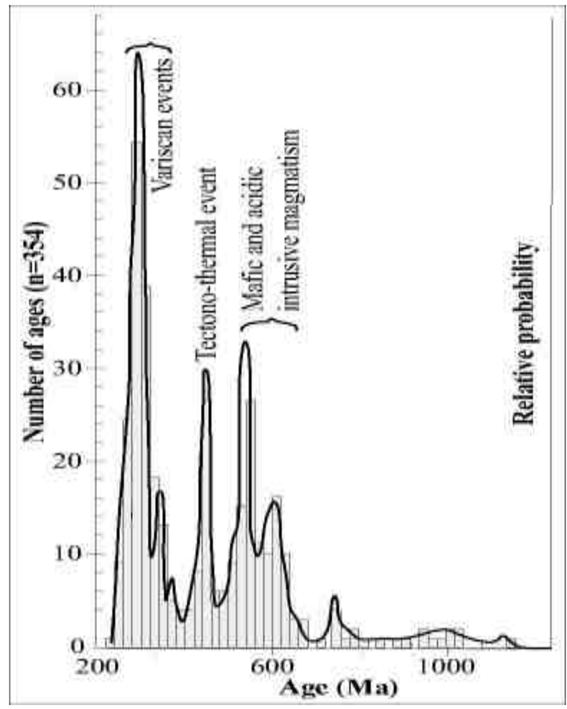

Fig. 1 – Probability density curves of U-Pb concordant zircon data from Calabria (time interval 200-1200 Ma).

The augen gneisses of the CPt were dated at ~520-545 Ma (MICHELETTI *et alii* 2007; FIANNACCA *et alii* 2011) and derived from shoshonitic to high-K calc-alcaline granitoids connected to a post collisional regime, probably at the transition from compressional to extensional tectonics (FORNELLI *et alii* 2007). The emplacement age of the protoliths of the augen gneisses together with their geochemical affinity are comparable with the features of granitoids widespread at the northern edge of the West African Craton. This voluminous high-K calc-alkaline plutonism seems to characterize the final stages of Pan-african orogeny in northern margin of the West African Craton in the period 605–530 Ma (GASQUET *et alii* 2005). In this scenario the mafic activity (metagabbros and metabasites of Calabria) along a (mature?) magmatic arc pre-dates (20-30 Ma earlier) the acidic hybrid plutonism recorded by the augen gneisses (FORNELLI *et alii* 2011). The Cambrian – Ediacarian mafic and acidic magmatism corresponds to tectonic setting at transition from an active (compressive-transtensive) to a passive (extensional) continental margin.

ORDOVICIAN-SILURIAN TECTONO-THERMAL ACTIVITY

Calabria-Peloritani rocks record the Early and Middle Palaeozoic tectono-thermal activity accompanied by widespread magmatism (effusive and intrusive) retained as related to the rifting phases preparing the opening of basins between the future Variscan basement and Gondwana (*e.g.* VON RAUMER *et alii* 2002).

Ordovician-Silurian ages (18 data ranging from 494±14 to 413±9 Ma relative to recrystallized zircon domains) from Cambrian-Ediacarian augen and fine leucocratic gneisses in Calabria can be related to this event (MICHELETTI *et alii* 2007, 2011). These gneisses are interleaved with the lower crust metapelites in the Serre for which a Rb-Sr isochron at 450±20 Ma was determined (SCHENK, 1990). We interpret these ages as related to an Eo-Variscan tectono-thermal activity, even if it cannot be excluded that these ages might result from rejuvenation due to the perturbation of U–Pb radiogenic system with partial Pb loss during the Variscan metamorphism. Ordovician porphyroids and andesites dated at ca. 456–452 Ma outcropping in Peloritani Mountain (TROMBETTA *et alii* 2004) are expression of the aforementioned pervasive magmatism revealed also in Sardinia (GIACOMINI *et alii* 2006).

VARISCAN EVENTS

Many U-Pb zircon ages obtained from metagabbros, metabasic rocks, fine-grained leucocratic gneisses and high grade metasediments of Calabria range from ~380 Ma to ~280 Ma (FORNELLI *et alii* 2011).

In Calabria-Peloritani augen gneisses ages younger than ~516 Ma (Peloritani Mt., WILLIAMS *et alii*, 2011) and than ~446 Ma (Calabria, MICHELETTI *et alii*, 2007) were not detected. The absence of Variscan ages could be related to the low temperature conditions (lower amphibolite facies) recorded by these rocks.

The Variscan ages cover the time span from crustal thickening to the collapse of the Hercynian orogenic belt. The younger ages (up to 231±5 Ma) could be related to the opening of the Tethys (MICHELETTI *et alii* 2008). The age peaks from about 380 Ma to 347 Ma could indicate crustal thickening phases and those at about 320, 300 and 280 Ma constrain Variscan multistage dehydration, decompression and partial melting. The age peak at about 300 Ma probably dates the end of the anatexis in the lowermost metabasites of the Serre section, concurrently at the intracrustal emplacement of huge volumes of granitoids (*e.g.* CAGGIANELLI *et alii* 2000). Since granulite facies conditions and partial melting were operative from the metamorphic peak to the decompressional stages, a duration of ~60-70 Ma might be inferred for granulite facies metamorphism and anatexis. The comparison with data from migmatitic metapelites in the upper part of the deep crust section of the Serre shows that these migmatites, too, underwent long lasting granulite facies metamorphism, decompression and anatexis from 323 Ma (age of monzodiorite dikes FESTA *et alii* 2011) quite synchronous with metamorphic peak, up to 270 Ma in which the last decompression and anatexis occurred (FORNELLI *et alii* 2011). An overall duration of 40-50 Ma can be estimated for metamorphism and anatexis in the upper part of the Serre section. Consequently, a diachronic Variscan evolution emerges in different levels of the deep crust in Calabria.

A look at the Variscan lower crust migmatitic metapelites and felsic granulites of the west Mediterranean realm comparable to the upper portion of the Serre section, reveals similarities. Regional granulite-facies conditions between 320 and 300 Ma might be inferred by chronological results of zircon in the Ivrea zone, where a duration of anatectic conditions of tens of millions of years was estimated by Vavra *et alii* (1996; 1999) and by PERESSINI *et alii* (2007). Long lasting granulite facies conditions during decompression are also recorded in Sardinia (*e.g.* GIACOMINI *et alii* 2006), suggesting that long lasting multistage granulitic, anatectic and decompression conditions should have affected the South European Variscides after the crustal thickening at about 347-340 Ma.

Interestingly, no Hercynian U-Pb zircon ages have been obtained from lower-medium grade metasediments from Mandatoriccio complex (Calabria, LANGONE *et alii* 2010) and Aspromonte Unit (N-E Sicily, WILLIAMS *et alii* 2011).

CONSIDERATIONS ABOUT SEDIMENTATION AGES

The augen gneisses derived from hybrid magmas with dominant crustal component (FORNELLI *et alii* 2007). They contain Neoproterozoic to Archean inherited ages obtained from rounded zircon cores locally fractured and suggesting a detritic origin. Fine leucocratic gneisses also contain Neoproterozoic inherited ages (MICHELETTI *et alii* 2011). In these rocks, inherited ages form a significant age group at 633-611 Ma (n=9) which is about 60 Ma older than the younger group containing mostly the magmatic ages (545 Ma). The ages older than 630 Ma define very small clusters or individual ages. Taking into account the thermal resetting induced by magmas and the possible effects of Ordovician and Variscan events on the modification of the isotopic composition, it can be concluded that the significant inherited ages at 630-610 Ma represent the maximum age of sedimentation of the source of the anatectic magmas. The time gap of about 60-80 Ma might account of the geological evolution from sedimentation to partial melting.

The analyzed zircon domains from high-grade metasediments grew or ricrystallized in Variscan times (MICHELETTI *et alii* 2008). The discordant ages defined discordia lines with upper intercepts at 1.1 Ga (MICHELETTI *et alii* 2008), 2.0 Ga and 2.3 Ga (SCHENK 1990). In addition, Schenk (1990), on the basis of the isotopic Sr evolution has deduced a sedimentation age comprised between 600 and 1000 Ma. Since: (1) primary intrusive relations between the protoliths of augen gneisses and metapelites are preserved (MICHELETTI *et alii* 2008) and (2) derivation of the acidic melts from such metasediments has been excluded as possible contaminant of protoliths of orthogneisses (FORNELLI *et alii* 2007). It derives that sedimentary protoliths of the metasediments of the lower crust are older (<630 Ma) than those which produced the acidic magmas that contaminated the orthogneisses.

CONCLUSION

As concern the views of U-Pb zircon ages from rocks of the CPt, it emerges a bimodal Cambrian-Ediacarian magmatism**,** Ordovician recrystallization and a Variscan metamorphism under intermediate-high temperature. A discussion about the absence of Variscan zircon ages in Mandatoriccio complex and Aspromonte Unit will be made to help define the geological evolution of Calabria-Peloritani terrains.

Contribution to a possible reconstruction of the Hyblean lithospheric column on the basis of deep-seated xenoliths from Miocene tuff breccias

ROSALDA PUNTURO (*)

Key words: *Sub-Hyblean lithosphere, deep seated xenoliths, petrography, petrophysics.*

INTRODUCTION

The occurrence of a variety of deep-seated xenoliths within Miocene diatremes and Quaternary lava flows from the Central-eastern section of the Hyblean Plateau (southern corner of Sicily) stimulated, over the last two decades, numerous research papers, some of which have been particularly devoted to understanding the sub-Hyblean lithosphere, whose nature is still matter of debate. Indeed, should it be considered part of the African continental block or, differently, can we envisage it as an old fossil ocean remnant? Since the geological implications of such two different models diverge, one should behold all of the currently available evidences, whose accurate analysis may allow reliable modelling to be set out.

In this paper, attention focuses on xenolith rich outcrops found within the Miocene tuff breccias from Valle Guffari (Fig.1a,b); this locality, because of the great variety as well as abundance in deep-seated xenoliths, may be considered as one of the most interesting in the Central Mediterranean area.

Our goal is to provide direct petrographic, compositional and petrophysical data which may contribute to define the nature of the sub-Hyblean lithosphere.

MAIN FEATURES OF DEEP-SEATED XENOLITHS

On the basis of petrographic and compositional featurs, collected xenolith population may be divided into: a) ultramafic, which consist of spinel facies peridotites and pyroxenites; and b): feldspar bearing suite, mostly represented by metabasite rocks and anorthosites. The size of many specimens ranges from about 2 to 30cm (most abundant 6-8cm); the shape is rounded and most of them are relatively fresh and suitable for our purposes.

Spinel facies peridotite (harzburgite and lherzolite), they show protogranular and (rare) porphyroclastic texture, with

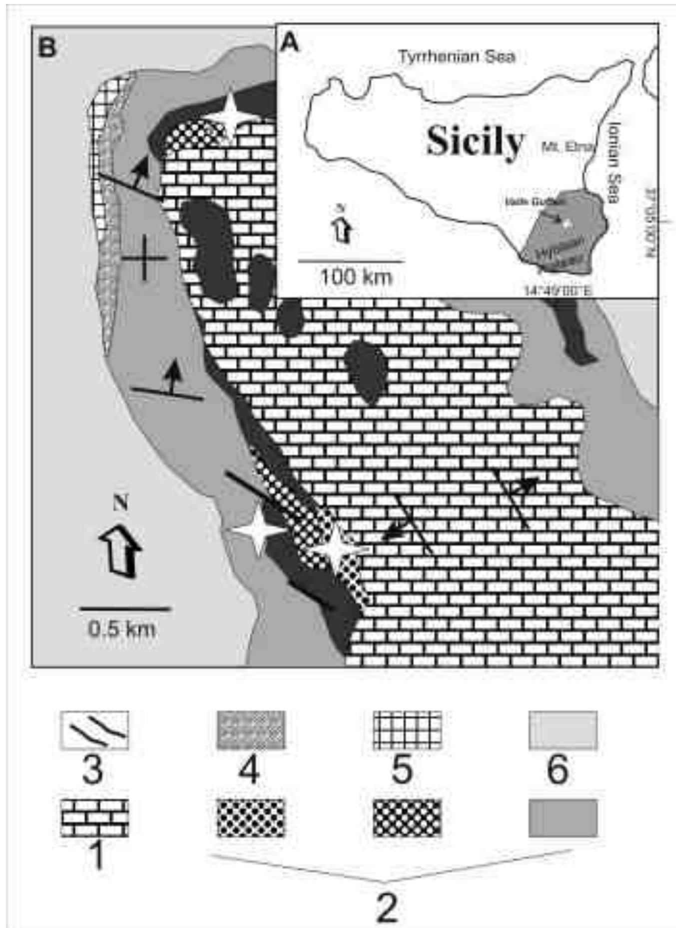

Fig.1- A): Location of the Hyblean Plateau (Sicily). B): Geological sketch map of Valle Guffari. 1. Calcareous marlstone; 2. Tuff breccias containing different xenoliths. Breccias are distinguished into three sub-facies on the basis of grain size and layering. 3. Dykes. 4. Poorly layered marly limestone. 5. Breccias with fragments of pillow lavas. 6. Tholeiitic sub-aerial lavas. (modified after PUNTURO *et alii*, 2000)

equigranular mosaic texture being very rare. Intergranular glass and veinlets of metasomatic glass are ubiquitous. Olivine and orthopyroxene are kink-banded, whereas Cr-diopside and Cr-spinel are smaller in size (Fig. 2 a, b). Moreover, it is worth noting that some of them exhibit evidence of either cryptic and modal metasomatism, this latter testified by phlogopite occurrence.

Spinel-bearing pyroxenites consist of Cr-diopside websterite, Al-augite websterite, spinel and garnet clinopyroxenite, with

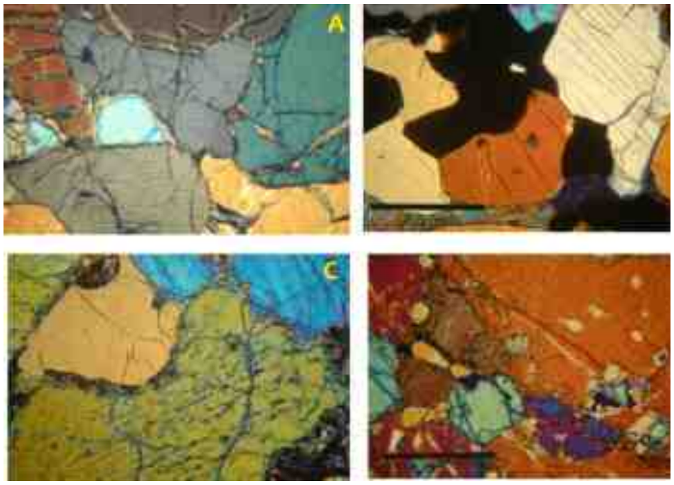

Fig.2 - Selected photomicrographs of ultramafic xenoliths. A: protogranular peridotite. B: Holly leaf shaped spinel in peridotite. C, D): Pyroxenite. Exolution lamellae within pyroxene.

intergranular glass ubiquitous. Cr-diopside websterite, which very often occurs as veins within peridotite, exhibits xenoblastic granular or polygonal texture; Garnet (Py54.5Alm32Grs13.5) may be also present. Al-diopside websterite exhibits polygonal texture, with strongly exoluted pyroxene (Fig.2c). Sub-solidus re-equilibrated garnet and (very rare) amphibole may also occur. Finally, Al-augite pyroxenite rocks, which are the ultracoarse specimens (>20mm) are not very abundant; they exhibit igneous cumulitic texture, with some neo-blastic sub grains. Pyroxene megacrysts are well preserved.
As far as the inaccesible crust, it is represented by feldspar bearing metabasite rocks and anorthosite (Atzori *et alii*, 1999; Scribano *et alii*, 2006; Punturo, 2010).
Moreover, PT estimates carried out on pyroxenite specimens, provided equilibration values of about 0.98GPa at 740°C (spinel pyroxenite) and 1.32 GPa at 1040°C (garnet pyroxenite). Unfortunately, no reliable PT conditions could be obtained from metabasites because of evident disequilibrium features; nevertheless, we can rely on Nimis & Ulmer (1998) calculations, which provided P values of 0.5 GPa for clinopyroxene within gabbros.

PETROPHYSICS

Petrophysical investigation has been carried out on three lithotypes considered to be representative of the Hyblean lithosphere: spinel harzburgite, pyroxenite and metabasite. On these samples, which were cut into 43mm edged cubes, seismic properties (Vp, Vs, density, seismic anistropy) were determined as a function of pressure (up to 600MPa) and temperature (up to 600°C at 600MPa), with a multianvil apparatus (see Punturo et alii, 2000). For the three lithotypes, average compressional velocities range from 7.15 km/s (harzburgite) to 7.46km/s (pyroxenite) to 6.41km/s (metabasite). Similarly, shear wave velocities are 4.02km/s, 4.22km/s and 3.59km/s. As far as Vp-related seismic anisotropy, values are 2.02% and 1.26 in ultramafic xenoliths, whereas it drops down to 0.91% in metabasite. Nevertheless, all of the three specimens are characterised by very weak shear wave splitting within the foliation plane (0.08km/s). Density at 600MPa and 600°C ranges from 3.295g/cm^3 (pyroxenite) to 2.958g/cm^3 (metabasite).

OPEN QUESTION: THE LITHOLOGICAL MODEL

Even though xenoliths provide us direct information about the inacessible portions of the lithosphere, it is not easy to reconstruct the Hyblean column. Attempts are based on petrographical and compositional features, which also provided pressure-tempeature estimates, and on petrophysical data; these latter may permit available geophysical data to be constrained and interpreted at a better extent. One important point is related to the representativeness of xenoliths “sampled” by diatremes: in the case of the Hyblean area, it is worth noting the lack of some typical crustal lithologies (e.g. granitoid rocks, felsic granulite, low and medium grade metamorphic rocks). So, several features should be analysed and compared in order to embrace any diverging thesis, i.e. continental *versus* oceanic nature of the sub-Hyblean lithosphere.

Quartz deformation mechanisms in shear zones inferred by quantitative microstructural investigation: the case study of Kavala (Rhodope Massif, north-eastern Greece)

ROSALDA PUNTURO (*), ROSOLINO CIRRINCIONE (*), EUGENIO FAZIO (*), PATRIZIA FIANNACCA (*), HARTMUT KERN (°), KURT MENGEL (+), GAETANO ORTOLANO (*), ANTONINO PEZZINO (*)

Key words: *Quartz grain size, progressive deformation, strain rate, seismic properties, granodiorite.*

INTRODUCTION

As it is known, the quantification of strain within shear zones improves our comprehension of crustal scale geological processes, like syn-shearing pluton emplacement.

To this aim, we studied the Kavala (Symvolon) syn-tectonic pluton, which crops out in north-eastern Greece and is mainly composed of early-Miocene granodiorite. The pluton represents the south-western termination of the Rhodope Core Complex, which was exhumed as a result of large scale extension from mid-Eocene to mid-Miocene times.

DINTER et alii (1995) constrain the intrusion and incipient mylonitization of the these granodiorites at 21-22 Ma (zircon and titanite U-Pb dates and hornblende Ar-40/Ar-39 dates), suggesting that the plutonic body resided at temperatures between 300 and 500 °C for 5-7 m.y., during which coaxial deformation may have continued.

Field investigation highlighted the presence of a NE-SW monotone stretching lineation consistent with the shape elongation of the outcropping pluton, whose intensity in deformation increases towards the contact with the host gneiss.

By taking into account the progressive deformation in the shear zone, we collected a sample suite of representative mylonitic rocks.

Lavoro eseguito nell'ambito del progetto P.R.I.N. 2007 'Strain rate in mylonitic rocks and induced changes in petrophysical properties across the shear zones (MIUR fund 20104005015).

QUANTITATIVE MICROSTRUCTURES

On thin sections cut parallel to the stretching lineation and perpendicular to the main foliation plane, we performed quantitative microstructural investigation; re-crystallised quartz domains were investigated by optical assisted-image technique.

Quantitative analysis on quartz grains (800 ca. grains per sample) revealed axial ratio (AR, i.e. the ratio between major and minor axis of particles) ranging between 2.2 and 17); grain size ranges from 1 to 70 μm^2 (median value= about 23 μm^2).

Moreover, we also determined quartz c-axis orientations, whose patterns provided us information concerning the shearing temperature range (350-550 °C) that, in this case, was in turn influenced by heat transfer during the pluton emplacement. Petrographic evidence confirmed the above aspects, since even at the microscale, magmatic and mylonitic textures coexist.

Deformation mechanisms of quartz have been therefore studied by applying flow-law equation proposed by HIRT et alii (2001) and by using the re-crystallised quartz piezometer calibration of STIPP & TULLIS (2003). For the selected specimens, the shear stress has been inferred to be in the range 10-100 MPa. with a mean shear strain rate of 4×10^{-8} (s^{-1}).

Results obtained are in agreement with field observations, which suggest an increasing strain gradient in the pluton; in addition, they testify as our samples are distributed across the regimes 2 and 3 of quartz dynamic recrystallisation (HIRTH & TULLIS, 1992).

PETROPHYSICAL INVESTIGATION

Finally, our attempt was also to correlate quantitative microstructural features with petrophysical aspects. To this aim, we carried out a petrophysical investigation at confined pressure conditions (up to 400 MPa), which highlighted that seismic properties are related to the structural frame of the rock. Indeed, compressional waves are oriented with maximum values within the foliation plane, with Vp related seismic anisotropy ranging from 2.16 to 6.92%. Shear wave acoustic birefringence shows its maximum along the stretching lineation direction. Vp/Vs ratios

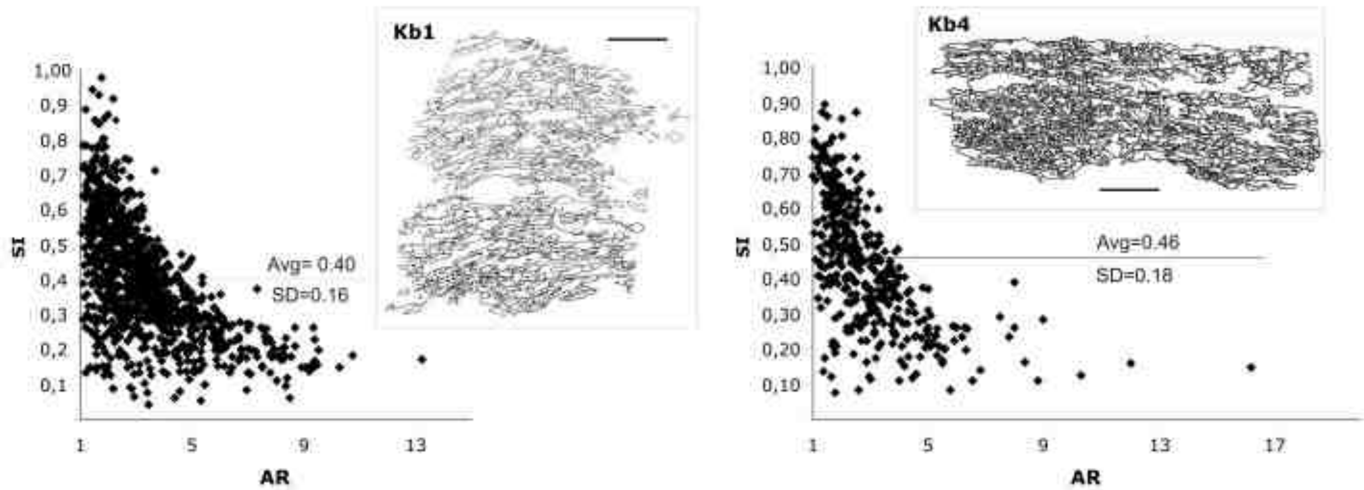

Fig. 1 – Quantitative microstructural analysis performed on two specimen (Kb1 and Kb4) showing an increasing finite strain. The shape index (SI) is grain-size independent and is calculated as follows: SI= $4\pi A_i / P_i^2$ where A_i is the area and P_i the perimeter of each grain. The scale bar in the inset showing the grainboundary map of quartz domain is 75 µm.

are in the range of 1.67 – 1.70.

This multi-scale approach, which spans from field aspect to laboratory scale, opens new perspectives in the calculation of strain rate of progressively natural sheared rocks.

Petrologic constraints on post-Variscan andesite dyke magmatism in the Sila Massif (northern Calabria)

VANESSA ROMANO (*), ROSOLINO CIRRINCIONE (*) PATRIZIA FIANNACCA (*), ANNUNZIATA TRANCHINA (*) & IGOR M. VILLA (**)

Key words: *andesites, calc-alkaline, dyke magmatism, Sila Massif.*

INTRODUCTION

During the late Paleozoic-early Mesozoic huge volumes of plutonic and volcanic rocks, as well as widespread basic to acidic dyke swarms, were produced.

This magmatic activity was related to extensional tectonics that took place after the final stages of the Variscan continental collision, causing wrenching and faulting of the crust and subsequent continental break-up leading to the definitive Jurassic opening of the Tethys ocean (e.g., WILSON *et alii*., 2004).

In south-western Europe the dyke magmatism shows a well defined time distribution in terms of magmatic affinity (calc-alkaline, alkaline and tholeiitic; OREJANA *et alii.*, 2008 *and references therein*).

Calc-alkaline magmas were mainly produced during the Permo-Carboniferous and are now disseminated throughout Europe.

Late- to post-Variscan dykes also outcrop in the Calabria Peloritani Orogen (CPO; Southern Italy), but information on the petrological features and geodynamic meaning of the CPO dyke magmatism is still very scarce, with only very few studies up to now carried out in both the northern (Sila Grande; FESTA *et alii*., 2010 *and reference therein*) and southern sector (Serre Massif; ROMANO *et alii*., 2011) of the orogen.

In this study, we report information about the petrographic features, mineral chemistry, whole-rock major and trace elements and Sr-Nd isotopic composition of a dyke crosscutting the late-Variscan granitoids of the Sila batholith (MESSINA *et alii*., 1991a,b; AYUSO *et alii*., 1994) in the area of the Lake Ampollino (Sila Massif, northern Calabria).

DISCUSSION

Lake Ampollino dyke has a tabular shape and is 3 m thick; it shows sharp contacts with the granitoid host rocks and a total absence of deformation or metamorphic transformations.

Dyke samples have a porphyritic texture, with phenocrysts of euhedral and normally zoned plagioclase (An_{52-37}) and minor subhedral K-feldspar (Or_{95-100}) set in a fine to medium groundmass mainly consisting of subhedral plagioclase, biotite ($Ann_{35}Phl_{15}East_{12}Sdph_{38}$) and less abundant quartz, K-feldspar and tiny amphibole (Fe-rich hornblende) grains. Opaque, titanite, zircon and acicular or stubby prismatic apatite grains complete the paragenesis. Chlorite, white mica, epidote and Fe-Ti oxides appear as secondary phases.

Lake Ampollino dyke shows an andesitic composition (SiO_2 = 59-61 wt.%) and a calc-alkaline affinity with a medium to high-K content.

Chondrite-normalized REE patterns are strongly fractionated (La_N/Yb_N = 8.1-8.9) and show a negative Eu anomaly (Eu/Eu* = 0.70-0.75), suggestive of plagioclase fractionation.

Primitive mantle-normalized trace element patterns (Fig. 1) show a general LILE enrichment relative to HFSE with peaks at Pb and negative Nb-Ta, Sr and Ti anomalies, i.e. typical features of subduction-related magmas (PEARCE, 1983).

All these geochemical features have been also observed in many other sectors of the Variscan chain, such as the Sardinia-Corsica Domain (SCD; ATZORI *et alii*., 2000; TRAVERSA *et alii*., 2003) and the closer Serre Massif in southern Calabria (ROMANO *et alii*., 2011) and they have been interpreted as the result of variable crustal contamination of magmas derived from

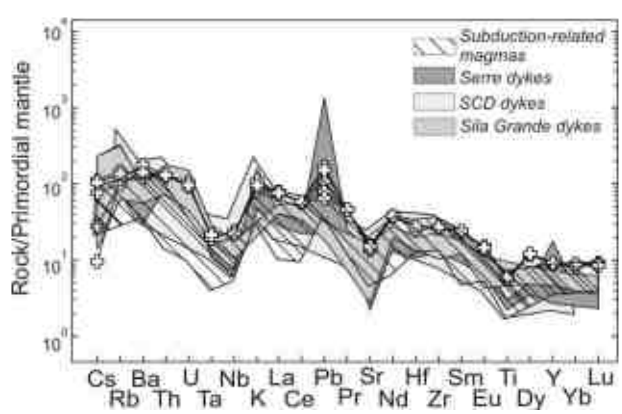

Fig. 1 –Trace element spiderdiagrams for Lake Ampollino dyke normalized to primitive mantle composition (MCDONOUGH & SUN, 1995). Subduction-related magmas from PEARCE (1983); SCD dykes from ATZORI *et alii.* (2000) and TRAVERSA *et alii.* (2003); Serre dykes from ROMANO *et alii.* (2011). Sila Grande dykes from FESTA *et alii*. (2010).

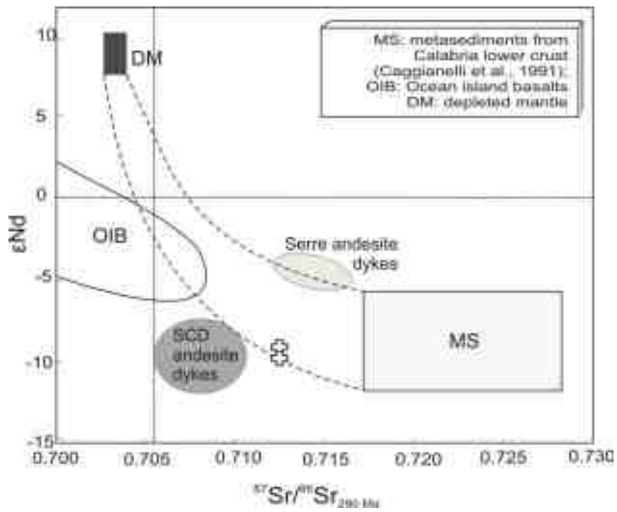

Fig. 2 – εNd vs. $^{87}Sr/^{86}Sr_{290\ Ma}$ diagram for Lake Ampollino dyke. DM: depleted mantle; MS: metasediments from Calabria lower crust (CAGGIANELLI *et alii*., 1991). Dashed curves are two possible mixing lines between DM and MS (ROTTURA *et alii*., 1991). Serre andesite dykes from ROMANO (2012); SCD andesite dykes from TRAVERSA *et alii*. (2003).

subduction-modified lithospheric mantle sources.

Sr-Nd isotopic ratios of the studied dyke recalculated at 290 Ma ($^{87}Sr/^{86}Sr_i$ = 0.7123-0.7125; εNd_i = from (-9.3) to (-9.8)) demonstrate a significant assimilation of crustal components.

In the εNd_i vs. $^{87}Sr/^{86}Sr_i$ diagram (Fig. 2), studied rocks plot indeed in the enriched portion of the graph, along a line of possible mixing between melts from a depleted mantle source and the Calabrian metasedimentary crust (CAGGIANELLI *et alii*., 1991, ROTTURA *et alii*., 1991), suggesting interaction with metasedimentary crustal rocks.

CONCLUSION

This study has provided a petrographical and minero-chemical characterization of an andesitic dyke, intruded in the late-Variscan granitoid rocks of the Sila batholiths and cropping out near the Lake Ampollino (northern Calabria).

This dyke is characterized by a porphyritic texture and a mineral assemblage consisting of plagioclase, biotite, K-feldspar, quartz and amphibole, in order of decreasing abundance.

The studied rocks show a calc-alkaline affinity and have field and geochemical features very similar to those observed in a number of post-orogenic magmatic products widespread in many other sectors of the Variscan chain.

In this study, in agreement with previous models proposed for post-Variscan andesite dykes from the Mediterranean area (e.g., ROTTURA *et alii*., 1998; CORTESOGNO *et alii*., 2004), the specific trace elements and isotopic compositions of the studied dyke are considered to be consistent with generation of the andesite magma by interaction of melts derived from subduction-modified lithospheric mantle sources with crustal rocks.

Structural and petrological investigations on a crustal-scale ductile shear zone in the Sila Piccola Massif: new geodynamic implications for the Castagna Unit (Northern Calabria, Southern Italy)

SACCO V. (*), CIRRINCIONE R. (*), ORTOLANO G. (*), PEZZINO A. (*)

Key words: *Poly-orogenic evolution, Shear zone, Sila Piccola Massif*

INTRODUCTION

In the Alpine stacked-nappe edifice of the Calabrian Peloritani Orogen (CPO), the "Castagna Unit" (DUBOIS & GLANGEAUD, 1965) represents a pervasively mylonitized horizon consisting of medium-high grade metamorphic rocks (mostly paragneiss, augen gneiss, leucocratic orthogneiss and minor micaschist, marble and amphibolite gneiss), intruded by late-Hercynian granitoid rocks. This unit, entirely cropping out in the northern CPO (both in the Sila Massif and Coastal Chain), is located in the lower-intermediate position within the Calabride continental crust (OGNIBEN, 1973). An integrated structural and petrological study has been performed in order to reconstruct the tectono-metamorphic history of this discussed portions of the Calabrian crystalline basement.

This study, focused on the Sila Piccola area (Fig.1a), delineates an intricate poly-orogenic tectono-metamorphic evolution mainly related to the ductile deformative event responsible of the pervasive mylonitic fabric. Yielded results allowed to better elucidate the geological significance of the Castagna Unit within the complex geodynamic framework of the northern sector of the Calabria Peloritani Orogen.

MESO- AND MICRO-STRUCTURAL INVESTIGATIONS

Structural and micro-structural analysis on orthogneiss and paragneiss, highlighted as the pervasive and well developed mylonitic fabric (S_m)(Fig.1b) obliterated previous metamorphic surfaces, locally preserved as relics in the low strain domains of the metapelitic horizons. A retrograde syn-mylonitic metamorphic overprint, developed under upper amphibolite to lower greenschist facies conditions has been also identified.

Petrological investigations of these preserved micro-domains in mylonitic metapelite allowed reliable P–T constraints to be detected. The observed *quasi*-absent crystal zoning in garnet porphyroclasts (Fig1.c) has been interpreted, here, as a petrological evidence of pervasive re-homogenising effects of garnet interiors supporting the hypothesis of long residence time at high T conditions in the lower crust. Moreover, the narrow high-Mn rim content in the garnet crystals suggested a clear evidence of a retrograde metamorphism.

(*) Dipartimento di Scienze Biologiche, Geologiche ed Ambientali- Università degli Studi di Catania, Corso Italia, 57-95129 Catania, Italy.

INTEGRATED PT CONSTRAINTS

Thermodynamic modelling, by means of pressure-temperature (P-T) pseudosection computations, in the MnNaCaKFMASH system (Fig.1f), was performed taking into account the narrow retrograde garnet rims, allowing to obtain reliable P–T contstraints with P ranging from 5.7 to 6.8 Kbar at average T of 595 °C, probably consistent with the early stages of the retrograde metamorphic trajectory related to the shearing event at upper amphibolite facies conditions. Unfortunately, pre-shear parageneses resulted not useful to give reliable information about the prograde evolution or the peak metamorphic conditions due to the pervasive re-homogenizing effects involving the prograde aseemblages.

A combination of microstructural and petrological investigations, mainly in the leucogneiss horizons, allowed the late stages of this syn-mylonitic retrograde evolution to be reconstructed. In detail, the *c*-axis pattern analysis allowed to infer the shearing temperature consistent with lower greenschist facies conditions (i.e. 400-450 °C) as supported by a dominant basal <*a*> activated slip system with subordinate evidence of prism *c*-slip system activation, consistent with higher shearing temperature (Fig.1e).

The observed bi-modal compositional distribution of phengite content in the syn-shear white mica (Fig.1d) suggested the hypothesis of two different baric regimes related to the ductile deformative event. The high-phengite white mica, with Si a.p.f.u. 3.23-3.40, is probably related to an higher pressure mylonitic stage (400 to 800 MPa) (Fig.1g); the low to intermediate phengite one (e.g. Si a.p.f.u.3.00-3.23) has been here interpreted as relic of a previous mylonitic stage developed at lower pressure conditions (< 400MPa).

CONCLUSIONS

New implications about the deformative and metamorphic history of the Castagna Unit support the hypothesis of two different mylonitic events (Fig.1h). The former one is characterized by a HT-LP mylonitic event (D1) showing an early metamorphic stage ($D1_A$), constrained by means garnet isopleths thermobarometry in the low strain domains of mylonitic metapelite horizons, and a later stage ($D1_B$) identified, mainly by the analysis of the leucogneiss horizons, taking into account the low-phengite content in the syn-shear white mica and the quartz LPO pattern analyses. The following retrograde stage locally developed HP-LT mylonitic overprint (D2), constrained through high phengite content in the syn-mylonitic white mica and the quartz *c*-axis orientation pattern investigations.

In this scenario, the "Castagna Unit" can be interpreted as a late to post-Hercynian shear zone, as also enhanced by field evidence of late-Hercynian undeformed leucocratic dikes crosscutting the mylonitic foliation, probably ascribable to the Sila batholith emplacement (GRAESSNER et alii, 2000) subsequently, locally, re-worked during the building of the Alpine Orogen, as supported by geochronological data reported in the literature of a 56My (BORSI & DUBOIS, 1968).

Orogenic metamorphism recorded in amphibolites from Liguride accretionary wedge (Southern Apennine-Italy)

MARIA T. CRISTI SANSONE (*), GIACOMO PROSSER (*), GIOVANNA RIZZO (**)

Key words: *amphibolites, Frido Unit, orogenic metamorphism, Southern Apennines.*

GEOLOGICAL SETTING

Ophiolites, attributed by many Authors to the Jurassic Tethyan ocean (VEZZANI 1970; AMODIO-MORELLI *et alii*, 1976; SPADEA, 1976; 1982; 1994; KNOTT, 1987, 1994; LANZAFAME *et alii*, 1979; TORTORICI *et alii*, 2009), are part of the Liguride Complex in the Southern Apennines (OGNIBEN, 1969). This fold-and-thrust belt developed between the Upper Oligocene and the Quaternary (PATACCA & SCANDONE 2007), during convergence between the African and European plates (GUEGUEN *et alii* 1998; CELLO & MAZZOLI 1999; DOGLIONI *et alii* 1999).

The Liguride Complex has been interpreted as the suture zone between the two converging plates and includes sequences characterized by an HP/LT metamorphic overprint (Frido Unit; VEZZANI, 1969) and sequences devoid of an orogenic metamorphism (North Calabria Unit, BONARDI *et alii*., 1988).

The Frido Unit has been interpreted as a portion of an accretionary wedge developed during the NW-oriented subduction of the Liguride sector of the Tethyan ocean (KNOTT, 1987, 1994; MONACO *et alii*, 1991; MONACO & TORTORICI, 1995). Ophiolites of the Frido Unit consist of serpentinites, metagabbros, metabasalt, diabase and a sedimentary cover (VEZZANI, 1970; SPADEA, 1982, 1994) characterized by blueschist-facies metamorphic imprint (HP-LT; SPADEA, 1994; SANSONE *et alii*, 2011; SANSONE *et alii*, 2012 in prep.).

According to CELLO & MAZZOLI (1999), the Frido Unit records an early orogenic event and a subsequent retrogression under the greenschist facies. However, this interpretation is not supported by the occurrence of glaucophane and Mg-riebeckite rimming tremolite-actinolite in metadolerite dykes (SANSONE, 2009; SANSONE *et alii*, 2011). Thus minerals related to the HP-LT overprint outlast the greenschist assemblage, the latter interpreted as originated in a oceanic environment (SANSONE *et alii*, 2012 in prep.).

PETROGRAPHICAL FEATURES

Amphibolites occur as tectonic slices associated with strongly retrograded gneisses. They are few meters to some tens of meters thick, display a banded fabric and a granoblastic texture. Mineralogical assemblage is composed of: brown and/or green hornblende, plagioclase, blue amphiboles, pumpellyite, chlorite, quartz. Accessory phases are titanite, apatite, opaque minerals, Fe-hydroxides, zircon and epidote. Amphibolites are crosscut by planar and transverse veins containing: quartz, pumpellyite, blue amphibole, albite, chlorite and Fe-hydroxides.

The brown hornblende has subidiomorphic habit and high relief. Some crystals have rims, coronas or show partial replacement by blue amphibole. Evident inclusions of apatite, opaque minerals, epidote and zircon are present.

The crystals of green hornblende. have subidiomorphic habit and high relief. Some crystals have rims or coronas of blue amphibole.

Plagioclase crystals in the matix are intensely altered into sericite and saussurite. The pumpellyite is pseudomorphic after plagioclase. In veins albite show xenomorphs habit and deformation twinnig.

Blue amphibole occurs as coronas rimming brown amphiboles or as single crystals. They show xenomorphic habit

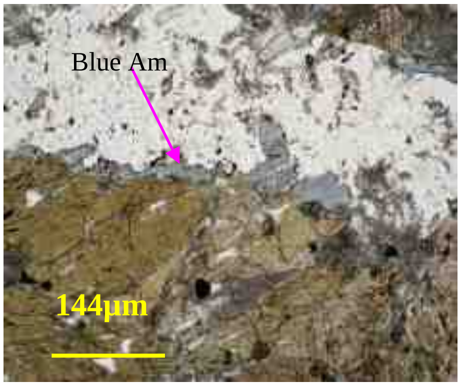

Fig. 1 – Blue amphibole coronas at the border of an albite-quartz vein.

(*) Dipartimento di Scienze Geologiche, Università degli Studi della Basilicata – Potenza.

(**) Dipartimento di Chimica, Università degli Studi della Basilicata – Potenza.

and high relief. Blue amphibole is more frequent along the border of the albite-quartz veins (Fig. 1).

CONCLUSIVE REMARKS

The petrographical study of amphibolites of the Frido Unit (Southern Apennines) shows HP/LT blue amphiboles occurring in the veins, corona and rim developed at the expense of brown and/or green amphiboles.

Orogenic HP/LT metamorphism records the underplating of the ophiolitic suite, together with slabs of continental crust rocks, at the base of the Liguride accretionary wedge during subduction of the western Tethys.

Mineralogical assemblage developed is typical of the lawsonite-glaucophane facies. This event is documented by coronas and rim developed from brown and green amphiboles in amphibolites and by singles crystals of blue amphiboles in the veins.

Migmatization processes in the Sila Unit of the Northern Catena Costiera (Calabria, southern Italy)

MARIA ROSA SCICCHITANO (*), FRANCESCA LIBERI (**) & EUGENIO PILUSO (*)

Key words: *Calabrian Arc, lower crust, migmatites, post-Variscan evolution, P-T pseudosection.*

INTRODUCTION

The studied rocks belong to the deepest portions of the Variscan continental crust section which constitutes the highest structural element of the Northern Calabrian Arc (fig. 1). This lower crustal level consists mainly of Grt-Bt gneisses, Cpx-Opx granulites, migmatites, metaultramafic rocks intruded by Permo-Triassic gabbros. The Variscan and late-Variscan metamorphic evolution has been defined by several authors (GRAESSNER & SCHENK, 2001 in the Sila massif; FORNELLI *et alii*, 2002 and ACQUAFREDDA *et alii*, 2006 in the Serre; PILUSO & MORTEN, 2004 in the Catena Costiera); in particular, a migmatitic event has been evidenced at 295 Ma by GRAESSNER *et alii* (2000).

New petrographic, geochemical, petrological and geothermobarometric data carried out on the migmatites cropping out in the Northern Catena Costiera suggest that a second migmatitic event affected these rocks during a decompression stage that testify for a lithospheric thinning. This fact, together with the emplacement of Permo-Triassic gabbros at the base of the crust, may be related to a rifting geodynamic framework that marks the beginning of the Alpine cycle.

Of course, only geochronological data could validate or not this hypothesis. For such reason, we characterized for the first time monazite grains observed in four migmatites samples of the Northern Catena Costiera by Scanning Electron Microscopy in order to investigate their microstructural relationships and their chemical zoning. This is the critical step to select the suitable domains for the subsequent electron microprobe and isotopic analyses.

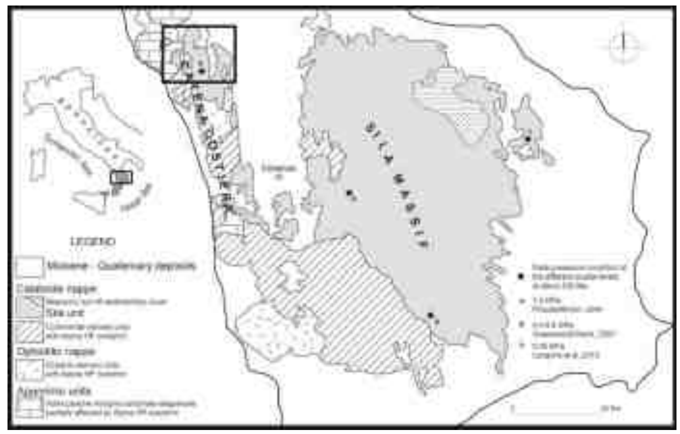

Fig. 1 – Geologic sketch map of the Northern Calabrian Arc (from LIBERI *et alii*, 2011).

THERMOBAROMETRY AND CONCLUSION

The tectonometamorphic evolution of the migmatites outcropping in the Northern Catena Costiera follows a clockwise P-T path (fig. 2) similar to those suggested by GRAESSNER & SCHENK (2001) in the Sila Massif, FORNELLI *et alii* (2002) and ACQUAFREDDA *et alii* (2006) in the Serre Massifs and PILUSO & MORTEN (2004) in the Catena Costiera. According to ACQUAFREDDA *et alii* (2006), the prograde stage of the migmatites cropping out in the Northern Catena Costiera likely occurred in the kyanite stability field but the subsequent thermal equilibration caused the disappearance of this phase. The first anatectic event started at the H_2O-saturated solidus at $P > 0.7$ GPa and $T \approx 670\text{-}680$°C and proceeded firstly with a Ms dehydration-melting reaction at $P > 0.8$ GPa and $T \approx 740\text{-}770$°C and then with a Bt dehydration-melting reaction at $P > 0.7$ GPa and $T \approx 800$°C. The metamorphic climax at P-T conditions of 0.8-0.9 GPa and 800°C was followed by an isothermal decompression during which the first melt crystallization led again to the Bt stability field. During this decompression stage, a new anatectic event occurred by a Bt dehydration-melting at $P < 0.7$ GPa and $T \approx 780\text{-}800$°C; the second melt final crystallization occurred at the H_2O-saturated solidus at $P < 0.4$ GPa and $T \approx$

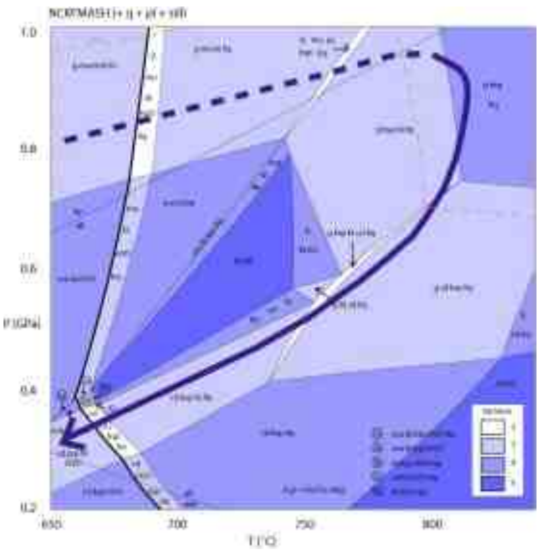

Fig. 2 – P-T pseudosection constructed using the XRF composition of a nebulitic sample showing a clockwise P-T path for the migmatites of the Northern Catena Costiera. Compositional isopleths for Grt are shown as dashed lines.

660-670°C. GRAESSNER & SCHENK (2001) and PILUSO & MORTEN (2004) refer the first anatectic event to a Variscan collisional stage, whereas FORNELLI *et alii* (2002) and ACQUAFREDDA *et alii* (2006) sustain that melting begins during a collisional stage and proceeds during subsequent decompression event.

A second anatectic event characterized by an extensive biotite dehydration-melting was recognized for the first time in the migmatites of the Catena Costiera. This anatectic event might be due to heating related to the Permo-Triassic gabbros emplacement, which have a minimum cooling temperature of about 800°C at 0.55 GPa (LIBERI *et alii*, 2011).

Migmatite Structures development in the Austroalpine continental basement (Valpelline unit) during Permian extension

MICHELE ZUCALI[1,3], PAOLA MANZOTTI[2], VALERIA DIELLA[3], CLAUDIO PESENTI[1,4], MARIA IOLE SPALLA[1,3], LUCIA GOVETTO[1]

Key words: *Migmatite, Austroalpine, basement, Permian.*

INTRODUCTION

The Valpelline unit is a km-sized slice of continental crust constituting part of the Austroalpine Dent Blanche nappe (NW Italy). Its pre-Alpine evolution holds important aspects for the Palaeozoic crustal structure at the northern margin of the Adria continent, for the history of rifting in the Alpine region, and thus for the thermo-mechanical regime that preceded the onset of the Alpine convergence (Gardien et al. 1994; Manzotti, 2011; Manzotti et al., 2012).

Pre-Alpine P-T-d-t paths demonstrate that the Valpelline unit experienced an early re-equilibration under intermediate pressures amphibolite facies conditions and a following migmatite stage (Manzotti and Zucali, 2012). This latter deeply influenced the rheology of deforming rocks during Carboniferous and Permian, mainly due to viscosity and fabric gradients generated by the heterogeneous distribution of melt. U-Pb dating of accessory phases (zircon and monazite) indicates a Carboniferous to Permian age for the migmatite formation.

The Crati Valley Extensional System: field and subsurface evidences

FRANCESCO BROZZETTI (*), DANIELE CIRILLO (*), FRANCESCA LIBERI (*), ELENA FARACA (**) & EUGENIO PILUSO (**)

Key words: *Northern Calabrian Arc; Crati basin; Quaternary extension; field mapping; seismic profiles interpretation; detachment fault*

INTRODUCTION

Since the Middle Miocene, the Calabrian arc registered the onset of narrow basins within which a clastic marine succession deposited with an eastward-younging trend: from the Serravallian in the Amantea basin (MATTEI *et alii*, 2002) to Tortonian-Messinian in the Fagnano basin, and to Pleistocene in the Crati graben (LANZAFAME AND ZUFFA, 1976; TORTORICI *et alii*, 1995; SPINA *et alii*, 2011). There is no agreement on the tectonic context in which such succession sedimented but, in spite of the different interpretations, all the cited authors agree that extensional tectonics affected the Crati basin during the Pleistocene and that, at least since the Middle Pleistocene, it drove its tectono-sedimentary evolution.

Three main extensional fault systems striking NE-SW, NW-SE and N-S were recognized to develop during the extensional phase in northern Calabria (VAN DIJK *et alii*, 2000; CIFELLI *et alii*, 2007; SPINA *et alii*, 2009, 2011; TORTORICI, 1982). According to TORTORICI (1982), the former two fault systems were active during Miocene and Pliocene times, whereas the NS-striking system, generated during the Early Pleistocene, would be presently active. We investigated these subjects through structural analysis along the faults and by interpreting three commercial seismic reflection lines (locations in Fig. 1b) that were the basis to draw, acrossing the central part of the Crati basin. These lines allowed us to draw, a balanced geological section, interpreted down to the depth of 8 km, The section is strictly constrained at surface by published geological map and new collected field data.

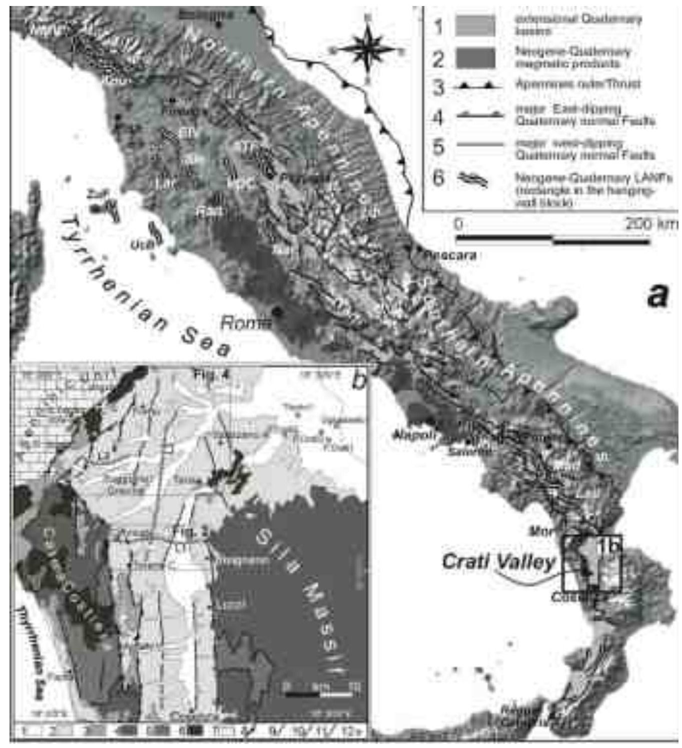

Fig. 1 – a) Structural sketch map of the Apennines showing the Quaternary extensional fault systems and Neogene-Quaternary LANFs recognized in the literature. (b) Geological sketch map of the Crati graben in the northern Calabrian Arc context. 1: Holocene deposits, 2: Plio-Pleistocene deposits, 3: Miocene deposits, 4: Variscan continental crust (Sila unit) not affected by HP metamorphism, 5: Continental-derived units with HP metamorphic overprint, 6: HP-LT Ophiolite units, 7: carbonate shelf Apenninic units, partially affected by HP overprint, 8: Quaternary east-dipping, major normal faults, 9: other Quaternary normal faults, 10: tectonic contacts, 11: Seismic line trace, 12: Borehole locations.

THE CRATI BASIN

The Crati graben is placed between the Calabrian Catena Costiera, to the west, and the Sila massif , to the east. Both these ridges are structural highs formed by a crystalline basement complex consisting of a nappe stack emplaced during Eocene-Early Miocene times, and the an dissected, during the Quaternary, by a set of N-S and NNW-SSE NS striking extensional faults. The basin infill consists of two upper Pliocene - lower Pleistocene transgressive cycles (fan-delta conglomerates, sands and clays), followed upward by Middle-

* DiSUT – Università degli Studi “G. D’Annunzio” Chieti-Pescara

** Dipartimento di Scienze della Terra, Università della Calabria, Arcavacata di Rende (CS)

Upper Pleistocene marine terrace deposits (reddish conglomerates and coarse sands with minor grey siltites) and recent alluvial sediments. The geological architecture is strongly controlled by the extensional tectonics. Meso-structural data are consistent with a N-S trending major fault bounding westward the basin. The contractional and strike slip deformations described in the Pliocene units (VAN DIJK *et alii*, 2000; TANSI *et alii*, 2007; SPINA *et alii*, 2011) do not affect the Quaternary succession, that is instead broadly displaced by N-S and NNW-SSE striking normal faults. These latter are particularly widespread in the central part of the basin;. Neverthelessand their kinematics, the kinematics of the faults surveyed in the outcropping Pleistocene deposits is unambiguously extensional.

SUBSURFACE DATA

Three seismic lines (reported in Fig. 1, as L1, L2 and L3) from the Vi.D.E.P.I. project (joint venture among the Italian Economic Development Ministry, Assomineraria and Italian Geological Society), available at http://unmig.sviluppo economico.gov.it/videpi/ (Vi.DE.PI., 2011), have been investigated the deep geometry of the Crati basin. In particular, their seismic interpretation highlighted suggests that this basin is driven by and east-dipping master fault, named herein after the North Calabria Detachment Fault (NCDF), which has been active at least since the Early Pleistocene. The seimic image of the NCDF corresponds to a major east-dipping reflector that reaches the surface along the eastern slope of the Catena Costiera Calabra, and dips eastward at an average angle of 30°. The subsurface geometry of the syntectonic deposits, their structural setting and the detailed review of their stratigraphy suggest that the high-angle normal faults, branching upward from the NCDF, and mapped in the field, are characterized by a progressive eastward-younging. The most recent of these splays bounds westward the present (Holoceneic) floodplain of the Crati river.

Seismic and field data were integrated to draw the Cervicati – Santa Sofia d'Epiro section (L1), which was subsequently interpreted and restored. The restoration was performed through the Move2011 package and; it allowed us to estimate the total extensional component and the cumulative displacement associated to the NCDF in the central part of the Crati graben. Along the section the estimate of the overall extension reaches the 3.8 km, equivalent to the 36% of the pre-extensional length. Considering that the onset of the NCDF should slightly pre-date the oldest documented sin-tectonic deposits, it is reasonable to suppose that the beginning of the fault activity is not younger than the Early Gelasian (~2.58 My) This values allowed us to obtain a long-term extension rate close to, of ~1.6 mm/y

CONCLUSIONS

Surface data and seismic lines interpretation, converge to highlight that the Quaternary evolution of the Crati basin was driven by a persistent extensional stress in field characterized by a nearly E-W minimum compression-extension axis.

The main expression of the Quaternary extension is a regional scale detachment fault, named the North Calabria detachment fault (NCDF), outcropping along the eastern border of the Catena Costiera, at least from S. Fili to as far as Saracena. The NCDF is associated to a constant top-to-east average sense of shear and directly determined the shape, the deep geometry and the tectono-sedimentary setting of the Crati basin. In fact, it behaves as the detachment horizon of both the sinthetic and antithetic high-angle fault sets, bounding westward and eastward the Crati basin. The NCDF geometry is characterised by a major fault plane showing a marked staircase trajectory, reaching the depth of nearly 7 km below the inner side of the Sila Massif. The flat-ramp geometry exerts a marked control on the hanging wall deformation and appears to strongly influence the preferential location of the high-angle splays and their depth of branching from the detachment.

The new-collected field data suggest that the NCDF was uninterruptedly active at least since the Early Pleistocene. On the other hand, surface and sub-surface data agree in excluding post-Pliocene contractional or trascurrent structures.

The NCDF gave rise to an asymmetrical extensional system in which the displacement occurred on the east-dipping fault set (>4km) largely exceeds that occurred on the antithetic set (~1.5 km). Due to the lower dip-angle of the east-dipping faults, also their contribute to the finite extension clearly prevails.

Finally the reconstructed extensional system and its kinematic evolution agree with the available data on the Late Pliocene to recent exhumation and uplift in the northern Calabria.

Morphometric analyses and morphotectonic investigations in the Romagna Apennines: preliminary results

RICCARDO CAPUTO (*), NARESH RANA (*, ^) & RISHIKANTA NGANGBAM SINGH (*, °)

Key words: *seismotectonics; morphotectonics; tectonic geomorphology.*

INTRODUCTION

In order to better understand the recent landscape evolution and in the attempt of quantifying the influence of (active) tectonics in the Romagna sector of Northern Apennines, we are carrying out a research project focusing on the morphometric analyses and morphotectonic investigations of the area. Two basic Remote Sensing approaches have been applied for this purpose: 1) the digital processing of a high-resolution (10 m) Digital Elevation Model provided by Regione Emilia-Romagna and 2) a detailed stereographic analysis of a complete set of IGM panchromatic air photos (1:25,000).

Morphometric analyses

A number of models have been suggested for explaining the coupling of tectonics and geomorphic processes during landform development, while several studies have been made to infer tectonic process rates by documenting the shapes of these landforms (*e.g.* BURBANK and ANDERSON, 2001). The first investigation approach applied to the whole area allowed to extract the principal morphometric parameters.

Firstly, the DEM grid has been processed with the Hydrology tool (ArcGIS) to fill the pits and to create accumulation and flowdirection grids in order to obtain i) water divide, ii) stream network and iii) stream orders of the major drainage basins.

Secondly, the major morphometric parameters like drainage density, terrain roughness, swath profiles, sinuosity index, hypsometric integral and hypsometric curve have been extracted from the DEM grid applying different ArcGIS tools and other specific softwares (Streamprofiler, Excel, Matlab).

Additionally, long profiles (*e.g.* HACK, 1973) have been systematically obtained for major stream orders (Fig. 1), while the k_{sn} (normalized channel steepness; *e.g.* SNYDER *et alii*, 2000) has been quantified both linearly and areally using ArcGIS, Matlab and Surfer software packages (Fig. 2).

Morphotectonics investigations:

The second investigation approach allowed to recostract the 3D geometry of the terraced surfaces associated with the fluvial and valley evolution. In particular, the detailed analysis of airphotos observed in stereographic view allowed to carry out a precise mapping of all terraced surfaces giving emphasis to their inner and outer edges.

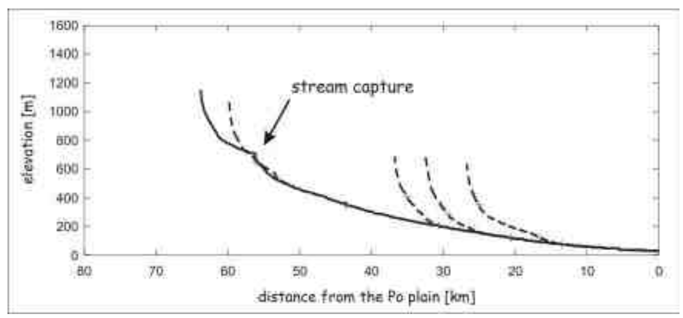

Fig. 1 – Example of longitudinal profile of the main trunk (blue) of Montone River with its major tributaries (pink). Major knick-points (crosses), picked from the gradient vs drainage area graph (see below), stress river gradient anomalies. These anomalies have been checked with respect to local geology to exclude lithological effects. The knick-point marked by the arrow has been correlated to an important stream capture, possibly caused by lateral tilting.

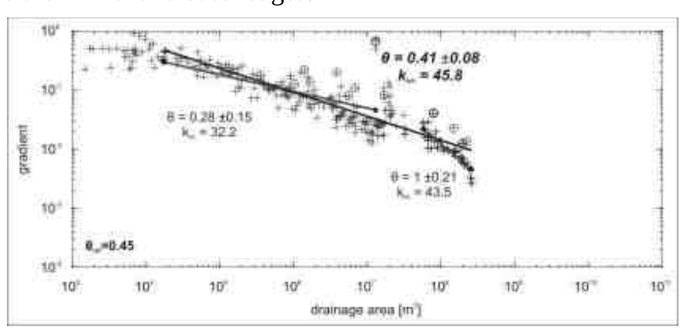

Fig. 2 – Example of gradient vs drainage area from the Montone hydrographic basin. The regression line suggests an intermediate uplift-rate as compared to the regional trend. The graph can be separated into three sectors characterised by progressively decreasing concavity values (θ) and associated with different behaviour of the stream: colluvial (< ca. 10^4 m^2), bedrock channel (10^4-10^7 m^2) and alluvial channel (> ca. 10^7 m^2). Local peaks in data distribution document slope anomalies.

Lavoro eseguito nell'ambito del progetto DPC-INGV ed in collaborazione con Regione Emilia-Romagna.

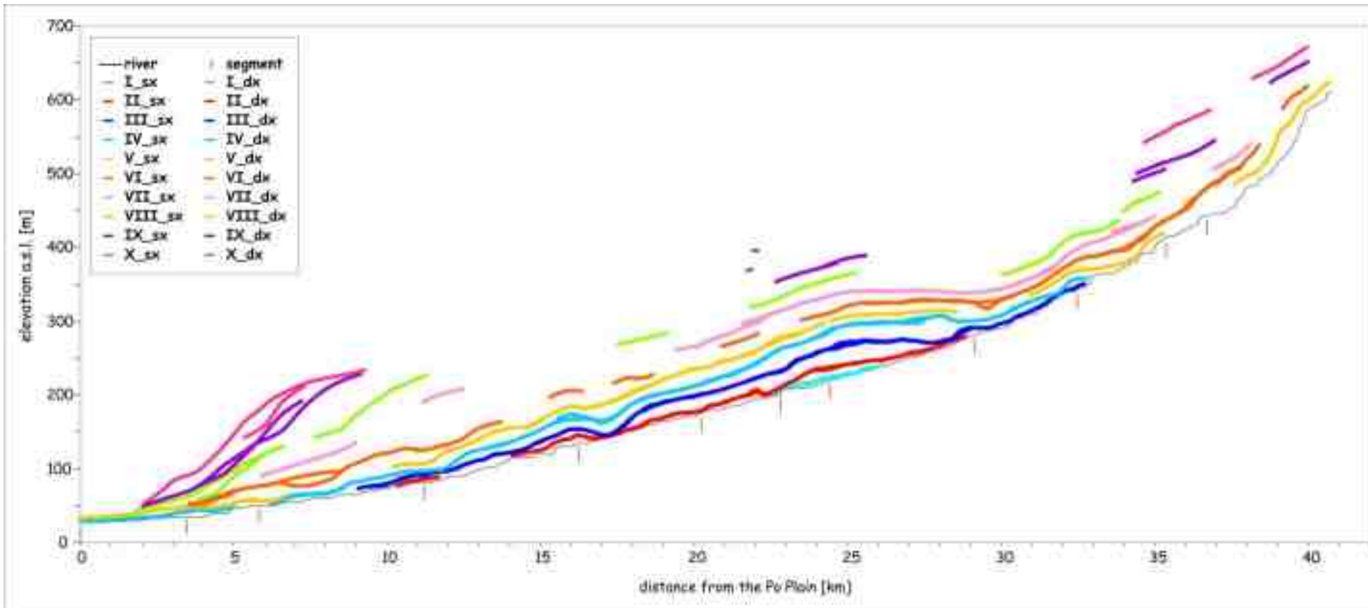

Fig. 3 – The fluvial terraces mapped along the lower reach of the Montone River and projected on a rectified profile running parallel to the valley axis. At least 11 order of terraces have been recognised showing clear evidence of recent folding as emphasised by the anticline and syncline symbols. The location of the major and minor anticlines (blue) and synclines (purple) are also shown.

The information from airphotos is then transfered to large scale topographic maps with regular countour intervals at 5 m and auxiliary coutouring at 1 m. The obtained morphological information was also completely vectorialised and georeferenced.

Field work was then performed to verify the results of the remote sensing approach as well as the reliability and the precision of the mapped features.

Based on this procedure (described in more detail by CAPUTO *et alii*, 2008) it was possible to systematically read out the altitude of the inner edges with an uncertainity of few meters. This information is used to reconstruct a rectified profile along the valley axis on which it is possible to project the mapped fluvial terraces (Fig. 3).

Although this multidisciplinary project is still in progress , the preliminary results clearly show evidences of recent tectonic activity. In particular, the several orders of fluvial terraces document the regional uplift affecting the whole region, while local anomalies of the morphometric parameters as well as geometric anomalies of the fluvial terraces suggest the occurrence of some major fault-propagation anticlines, which are likely caused by relatively shallow, but blind, reverse faults representing out-of-sequence-structures in the frame of the orogenic wedge characterising the Romagna Apennines.

Tectonic and sedimentary evolution of the Ofanto thrust-top basin

M. CESARANO (*), E. CASCIELLO (**), P. ESESTIME (***) & G. PAPPONE (°)

Key words: *Southern Apennines Allochtonous, Apulian Platform, buttressing, Pliocene-Pleistocene, flexural normal faults.*

INTRODUCTION

The Ofanto basin is a wide synclinorium, about 30 km in length, located between the axial and external zones of the Southern Apennine chain and characterised by an unusual E-W trend (Fig. 1). The substratum of this Pliocene basin is formed by pelagic units of the Southern Apennines Allochtonous (SAA) (i.e. Sicilide and Lagonegro Units), with overlying Late Miocene siliciclastic deposits of the Castelvetere Flysch. Well data constrain the age of thrusting of the SAA on the Apulian Carbonate Platform as Early Pliocene in this sector of the chain. Coeval to the migration of the SAA was the deposition of Pliocene marine sediments of the Ariano Unit on top of the translating thrust sheets. The E-W trend of the Ofanto synclinorium represents an anomaly in the regional NW-SE structural trend of the Southern Apennines, which has been attributed either to major (lithospheric) strike-slip faults (Ortolani 1974; Schiattarella et al. 2005), or to the effect of deep thrust faulting in the Apulian Platform (Hyppolite et al. 1994).

This work integrates the analysis of the synorogenic Ofanto basin together with the interpretation of about 300 km of reflection seismic lines and well data to define: a) the syntectonic characteristics of the Ofanto basin infill and its age based on new biostratigraphic studies; b) the 3-D geometry of the Ofanto basin evolving during the coeval emplacement of the SAA and subsequently deformed by the shortening that affected the underlying Apulian carbonate platform; c) the tectonic evolution and timing of deformation of this segment of the Apennine fold and thrust belt.

THE BASIN INFILL

To investigate the filling of the basin, field mapping was integrated with sampling for planktonic foraminifera along 10 stratigraphic sections in order to increase the database found in the literature (Hippolyte et al. 1994). The main outcome of this study is the recognition of three generations of conglomerates, spanning in age from Early Pliocene to Early Pleistocene and characterised by an approximately centrifugal distribution with respect to the E-W trend of the Ofanto syncline. These conglomerates together with their unusual distribution along the northern margin of the basin indicate that tectonic activity controlled the location and evolution of depocentres.

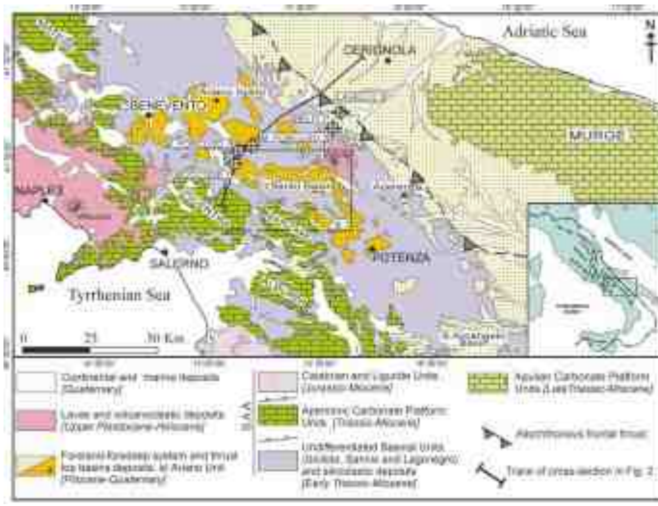

Fig. 1 – Geological map of the Southern Apennines with the location of the Pliocene-Pleistocene East-West trending Ofanto Basin

SEISMIC INTERPRETATION

The subsurface structural setting of the Ofanto basin was investigated using borehole data and the interpretation of a 2D seismic grid with a total length of approximately 300 km. The primary objective of this analysis is to define the geometry of two key surfaces: 1) the base of the Pliocene infill of the Ofanto basin, and 2) the top of the Apulian Carbonate Platform. All the studied seismic sections show an overall asymmetry of the basin's profile with the northern margin more steeply inclined than the southern one and all sections show that the base of the Pliocene basin is involved in thrust deformation. The southern and northern margins are deformed by north-verging thrusts and by south-verging back-thrusts, respectively, that have also been recognised in field-based studies (Fig. 3) (Casciello & Cesarano, 2000).

Seismic sections indicate that a large normal fault in the Apulian carbonates is present below the northern margin of the Ofanto syncline. The M. Forcuso 1 and the Ciccone 1 wells are drilled in the footwall and hangingwall of this normal fault and indicate a vertical displacement exceeding 1 km. In addition, the Ciccone 1 well encounters a lower Pliocene breccia in the hangingwall of the normal fault that suggests a Late Miocene –

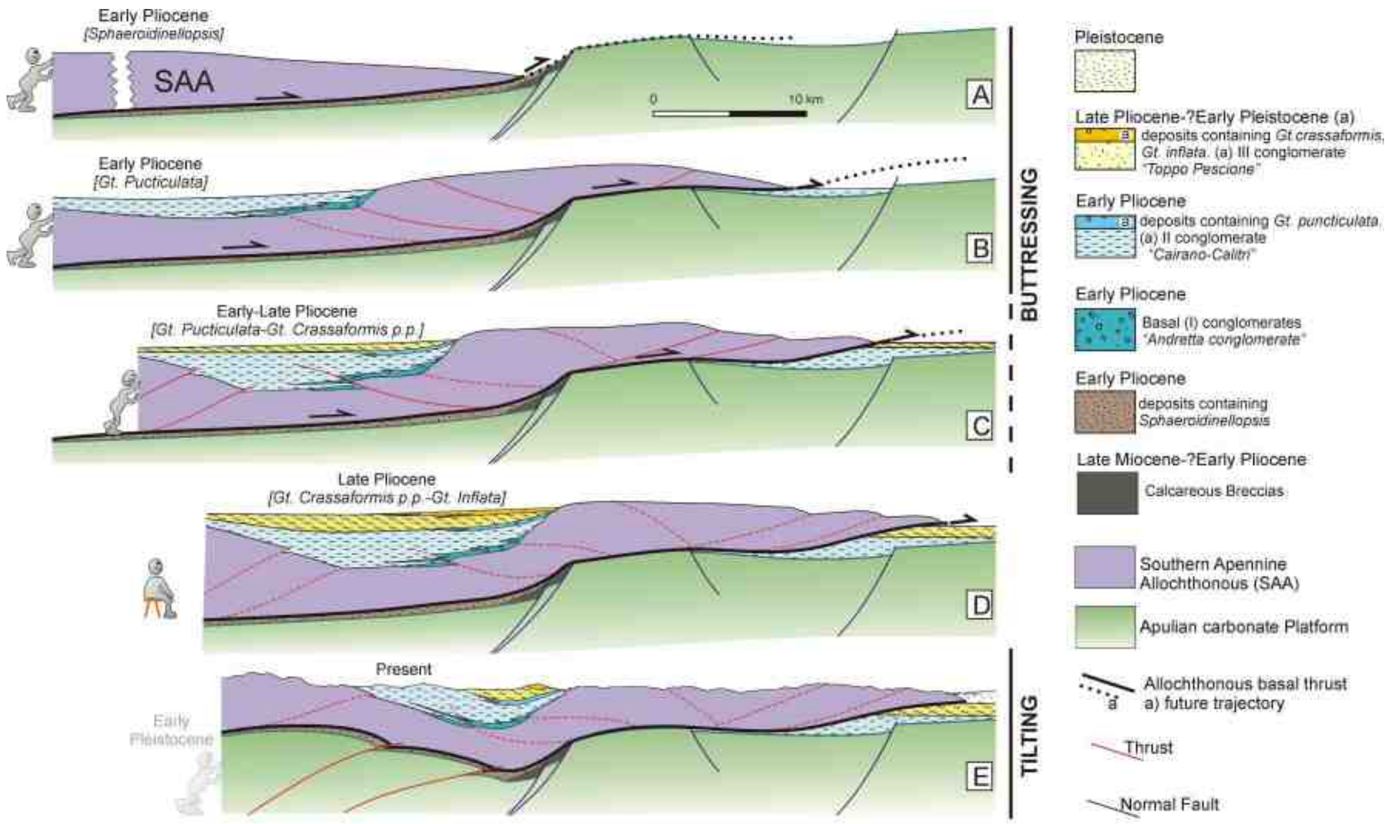

Fig. 2 – Cartoon illustrating the tectonic and sedimentary evolution of the Ofanto thrust-top basin during the Pliocene and Pleistocene. N.B. vertical distance not to scale, horizontal scale is approximate.

Early Pliocene age for this normal fault. Conversely, the lack of Pliocene deposits and of the post-Cretaceous section in the wells M. Forcuso 1 and 2 suggest erosion of the uplifted footwall block. The fault displacement does not propagate up-dip into the Allochthonous, presenting a fault-tip at the level of its basal thrust, indicating that normal fault activity occurred prior to its emplacement.

A different set of structures involving the Apulian carbonates is represented by reverse/thrust faults, and associated folds, which displace the basal thrust of the Allochthonous. These contractional structures are thus posterior to the emplacement of the SAA thrust sheets. The overall trend of these thrusts in the Apulian carbonate platform is NW-SE.

CONCLUSIONS

Two consecutive stages, marked by different tectonic processes, characterise the evolution of the Ofanto basin.

The first stage, lasting throughout the Early Pliocene (post 5.33-3.57 Ma) and possibly extending into the lowermost part of the Late Pliocene, is the main translation of the SAA over the Apulian carbonate platform, which behaved as the inactive footwall, passively influencing the emplacement of the Southern Apennine Allochthonous with its pre-existing structures (Fig. 2 A-C). The main tectonic process resulting from this interaction is the buttressing and thickening of the Allochthonous against the escarpment of the normal fault and the development of the Ofanto syncline. In a later stage, almost certainly Early Pleistocene in age, the footwall of the SAA (i.e. the Apulian carbonates) became involved in the shortening and developed NW-SE trending reverse faults that cut through the basal thrust of the SAA (Fig. 2E). The net result of this stage of tectonic activity is the eastwards tilting of the Ofanto syncline and broad NW-SE folding of the Late Pliocene-?Early Pleistocene conglomerate around the western termination of the basin.

Geodynamic constraints of the peri-Tyrrhenian orogen (Tyrrenian Sea-Apennines) from lineament swarm analysis

PAOLA CIANFARRA(*) & FRANCESCO SALVINI (*)

Key words: *Lineament, stress field, Tyrrhenian orogen*

Regional geodynamics is responsible of a series of effects that notably include tectonics and seismicity. They in turn control the morphology of the surface of the planet. The regional dimension of the peri-Tyrrhenian orogen reveals that its evolution is deeply involved in a lithospheric scale dynamics. As a result, we expect different observable and/or measurable effects at the various scales from the outcrop evidences to the sub-continental deformation corridors. Effects at the various scales not necessarily are directly related, and their relations should be carefully understood taking into account both their geometry and spatial distribution. A classical example is represented by an en echelon system. Each single fracture is the effect of a local extension, yet their spatial distribution shows that these local stresses are the effect of a larger scale shear zone with a different orientation.

Remotely sensed images proved the existence on the Earth surface of linear features with dimensions spanning over three order of magnitude: from hundreds of meters to thousand of kilometers. Such features are referred to image lineaments and are generally related to alignment of morphological features in continental environment such as onshore crests, ridges, valleys and troughs. In the oceans lineaments relate to the scars associated to the seafloor spreading and fracture zones. Synthetic scale images of tectonically active regions revealed the existence of groups of regional scale lineaments on the earth surface appearing as image textural anisotropies. They clusters around preferential orientations to form lineament domains. These domains occupies well defined areas to form lineament swarms.

Lineament domain analysis on regional scale images of the Earth surface proved a useful tool to investigate regions characterized by active tectonics (Wise et al., 1985; Funiciello et al., 1977; Cianfarra & Salvini, 2008).

Both the Tyrrhenian Sea and the Apennines are geodynamic blocks within the collisional puzzle between Africa and Europe in the Central Mediterranean area.

In this work we explore the possible relations between these two blocks by lineaments analysis. The found lineament domains were interpreted as reflecting the structural grain of these two geodynamic regions. Lineament detection was done by using original automatic methods. Domains were identified by statistical analysis. This work analyses lineaments detectable by simulating different directions of lighting condition on the DEMs. This allowed to properly evaluate the influence of the light condition changes in the lineaments produced by morphological features. The comparison among the analyses showed that the different lighting conditions induce rotations of few degrees of the mean azimuth of each lineament domain. This rotation relate to the result of two contrasting effects: tectonics, that tends to enhance linear morphologies, and erosion that progressively smoothes them. Lineament domains characterised by small rotations relate to morphologies where the tectonic processes prevail on the erosional ones. Lineament domains therefore have rotations inversely proportional to their tectonic activity.

The active faults bordering the Lunigiana and Garfagnana grabens (Northern Apennine): new constraints from knickpoint analysis

DI NACCIO D. (*), BONCIO P. (*), BROZZETTI F. (*) & PAZZAGLIA F.J. (**)

Key words: *active fault, knickpoint, Northern Apennine, SL-index.*

INTRODUCTION

The fluvial network is extremely sensitive to active tectonics and geomorphic analysis has the potential for providing insights into tectonic forces acting on the landscape, styles and patterns of deformation.

This work integrates existing structural-geological data with a new detailed geomorphic analysis of the fluvial network to characterize active and potentially seismogenic faults bordering the Lunigiana and Garfagnana basins in the Northern Apennine.

The two basins are NW-SE-oriented asymmetric grabens, bordered by several normal faults of poorly known recent slip history. The faults belong to sets of NE-and SW-dipping splays that sole into a major crustal detachment that plays an important, but not fully understood role in the deformation and uplift of the Northern Apennines. The location of the faults is well-constrained at the surface and at depth (ARTONI *et alii.,* 1992; CARMIGNANI *et alii*, 2000; CAMURRI *et alii.*, 2001; CARMIGNANI *et alii*, 2001; BERNINI & PAPANI, 2002; ARGANANI *et alii* , 2003; BROZZETTI *et alii*, 2007) and several medium-to-high energy earthquakes have occurred in the area in the last millennium (ROVIDA *et alii*, 2011), documenting that the area is one of the most seismically active of the Northern Apennines. Withal, lack of reliable instrumental seismological data on large earthquakes, very low deformation rates, and poor exposures of faulted Quaternary sediments, make problematic the identification and parameterization (e.g. fault length, slip rate..) of active and possibly seismogenic faults.

Computation of geomorphic indexes for the studied area consists of: a) stream profile analysis, including channel longitudinal profiles (stream-wise distance and elevation), contributing drainage area and Stream Length gradient index (SL); b) slope area analysis, including profile steepness and concavity; and c) knickpoint analysis, including their geometry and distribution.

In particular, convex segment of logitudinal profiles, called knickpoints, have been specifically investigated to evaluate coincidence with tectonic perturbation. Though a number of knickpoints seem to be influenced by local lithological factors, most of those measured along a number of major normal fault have a clear tectonic origin.

GEOLOGICAL SETTING OF THE LUNIGIANA AND GARFAGNANA GRABENS

The Lunigiana and Garfagnana grabens are part of a series of Early Pliocene to Quaternary NW-SE trending active extensional faults and intra-mountain basins that extend along the western side of the Northern Apennine.

It is characterized by a nearly 80 km long NW-SE oriented system of extensional structures which dissect the contractional structures of the Apennine orogeny.

The normal faults develop within an about 30-km wide asymmetric extensional zone, formed at the hangingwall of a NE-dipping low-angle detachment fault (LANF) (ARTONI *et alii.*, 1992; CAMURRI *et alii.,* 2001; ARGNANI *et alii.,* 2003). This was inferred to be the northern termination of a regional-scale system of NE-dipping LANFs (Etrurian Fault System, BONCIO *et alii.,* 2000) extending along the entire northern Apennines (BARCHI *et alii.,* 1998; BONCIO *et alii.,* 1998). At depth the basal detachment shows a staircase geometry with sub-horizontal flats (<10°) and moderately-dipping ramps (up to 45°) that can be traced down to a depth of about 12-15 km in seismic lines.

The NE-dipping faults generally have lower dip angles (30°-60°, increasing from W to E) compared to the SW-dipping faults (50°-70°). Moreover, the NE-dipping faults generally have higher cumulative displacement (>4 km) than the SW-dipping faults (up to 2.5 km). The easternmost NE-dipping faults (i.e. the faults closest to the graben axis) and the easternmost SW-dipping faults (the most far from the graben axis) are characterized by strong geomorphic evidence and are considered as late Quaternary, possibly active, normal faults (BROZZETTI *et alii.,* 2007).

Between the southern termination of the Lunigiana graben

(*) Dipartimento di Scienze Umanistiche e della Terra

(**)Department of Earth and Environmental Sciences, Lehigh University, Bethlehem, PA-USA

and the northern termination of the Garfagnana graben, there is a nearly E-W-striking, N-dipping fault zone with normal-oblique right-later kinematics. This fault zone delimits to the north the Apuane metamorphic core and was interpreted as a presently active transfer fault between the Lunigiana and Garfagnana extensional grabens (North Apuane Transfer Zone in BROZZETTI *et alii.,* 2007)

CHANNEL AND BASIN ANALYSIS

The relationships between the faults and watershed-scale geomorphology have been quantified using a 10 m digital topography to extract channel and basin metrics.

Alluvial rivers typically shows concave-up long profiles, referred to a graded, equilibrium profile. Deviations from a smooth, concave-up form may indicate that the fluvial system is in a transient state of adjustment to a base level due to tectonic, climatic, or rock-type perturbation.

In particular, the primary mechanism of landscape response to such perturbations is reflected by upstream migration of convex segments, called knickpoints (CROSBY & WHIPPLE, 2006; HARKINS *et alii.,* 2007).

Analysis of the longitudinal profile of the main channels in the Lunigiana (12 watersheds) and Garfagnana (19 watersheds) basins, have been accompanied by the well known power law relationship between channel gradient and upstream drainage area (SNYDER *et alii.,* 2000):

$$S = k_s A^{-\Theta} (1)$$

In equation (1) the long profile concavity (Θ) and steepness (k_s) are the slope and y-intercept respectively of a line regressed through a log-log plot of channel slope and drainage basin area.

The SL-index (HACK., 1973):

$$SL = (\Delta H/\Delta L)/L \ (2)$$

(where ΔH is elevation, ΔL is length of stream reach, and L is the total stream length measured from the divide to the midpoint of the stream reach under investigation) is very sensitive to changes in channel slope (KELLER & PINTER, 1996) and has been used to evaluate the relationship among possible tectonic activity, rock resistance and topography. Only the first order streams, are used because the lower orders best reflect tectonically controlled channel gradient variations in the landscape (MERRITTS & VINCENT, 1989). Furthermore the high variability of lithology outcropping in the studied area make difficult to separate and quantify the role of relative uplift and lithological resistance causing SL-index anomalies (knickpoints). Therefore, following the method proposed by GOLDRICK & BISHOP (1995), these effects were explored by considering the knickpoint elevation, measured on a trunk stream and on its tributary respect to their junction point. The knickpoint height associated to lithological variation yields likely different values for the trunk compared to its tributary. If the knickpoint, observed on uniform lithology, is the result of the same base level fall due to faulting at any point the channel records the same total height of this lowering. During the knickpoint upstream migration, the recorded height should logically be the same for the trunk channel and its tributary. Congruence between the values for the trunk and its tributary provides evidence that the knickpoint is due to faulting. Disparity does not exclude this, but it may result from a combination of lithological variation and base level change.

In the studied area, though a number of knickpoint seem to be influenced by local lithologic factors, most of those measured along a number of major normal fault have a clear tectonic origin.

In fact, the knickpoints closest to the fault trace, located in the footwall of the fault have heights that increase moving towards the centre of the fault and decrease towards the fault tips, mimicking the displacement profiles usually expected along fault segments (PEACOCK & SANDERSON, 1991; PEACOCK, 2002; KIM & SANDERSOND, 2005). This allow us to reasonably consider the knickpoint height as a proxy of the fault throw accumulated since the last equilibrium profile of the perturbed channel. Following this line of reasoning and assuming that the last equilibrium profile was reached mostly during the last interglacial period (Riss-Wurm interglacial 130-75 ka ago) was also inferred the late Quaternary throw rate of the investigated faults.

Finally, the variations of the knickpoint heights along-strike the faults (i.e. the throw profile) gives insights on the likely segmentation pattern of the fault system, with semi elliptical profiles probably indicating isolated segments, steeper profile gradients probably indicating fault interaction and bi-lobed or tri-lobed profiles probably indicating faults which are formed by two or three linked segments

A Multidisciplinary approach to define the Plio-Quaternary tectonics in the Termini Imerese Mts. (Northern central Sicily)

GENNARO C. (*), CONTINO A. (*), AVELLONE G. (*) & DI MAGGIO C. (*)

Key words: *structural geology, geomorphic analysis, quaternary faults, Termini Imerese Mts., Sicily.*

ABSTRACT

This paper aims to identify the Plio-Quaternary tectonic in a inner portion of the Maghrebian orogen (Termini Imerese Mountains, Sicily, fig. 1) using tecniques of quantitative geomorphic and structural analyses.

The Sicilian Maghrebide chain is made up of a stack of tectonic units formed during the Neogene. In this region, the lack of Plio-Quaternary basins with a syntectonic pattern prevents us from documenting the age of the most recent deformation, bringing about a need for a new approach for characterizing the Plio-quaternary tectonics.

The following were integrated: 1) geological and structural analysis for the recognition of the geometric relationships between the tectonic units and the reconstruction of the pre-quaternary deformation history; 2) geomorphic quantitative analyses to detect Quaternary tectonic events.

The structural analysis in the study area showed faults correlated to two main compressional tectonic events: 1) an early thrust system (with SW-ward vergence) and relative lateral ramps (destral N-S and sinistral EW oriented), consistent with a maximum compression oriented NE-SW, nearly horizontal (shallow-seated structures, see CATALANO *et alii*, 2000); 2) a later transcurrent and/or transpressive faults system, consistent with a maximum compression oriented N-S (deep-seated structures, see CATALANO *et alii*, 2000 and AVELLONE *et alii*, 2011). Furthermore, faults correlated with a extensional tectonic event, NW-SE and NE-SW oriented normal fault, have been recognized (according to CONTINO, 2005). On the whole N-S and E-W oriented transtensional fault are consistent with a nearly vertical maximum compression (fig. 2).

Recent techniques of quantitative geomorphic analysis highlight the control of the tectonics during the development of the river drainage and contribute to the recognition and characterization of Quaternary tectonic structures (BELISARIO *et alii*, 1999; DELLA SETA *et alii*, 2003); moreover, considering the small thickness of the Quaternary deposits, which does not easily record a possible tectonic control, we applied quantitative geomorphic analysis on the hydrographic network, since this develops during the Quaternary. The following specific steps were taken: 1) statistical analysis of the azimuthal distribution, by cumulative length, of the river

Fig. 1 – Structural sketch of northern central Sicily (modified from CATALANO *et alii*, 2011).

(*) Dipartimento di Scienze della Terra e del Mare, Università di Palermo, Via Archirafi 22 - 90123, Palermo, Italy.

Fig. 2 – Normal and trastensional faults along Termini Imerese quarry.

courses of different orders - river courses of the lowest order show cluster domains in the directions NW-SE, NE-SW, E-W and N-S; 2) analysis of spatial variation of the azimuthal spectra (BELISARIO *et alii,* 1999) performed by 21 transect, in order to recognize the transcurrent kinematics along the Quaternary faults - the latter are consistent, as regards kinematics and direction, with the NW-SE (right), NE-SW (left), N-S (right) and E-W (left) striking faults, individuated by structural analysis in the carbonate succession.

Finally, the application of various methods of investigation utilized enabled us to recognize how the geological structure and the river network of the studied area are influenced by Quaternary tectonics with a transcurrent kinematic component, documenting an overall congruency between hydrography and geological structure.

The various integrated methods of analysis represent a tool for the verification of every single result obtained.

Eastern Adriatic magnetic anomaly: an evidence for a Thetian thinned crust

P. MANCINELLI (*), G. MINELLI(*), C. GUGLIOTTA (*)

Key words: *Magnetic modeling, Adriatic sea, thinned crust.*

INTRODUCTION

This paper deals with the intriguing and still not extensively treated evidence of an high amplitude, long wavelength magnetic anomaly covering a large area of the north-eastern – central Adriatic Sea (Croatian offshore, Fig. 1). The presence of intruded gabbroid rocks in the Croatian archipelago (Jabuka Island, Fig.1) represents an additional open question. A 2D geophysical model and the derived conceptual geological section will be presented as realized along two sections (the NW-SE *Adria* profile and the WSW-ENE *L'Aquila-Sibenik* profile) which cross cut the magnetic anomaly (Fig.1). The model has been carried out by integration of surface and geophysical data (many of them already published), the latter concerning magnetic and gravimetric anomalies, tomographic and heat flow data. These data have been merged in an integrated data-base by using the MOVE software while geophysical modelling have been done using GM-SYS 4.7.

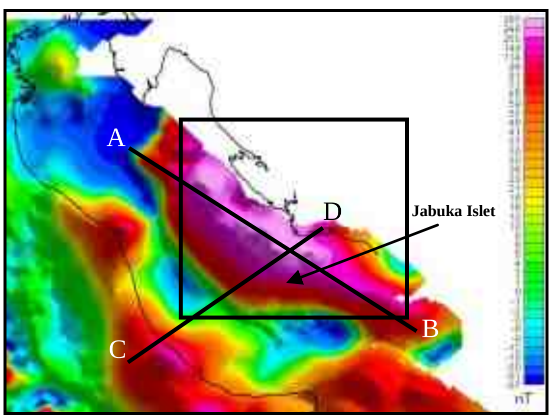

Fig. 1 – Integrated dataset Magnetic anomaly chart for Adriatic sea (mod. from Giori *et alii*, 2007). Study area in the square. A-B: trace of *Adria* profile; C-D: trace of *L'Aquila-Sibenic* profile (mod. from Giori *et alii*, 2007). A-B and C-D are traces of modeled sections in Fig. 3.

GEOLOGICAL SETTING

The central and north-east Adriatic region (External Dinarides and Adriatic foreland) is located in a complex geological framework which evolution and present-day deep-structural setting is still a matter of debate. In a wide geodynamic context (Fig. 2), this area occupies an intermediate position between the north-eastern-verging Apennine thrust belt (toward the West) and the south-west-verging Dinaric thrust belt (toward the East). The progressive, diachronous growing of these two thrust belts was accompanied by development of two superposed foreland basin systems, with opposite polarity and ages, having in the Adriatic Sea a common peripheral bulge zone. Both the present-day north-eastern - central Adriatic region and the External Dinarides developed following the long and complex evolution of a major lithospheric unit of African affinity known as Adriatic microplate or Adria (CHANNEL *et alii*, 1979; BOSELLINI, 2002). Carbonate platform-type deposition in these areas started in the Triassic and persisted up to the Eocene, punctuated by episodes of drowning or emersion (CIARAPICA & PASSERI, 2005). Extensional tectonics affected the Adriatic region since the Middle Triassic with extensive normal faulting also accompanied by gabbroid intrusions age-dated to 262-200 My (PAMIC & BALEN, 2005; JURACIC *et alii*, 2004 at Jabuka Islet, Fig. 1). Even if in the Croatian offshore there are no evidences of oceanic crust-derived rocks, the presence of those gabbroid intrusions suggest that a strong crustal thinning could have occurred at that time. As a result of the motion of the African and European plates, the latter overthrusted the Adriatic microplate causing the formation of the Dinaric orogen. According to KORBAR (2009; and references therein) the main tectonic deformation occurred since the Paleogene following a compression in north-eastern direction whose consequence is the present-day Dinaric thrust-belt. The upper portion of the sedimentary cover were affected by progressive thin-skinned deformation while the Adriatic foreland remained out of the deformation. After (Oligocene to Miocene), a late orogenic thick-skinned compressional uplift occurred masking primary thin-skinned deformations. Along the present-day coast of the Croatia, the Adriatic microplate is underthrusting the Dinarides (MORETTI & ROYDEN, 1988, KORBAR, 2009) along a north-eastern subduction observed in seismicity (KUK *et alii*, 2000). The subduction continues laterally into the Adriatic Sea extending toward and away from the island Vis, in the southern

Adriatic (according to SUMANOVAC, 2010).

Fig. 2 – Simplified present-day geodynamic scenario of the Central–Western Mediterranean region (mod. from CARMINATI *et alii*, 2012). The yellow square indicates the study area.

GRAVITY ANOMALIES, TOMOGRAPHY AND HEAT FLOW DATA

Both, tomographic and gravimetric data suggest the presence of an high velocity and cold volume beneath the Adriatic sea and the Dinaric chain. A large gravimetric positive anomaly results from residual mantle anomalies of the gravity field obtained filtering the crustal effect. In contrast surface gravity anomalies do not show the positive peak highlighted by TESAURO *et alii*, (2007). These observations suggest that the gravity anomaly is due to a deep, cold and high velocity body beneath Adriatic sea and Western Dinarides Chain. Considering Moho depth, lithospheric thickness and a simple Airy isostatic compensation model it results that across an hypothetical NW-SE transect there is isostatic compensation at Moho mainly explained considering that water column is quite thin and Moho depth remain around 30 km. Across an hypothetical SW-NE transect, Moho depth ranges between 30 and 40 km, this change don't allow a Moho isostatic compensation. Bouguer anomaly chart doesn't show the same clear resolution and this is probably due to different data acquisition methods and resolution (data are from MONGELLI *et alii*, 1975). For the entire Adriatic, observed heat flows range between 30-40 mW m^{-2} (SCROCCA *et alii*, 2003; TESAURO *et alii*, 2007 and references therein) suggesting a thermal gradient ranging about 35 °C Km^{-1}. This data fits with an high thickness, continental crust model. The only disagreement features with the previous hypothesis, it's the fact that the maximum flux in the Adriatic region is localized in the SAD (Southern Adriatic Depression) with flows rising over 80 mWm^{-2}, exactly above the maximum positive mantle gravity field potential anomaly.

MAGNETIC ANOMALIES

A long wavelength, positive anomaly which covers all the eastern central Adriatic, reaching over 300 nT, results from the magnetic total field anomaly chart (Fig.1). The cause of this anomaly haven't yet been clearly understood. Nevertheless, due to its regional dimension it could be caused by a deep, regional source. Considering an heat flow of 35 mWm^{-2} the thermal gradient obtained ranges about 30-40 °C km^{-1}, this means that, considering a Curie temperature of 580°C at atmospheric pressure (BLAKELY *et alii*, 2005), there is no permanent magnetization beneath 15-20 km. The magnetic anomaly shows a clear cut in its northern part (south the Istria peninsula, Fig. 1), and a clear western edge quite similar to the Italian coastline. The most important evidence imaged in Fig. 1 is the high intensity reached by the anomaly, its large extension and its progressive disappearing toward the Croatia onshore. Furthermore, it clearly shows a weak plunging trend toward SE which is very different in respect to the net cut registered toward NW.

GRAV-MAG MODELLING

A 2D modelling of magnetic anomalies has been carried out across two sections using different magnetic susceptibility and considering a Curie Temperature of 550°C and a Curie depth of 12-18 km considering an heat flow of 30-60 mWm^{-2} and a thermal gradient of 30-45 °C km^{-1}.

Bouguer anomalies have been also 2D modelled in order to constrain the magnetic model, this allow a better definition of the geometries of the anomalous bodies. Magnetic susceptibilities used during modelling ranges from 0.0001 CGSU, which is the average susceptibility for sedimentary rocks and 0.006 CGSU which is the average for gabbroid or basaltic rocks (TELFORD *et alii*, 1991). Null susceptibility have been used for the foreland infill and for all bodies below Curie depth. Densities used for the gravimetric modelling ranges between 2.3 g cm^{-3} for the foreland infill deposits and 2.9 g cm^{-3} for the deeper crustal basement according to previous gravimetric models (SUMANOVAC, 2010). Models in Figure 3 show as the main contribution to the anomaly is given by the depth and the geometry of the basement, being the relatively lower susceptibilities of Triassic-to-Pleistocene sequences. The most influential body (in red) is long about 250 km, thick more than 10 km and ranges from 2 km of depth to the Curie isotherm, its mean susceptibility is typical of gabbroid-basaltic rocks and its density is 2.7 g cm^{-3}.

CONCLUSIONS

The high magnetic anomaly recorded in front the Croatia coast till the middle of Adriatic sea can be related to regional-scale processes and a possible geodynamical evolution of Adria microplate can be turn out.

An infra-Triassic crustal rift due to a mantle plume rise in proximity of a passive margin produced isostatic uplift and Gabbroid intrusions. This process continued during the Jurassic but did not evolved to a complete oceanization of the crust.

The absence of sedimentation in the studied area from Jurassic to Paleogene as displayed on the available seismic reflection lines, could be explained in terms of the evolution of the Dinarides and Apennine thrust and fold belts respectively located

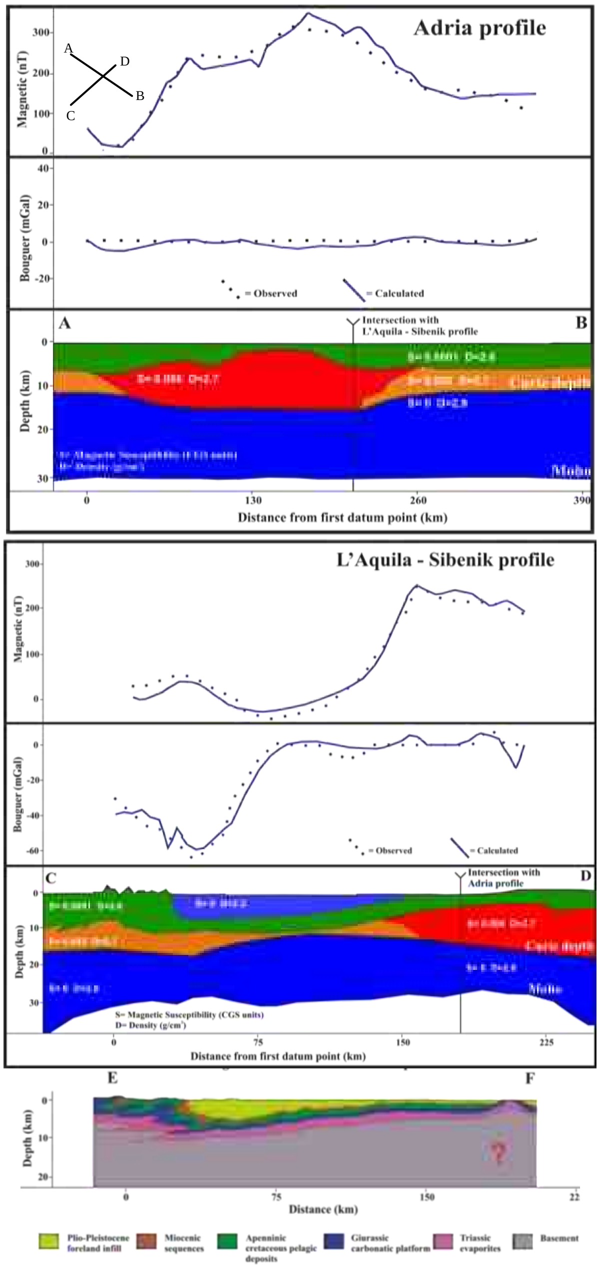

Fig. 3 – Magnetic and gravimetric model across the Adria (a) and L'Aquila-Sibenik (b) profiles; (c) geological cross section compared with the modeled L'Aquila-Sibenik profile. In (a) an heat flux of 30-60 mWs^{-2} with a thermal gradient of 30-50°C/Km gives a Curie depth (550°C) between 12 and 18 Km; in (b) an heat flux of 30-50mWs^{-2} with a thermal gradient of 30-40°C/Km gives a Curie depth (550°C) between 13 and 18 Km. Heat flux data from Scrocca *et alii* (2003). See Fig. 1 for position of modeled sections.

at East and West of the investigated area (Fig. 4).
In particular, since the Paleogene the Dinaric chain develops and the studied sector remain uplifted by peripheral bulging process of the thrust and fold belt system. In the Miocene the development of the Apennines thrust belt continued to bulging uplift till present day. In other words the studied area could had been a common peripheral bulge area of the two thrust belts.

Integrated analysis of quantitative geomorphic and structural geology: case study of the Caltanissetta Basin

CLAUDIO MUSCA (*), CARMELO GENNARO (**)

Key words: *central Sicily*, *quantitative geomorphic analysis*, *quaternary*, *quaternary transcurrent faults.*

INTRODUCTION

The "Caltanissetta Basin" is a vast area of central Sicily, from the upper Miocene to Pleistocene, has played the role of the foredeep respect to the emerging chain in the actually northern Sicily. According to a modern interpretation of this area of central Sicily represent a set of adjacent sedimentary basins, largely sintettonics, that covered the youngest and outer portion of the chain, which would show a deep tectonic duplex building. The intense tectonic activity have essentially changed this area of south-central Sicily. The most modern studies interpret it as the most forward part of the Maghrebian thrust belt, with formational mechanisms similar to those of the complexes of accretion, both on the ground (CRISTOFOLINI *et alii*, 1979; LENTINI, 1982; CARBONE *et alii*, 1982; LENTINI *et alii*, 1987; BIANCHI *et alii*, 1989; CARBONE *et alii*, 1989A) that offshore southern Sicily, where the overtrhusting of the foreland submerged sediments (CATALANO *et alii*, 1987; CATALANO, 1988; ANTONELLI *et alii*, 1988; ARGNANI *et alii*, 1987, 1989). This study is part of a PhD thesis addressed the structural geological analysis of a sector of the Caltanissetta basin between the latter is the city of Enna and south by the Braemi river that would provide also: 1) geological-structural analysis, 2) quantitative geomorphic analysis conducted on the river network for the study of quaternary tectonic events. The quantitative geomorphic analysis (CICCACCI *et alii*, 1986; BISCI *et alii*, 1988; CENTAMORE *et alii*, 1996, LUPIA PALMIERI *alii*, 1995, 1998; DAVOLI *alii*, 1999; CURRADO & FREDI, 2000; DELLA SETA, 2002, 2003, 2004, 2005) has as its goal the recognition of evidence of Quaternary tectonics in this area since the drainage network is developed during the Quaternary. Quaternary soils in the study area are: Capodarso sendstone, Geracello marly clays and sands of Lannari. Analytical techniques used consist of: a) in the statistical analysis of the azimuthal distribution of the rods river of different order, in order to discriminate the tectonic recent than the oldest and b) the analysis of the spatial variation of the azimuth spectra for the recognition of the kinematics along the transcurrent faults.

To enable this study methodology has been created a database, scanning the river system, including the areas covered in the left and right part of the southern Salso river; using as topographic map the tablets of the IGMI (scale 1:25.000) are been digitized, through the software ArcMap 9.3, all the possible routes of surface drainage and ranked according to the method of STRAHLER (1954).

Regarding the areal statistical analysis of the azimuthal distribution of the rectified river courses was conducted using the software Daisy 3 (SALVINI, 2001), recalling the previously created database.

The straight segments of river courses, for a combined length, have been analyzed separately for each of the different orders of rods to be able discriminate recent tectonic features of the older ones. Preliminary results of this analysis are represented through of the rose diagrams, in which the direction of the highest peak corresponds to that along which the majority of straight line segments, in terms of combined length; each peak corresponds one of the Gaussian curves recognized through the statistical analysis. The wind rose diagrams of the 1 st, 2 nd and 3 rd order have preferred orientations NW-SE and EW, while the growth of the order of the river courses (4 °, 5 °, 6 °, 7 ° and 8 °) other preferential flow directions appear as the NE-SW and NS. The presence of multiple alignments preferential to the growth of the order of river courses demonstrates the influence of tectonic structures on the development of the ancient river network. The structural station show plans of faults with direction NW-SE, NS and NE-SW perfectly congruent with the preferential alignments flow obtained with the analysis of the azimuthal distribution of river courses.

Was also carried out the spatial analysis variation of the azimuthal distribution of the hydrographic network (BELISARIO ET AL, 1999) of river courses of the same order. The method allows you to show transcurrent kinematics, considering the variation in space of the azimuthal distribution of the rods of 1 ° and 2 ° order, along a series of transects placed perpendicular to the fault alleged. The rods of 1 ° and 2 ° order are usually over 70% of the cumulative length of the entire river network.

With a fully automated process, along each transect, have been joined all the azimuthal spectra, each of which refers to a point referenced and regularly spaced along the transect. Each azimuthal spectrum, obtained by the respective frequency histogram corresponding, contains all the straight segments of the drainage pathways as a function of their distance from the corresponding point along the transept. The result of this process is a diagram in which the axis of the abscissa and the ordinate represent, respectively, the distance along the transept and azimuth values of the rods, between the angular values of 90° E and 90° W; each indent of the diagram represents the projection of the spectral peak at the relative azimuthal value and position along the same transect.

Have been so identified and reported in the country of strike-slip faults with NW-SE and NE-SW direction. In conclusion, the quantitative geomorphological analysis is a valuable tool in support of the classic structural survey; the application of this methodology on the not conservative rocks makes possible the structural analysis in those areas where outcrops extensive clay bodies. Moreover, the azimuthal variation of the river courses of 1 ° and 2 ° order from important indications on evidence of neotectonics in this area.

The interation of compressional and extensional tectonics during the Sicily Chain building

NAPOLI G. (*), NIGRO F. (°) & RENDA P. (*) (°)

Key words: *Gela Nappe, Neogene, out-of-sequence, Sicily, syn-orogenic extension, thrusting.*

INTRODUCTION

During mountain belts evolution commonly exist very closely relationships between in sequence thrusting, out-of-sequence faulting and extension. The simple foreland-breaking sequence of deformation characterizing the accretion of a sedimentary wedge during the subduction stage can be interrupted either by backward vergent deformation, syn-orogenic extension or backthrusting/thickening near the orogenic backstop (e.g., PLATT & VISSERS, 1989).

The evolution of chain-foredeep-foreland systems is characterised by contractional structures coupled by extensional deformations, both at the chain-foredeep and at the foredeep-foreland transition zone. As a consequence, the architecture of most foredeep depressions is generally envisioned as controlled by active regional thrusts and coeval subsidiary normal faults in their inner and outer edges. These structures may contribute to accommodate flexure of foreland plates induced by the load of advancing thrust sheets.

In Sicily lack a kinematic model relative to the chain building, including in sequence/out-of-sequence folding-and-thrusting and extension. The aim of this paper is to provide constraints to help unravel the structural evolution of the Sicily chain using stratigraphic data and relationships between map-scale structures.

GEOLOGICAL SETTING

The Sicilian Thrust System (STS) is a south-verging fold-and-thrust belt and represents the South eastern arcuate portion of the Apennine-Maghrebides thin-skinned fold-and-thrust belt.

The STS is made of a lot of thrust sheets, including Mesozoic-Lower Tertiary pre-orogenic multilayered sedimentary sequence and occupies the larger part of the island. (Fig. 1).

The thrust stack owes its origin to the deformation of pre-orogenic strata deposited in different palaeogeographic domains belonging to the Northern Africa passive margin.

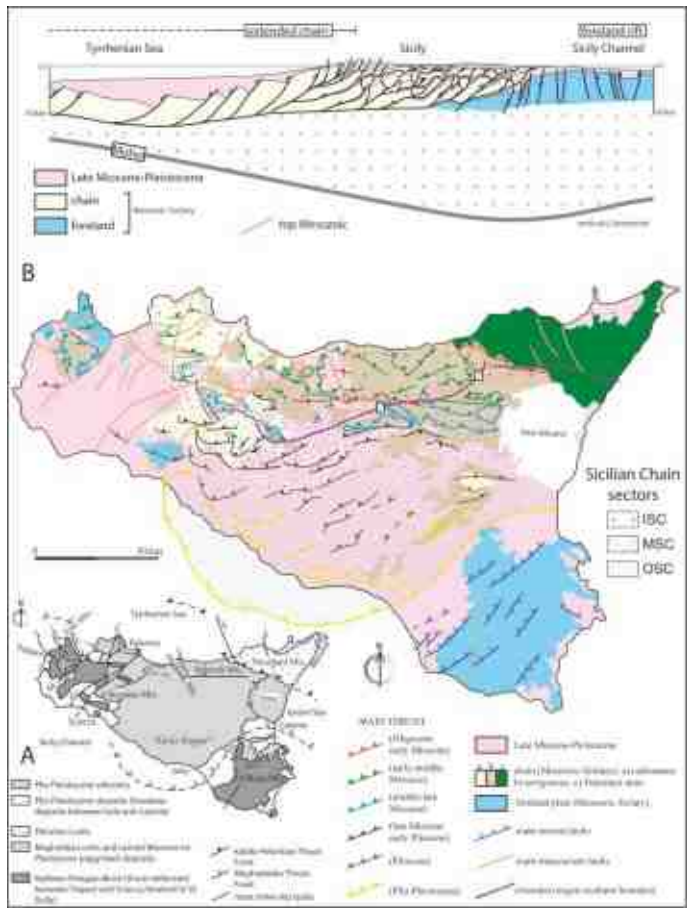

Fig.1 - (A) Main structural elements in Sicily. (B) Structural sketch of Sicily and schematic cross section. The thrust system has been divided into three zones: Inner Sicilian Chain (ISC), Middle Sicilian Chain (MSC) and Outer Sicilian Chain (OSC) on the basis of the timing of thrust activity.

The belt developed during the Neogene, following the closure of the Tethys Ocean and the continental collision between the Sardo-Corso Block and the Africa margin.

The thrust pile was detached from the underlying basement during Miocene-Pleistocene time interval and experienced both faulting, folding and stretching. A general hinterland-to-foreland thrust propagation is recorded in the syn-orogenic deposits (Fig. 2).

(*) Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo

(°) INGV, Sezione di Palermo.

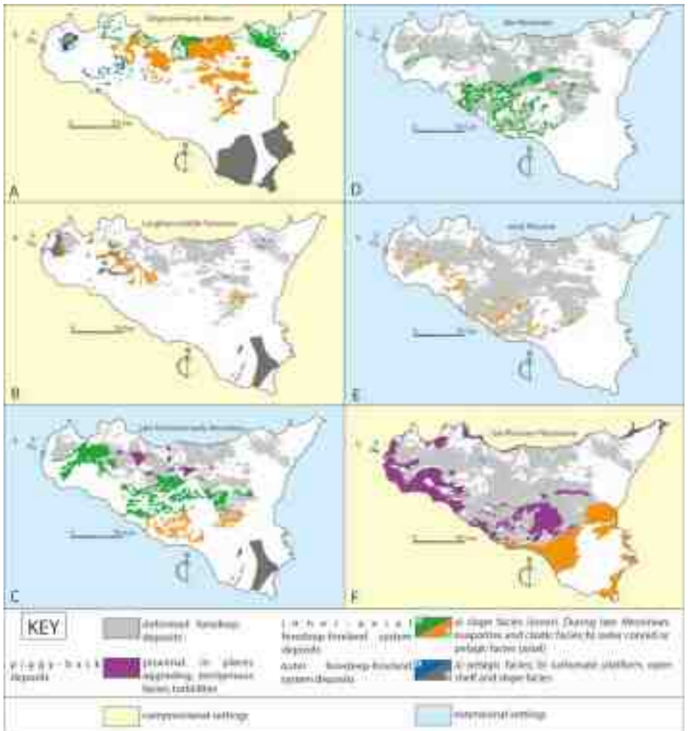

Fig.2 - Distribution, in the Sicilian Thrust System, of the facies of the foredeep-foreland and piggy-back deposits from Oligocene to Pleistocene that underwent contractional and extensional events.

During chain building, the Sicilian wedge experienced both extension and further out-of-sequence renewed thrusting in the inner stack, coheval with the growth in the toe region.

The progression of deformation is represented by different regionally-significant structural stages (layer-parallel shortening, folding-and-thrusting, extension and renewed thrusting, strike and normal/oblique normal deformations).

The STS can be separated into three main sectors (Figure 1B): the Inner Sicilian Chain (ISC), the Middle Sicilian Chain (MSC) and the Outer Sicilian chain (OSC).

The ISC extends W-E in northern Sicily and is a result of the Late Oligocene-Early Miocene thrust tectonics which dominated the Africa-Europe collision (OGNIBEN, 1960; GIUNTA, 1991; ROURE *et alii*, 1990a; CATALANO *et alii*, 2000).

The MSC and OSC mostly consist of Late Oligocene-Pleistocene foredeep deposits cropping out in central and southern Sicily, which were progressively involved in the compressional deformation (Broquet *et alii*, 1966; Giunta, 1991; NIGRO & RENDA, 2000) since the Middle-Late Miocene. The growth of the orogenic wedge since the Pliocene, generated by the accretion of syn-tectonic sediments, is represented by a stack of tectonic slices known as "Gela Nappe" (Beneo, 1958).

The recognised regional-scale structural setting allow us to reconstruct tectonic evolution (Fig.3):

I) piggy-back thrusting from the Late Oligocene to the Langhian, inducing the building of the Inner Sicilian Chain (ISC) that migrated progressively forelandwards. Extensional deformations were active in the foredeep-foreland system;

II) piggy-back thrusting from the Langhian to the Tortonian, inducing the building of the Middle Sicilian Chain (MSC) that migrated progressively forelandwards. Extensional deformations were active both in the foredeep-foreland system and in the ISC;

III) generalised extensional deformations in the chain-foredeep-foreland system from the Tortonian to the earliermost Pliocene;

IV) new onset of piggy-back thrusting since the Early Pliocene, allowed the building of the Outer Sicilian Chain (OSC) and out-of-sequence thrusting in the previous emplaced ISC and MSC. Extensional deformations were active in the foredeep-foreland system;

V) starting from the Late Pliocene, strike and normal/oblique normal deformations affected the ISC and MSC as the effects of the Southern Tyrrhenian Basin dynamics.

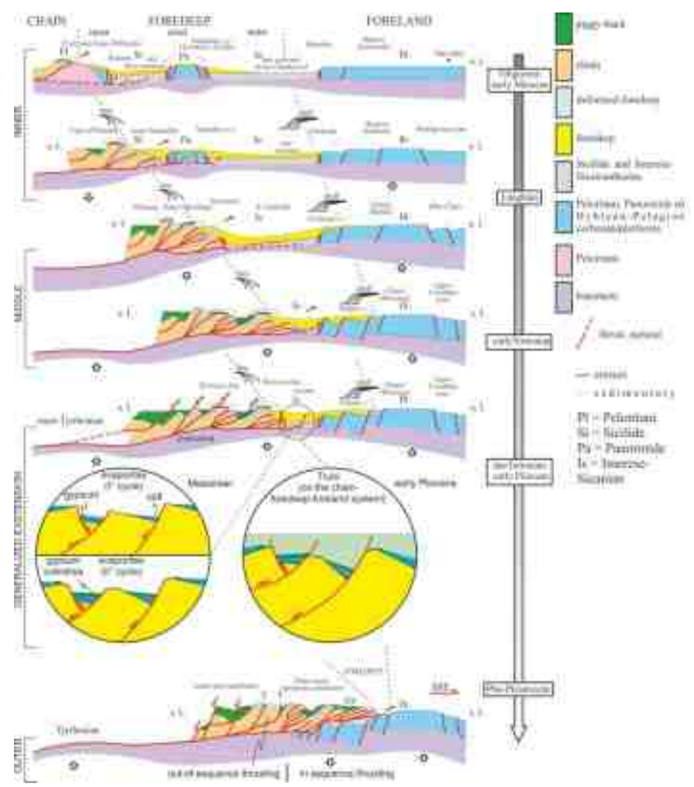

Fig.3 - Model of the tectono-sedimentary evolution of the Sicilian chain-foredeep-foreland system since the Oligocene, depicting the deformation of the pre- and syn-orogenic strata deposited in the different palaeogeographic domains and in the foredeep-foreland system. The ISC (Peloritani, Sicilide, Panormide and Imerese-Sicanian p. p.) and MSC (Imerese-Sicanian p. p.) were emplaced from Oligocene to the Late Miocene. Extension occurred during Late Miocene-Early Pliocene and extensional setting developed, allowing the deposition of evaporites and deep-water marls (Trubi Fm.). These conditions allowed renewed deformations of the Imerese-Sicanian and previous foredeep deposits (Gela Nappe emplacement).

The interplay between compression and extension during the STS emplacement has been developed in a continuous kinematics, as revealed by the analysis of minor structures.

Starting from the northern Sicilian coast, a process of crustal attenuation and subsidence has affected the chain since late Tortonian time (KEZIRIAN *et alii*, 1994; GIUNTA *et alii*, 2000). Repeated failure of the orogenic wedge also occurred during the Pliocene-Pleistocene time interval (NIGRO & RENDA, 2001).

During the Pliocene-Pleistocene time interval, dextral transcurrent tectonics affected northern Sicily and its Tyrrhenian offshore domains (BOCCALETTI *et alii*, 1982; FINETTI & DEL BEN, 1986). Strike-slip deformations inland were mainly accommodated by a W-E narrow shear zone with right-lateral kinematics (GHISETTI & VEZZANI, 1984; RENDA *et alii*., 2000).

Extensional structures was displaced along Plio-Pleistocene strike-slip faults, leading also to tectonic depressions in the off-shore areas north of Sicily (GIUNTA *et alii*, 2000). This neotectonic system may be connected to a W-E trending right-lateral simple shear system, which controls the recent development of the Southern Tyrrhenian margin (Fig. 4).

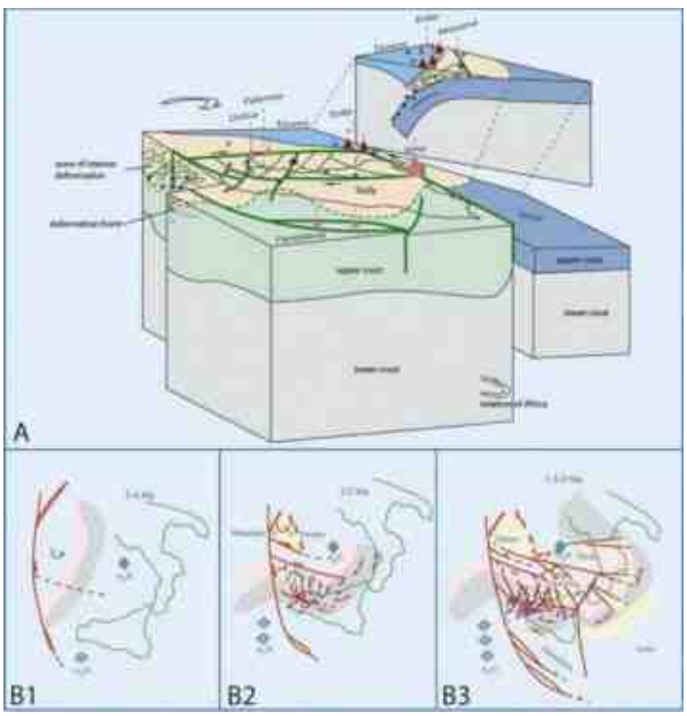

Fig. 4 – A) 3D of the Sicilian area and neighboring areas showing major neotectonic fault systems (in green), areas of the chain (beige) and non-deformed areas (light green). In the split is also visible the Ionian subduction zone in the Aeolian sector. B) evolution of the central Mediterranean neotectonic in the last 5 Ma connected with the gradual rotation of the African Plate. The dynamics of openings of the Tyrrhenian Basin appears controlled by the activity of crustal shear systems that in the nothern submerged Sicilian sector determine the formation of strongly subsidence basins which extend until in the emerged areas of the island.

Setting-up for late Cretaceous-late Neogene evolutive model of "Alpine" Corsica-Northern Apennine orogenic system: possible suggestions for Sardinia-south Tirrhenian Sea-Calabria System

GIANFRANCO PRINCIPI (*), VALERIO BORTOLOTTI (*), ENRICO PANDELI (*), FRANCESCA GARFAGNOLI (*), FRANCESCO MENNA (*) & GIUSEPPE NIRTA (*)

Key words: *Alpine Corsica, Northern Apennines, Regional Geology, Geodynamics, Perityrrhenian orogeneses*

ABSTRACT

In the mind of most geologists the Apennine orogeny started at the beginning of Neogene, whereas its internal and older units (Ligurids) developed in an "Alpine" like orogenic evolution.

To this geodynamic vision, we opposed for many years an evolutive model of a single "Alpine" Corsica-Northern Apennine orogenic System developed from Late Cretaceous-Paleocene up to now.

The arguments supporting this geodynamic hypothesis were based on the different data: 1)- age of the epiligurian deposits (i.e. Lanciaia Fm., Late Paleocene-Early Eocene, Monte Piano Marls, Middle Eocene) that rest unconformably upon east vergent ligurids tectonic piles); 2)- age of the emplacement (progressively younger to the east) of westwards derived ophiolitic olistoliths and olistostromes in the turbiditic formations (mainly Helminthoid-bearing carbonatic flysch, from late Cretaceous to Middle Eocene age) in the upper part of each External Ligurids successions. 3)- The lacking in the coeval Internal Ligurids turbidites (mainly siliciclastic) of ophiolitic debris; 4)- recent data about the ages of the Sardinian calcalkaline magmatism (38.3 Ma) shifts back at the Middle-Late Eocene the beginning of the arc-type magmatism in the western sides of Sardinia-Corsica massifs. If we consider that 5-10 Ma is needed for the geodynamic system to trigger the calcalkaline magmatism, we can likely hypothesize an age of ~ 50 Ma for the beginning of westwards "Apenninic" like subduction beneath to the east Corsica margin; 4)- this age, as well as those of older epiligurian formations, is older of almost the totality of HP-LT metamorphism of *Schistes Lustrés* in the "Alpine" Corsica, with the exception the age of a few (2) eclogites (from 87 to 60 Ma). However these latter are coeval with the emplacement of olistostromes and olistoliths inside the External Ligurids turbidites of the Northern Apennine; 5)- Also some recent seismic thomographic reconstructions, showing the presence of westwards dipping wide unbroken cold lithospheric mantle slabs (reaching at least 500 km) below the Sardinia and Corsica blocks (and extended to beneath Ligure-Balearic basin), bring new argument in favour of our model.

So the west verging Corsican nappes are generated with a big backthrusting during the inception of the Late Eocene-Early Oligocene ensialic Apenninic orogenic stage.

Furthermore, about the hypothesis that the inversion of subduction plane was due to inception of the system with a microcontinent (AlKaPeCa) in our opinion it is insustainable, specially inside the "Alpine Corsica" tectonic frame. The sialic slices, often strongly metamorphosed and eclogitized, are too much small, insignificant for to accomplish the role of a microcontinent. In our opinion, in general there aren't sure data coming to west mediterranean ophiolitic sequences and to sialic blocks in the perimediterranean alpine chains supporting the presence of microcontinent within the Western Tethys oceanic domain.

According to these argument we illustrate in five steps an external and internal development of the Corsica-Western Tethys-Northern Apennine lithospheres during the orogenesis imbued also with former models considering a continous west plunging subduction from Late Cretaceous-Paleocene up to now: *a*)- Upper Cretaceous-Early Paleocene, the inception of the west dipping oceanic subduction and formation of an oceanic "trapped crust"; *b*)- Upper Paleocene-Early Eocene, formation of first "external Ligurides" nappe and subduction still over the "critical depth " for the triggering of arc magmatism; *c*)- Middle Eocene-Early Oligocene, beginning of the arc magmatism, oceanic crust completely buried and inception of the coninent-continent collision; *d*)- Late Oligocene-Early Miocene, full ensialic subduction, formation of Tuscan nappes and increase of eastwards slab retrait; *e*)- Middle-Late Miocene to Quaternary, inception of the eastwards migrating extensional tectonics and magmatism in the northern Tyrrhenian area and

(*)Depart. of Earth Sciences, Univ. of Florence,Italy

Tuscany, shift of the orogenic front to the Marchean-Adriatic area.

This model, based on a single and complex orogenic system, excludes the presence of "alpine" orogen event before the Apenninic one. So, We propose to transfer an analogous model to other perimediterranean orogenic sectors, in particular to the Sardinia-Tyrrhenian Sea- Calabria convergent system.

Preliminary Geodynamic Section of Central Italy between the 41° and 42°N parallels

FRANCESCO SALVINI (*), PAOLA CIANFARRA (*) & MATTEO MAGGI (*)

Key words: *Geodynamics, Central Apennines, Admissible bilance cross- sections.*

The Central Mediterranean region represents the zone where the evolution of the Thetian collisional chain appears the most complex (Bigi et al., 1991; Cavinato et al., 1994; Parotto et al. 1996; Amato et al. 1997; Cassano et al., 2001; Cassinis at al, 2003; Billi & Salvini, 2003). In the Central Italian peninsula the chain is elongated roughly NW-SE and results from the Thetian suture by the collision between a European and an African microplate. The sector between the N 41° and N 42° parallels is one of the most complicate tiles of this puzzle (Salvini, 1993). Important geodynamic differentiations are present along both sides (Favali et al, 1993; De Alteriis, 1995).

An ideal E-W transect, from W, locates four main geodynamic blocks (Fig. 1). To the W is the Sardinia-Corsica Block of European origin with relics of the sedimentary wedge of his Thetian margin to the E (Bigi et al, 1991). It follows the Tyrrhenian Sea, a basin characterized by thinned continental crust topped with Miocene-Quaternary marine sediments directly lying on Paleozoic basement (Patacca et al., 1990; Serri et al., 2001).

The third block corresponds to the Italian Peninsula with its Apenninic structures that constitutes the orogen of the chain (Accordi & Carbone, 1988; Parotto & Praturlon, 2004). The accretionary prism continues to the E offshore, and it is still active, in the Adriatic Sea (Patacca & Scandone, 2004). This is the last block and represents the African margin underthrust to the chain and it is characterized by a meso-cenozoic carbonate succession deposited in shallow to open seawaters.

The main accepted geodynamic interpretation states that the Sardinia block represents a European microplates separated in Oligocene times (about 38 Ma, Patacca et al., 2008 and ref. therein). The Apennines is the accretionary prism formed from the collision in Mio-Pliocene times of the collision between this microplate and the sedimentary wedge of the Adriatic plate of the African domain (Adriatic Sea). Many geological evidences still wait to be properly framed:

i) the substantial lack of the European sedimentary wedge in the reconstruction of the collision zone;

ii) slices of deep water sedimentary successions associated with ophiolites, related to the suture zone, outcrop both to the N and to the S (Southern Apennines);

iii) along the proposed section slices of deep water sediments has been identified in front of both the westernmost and the easternmost sides of the chain;

iv) carbonate facies in the Apennines shows in Mesozoic times deeper waters conditions in the most eastern successions that is towards the African microplate (Accordi & Carbone, 1988);

v) in eastern Sardinia a Mesozoic succession of shallow water limestone outcrop (Tacchi), belongs to the European sedimentary wedge (Bigi et al., 1991), and shows strong analogies with the westernmost portions of the Apennine carbonate platforms (comp. Accordi & Carbone, 1988).

A preliminary, admissible balanced cross sections between the 41°N and the 42° N parallel has been prepared at the regional scale by using the layered-HCA method as implemented in the numerical FORC software (Salvini et al, 2001; Salvini F. & Storti F., 2004). This section has been compared to the computed lithosphere flexure of the region as derived from the present topographic profile.

Results provide the possible framing of the Apennine block within the African vs European domains, and the location of their suture zone. Found geometry may represent the basis for a complete geodynamic study of this complex region.

Origin and significance of the strike-slip tectonics in the Plio-Quaternary evolution of the Sicily collision belt

LUIGI TORTORICI (*), STEFANO CATALANO, GINO ROMAGNOLI, SALVATORE TORRISI & GIUSEPPE TORTORICI

Key words: collision belt, lateral extrusion, Sicily, strike-slip tectonics.

INTRODUCTION

In the Sicily orogenic belt the distribution of the distinct tectonic units that compose the Africa-Europe collision zone (Fig. 1) is conflicting with the NW-SE direction of the Nubia-Eurasia convergence (DEWEY *et alii*, 1989; HOLLENSTEIN *et alii*, 2003) and with the geometry of the resulting SE-verging thrust belt. The European units and the underlying neo-Tethyan accretionary wedge terrains are, in fact, located in the north-eastern sectors of the island, while the rest of Sicily is composed of the Africa-derived units that form the externalmost SE-verging thrust fan and the foreland areas. Several geological transects, crossing in a N-S direction the western and the eastern sectors of the island (BIANCHI *et alii*, 1986; ROURE *et alii*, 1990; CATALANO *et alii*, 1996; LENTINI *et alii.*,1994; MONACO *et alii*, 2000), clearly evidence a non-cylindrical deformation of the region, denouncing the primary role of the strike-slip tectonics that produced major NW-SE dextral shear zones, across the NE-SW oriented lineaments of the thrust belt. A new model of the collision tectonics in Sicily, based on the tentative restoration of the post-Tortonian deformation, is here proposed in order to estimate the contribution of the strike-slip tectonics in the late evolution of the Sicily collision belt and to provide new insights for constraining the effects on the island of the Calabrian arc migration and the Tyrrhenian opening.

GEOMETRY OF THE SICILY COLLISION BELT

The Sicily collision belt is the result of a complete orogenic cycle that included the subduction of the Neo-Tethyan oceanic domains beneath the European margin and the successive Europe and Africa continental collision (TORTORICI *et alii*, 2008). The modern tectonic picture of the island is characterised by two distinct sectors that are separated by a main WNW-ESE tectonic boundary, which is composed of discrete NW-SE oriented en-echelon dextral shear zones. To the north-east of this tectonic boundary, the innermost units of the orogen are exposed.

They consists of the Calabrian-Peloritani arc units (Fig. 1) of the Peloritani Mountains, which represents the basement nappes deriving from the European back-stop, and the Maghrebian units (Fig. 1), which represents the remnants of Neo-Tethyan accretionary wedge. These units are associated to Oligo-Miocene syn-tectonic deposits that constrain their pre-Tortonian deformation (ROURE *et alii*, 1990; LENTINI *et alii* 2000). The tectonic boundary between the Peloritani units and the Neo-Tethyan accretionary wedge was deeply modified by strike-slip tectonics and is now represented by the NW-SE oriented Lower Miocene "Taormina Line". In the footwall of this tectonic feature, the allochthonous Maghrebian units actually form a pellicular horizon that drapes a wide E-W oriented axial zone, extending continuously along the eastern portion of the Tyrrhenian coast of the island. The axial zone represents a wide ramp-anticline that developed at the hangingwall of a main oblique (dextral) Plio-Pleistocene crustal thrust (GHISETTI & VEZZANI, 1982). The core of this culmination is composed of Mesozoic platform carbonate sequences capped by Miocene turbiditic deposits. In the footwall of the axial zone, the allochthonous units are covered by distinct thrust-top basin deposits, ranging in age from the Late Tortonian to the Pliocene, and are emplaced on a Late Miocene foredeep succession.

In the southern sector of Sicily, the external domains of the SE verging Sicily collision belt are exposed. They consist of the Late Tortonian to Quaternary arc-shaped accretionary wedge complex of the Caltanissetta Basin, which is sandwiched between the imbricated Mesozoic passive margin sequences of the Sicanian Mountains, to the northwest, and the flexured Meso-Cenozoic carbonate successions of the Hyblean Foreland, to the southeast. The frontal units of the Neogene-Quaternary accretionary wedge are emplaced on Early Pleistocene deposits of the Gela Foredeep.

TECTONIC EVOLUTION OF THE SICILY COLLISION BELT

The distinct geometry of the thrust belt in the two adjacent sectors of Sicily is the result of a different Plio-Quaternary evolution of the two regions. In the southern e central portions of Sicily is possible to reconstruct the progressive SE-ward Plio-Quaternary propagation of the thrust front (Fig. 1), which was accompanied by the migration of the foredeep and the

(*) Dipartimento di Scienze Biologiche, Geologiche ed Ambientali – Sezione di Scienze della Terra, Università di Catania

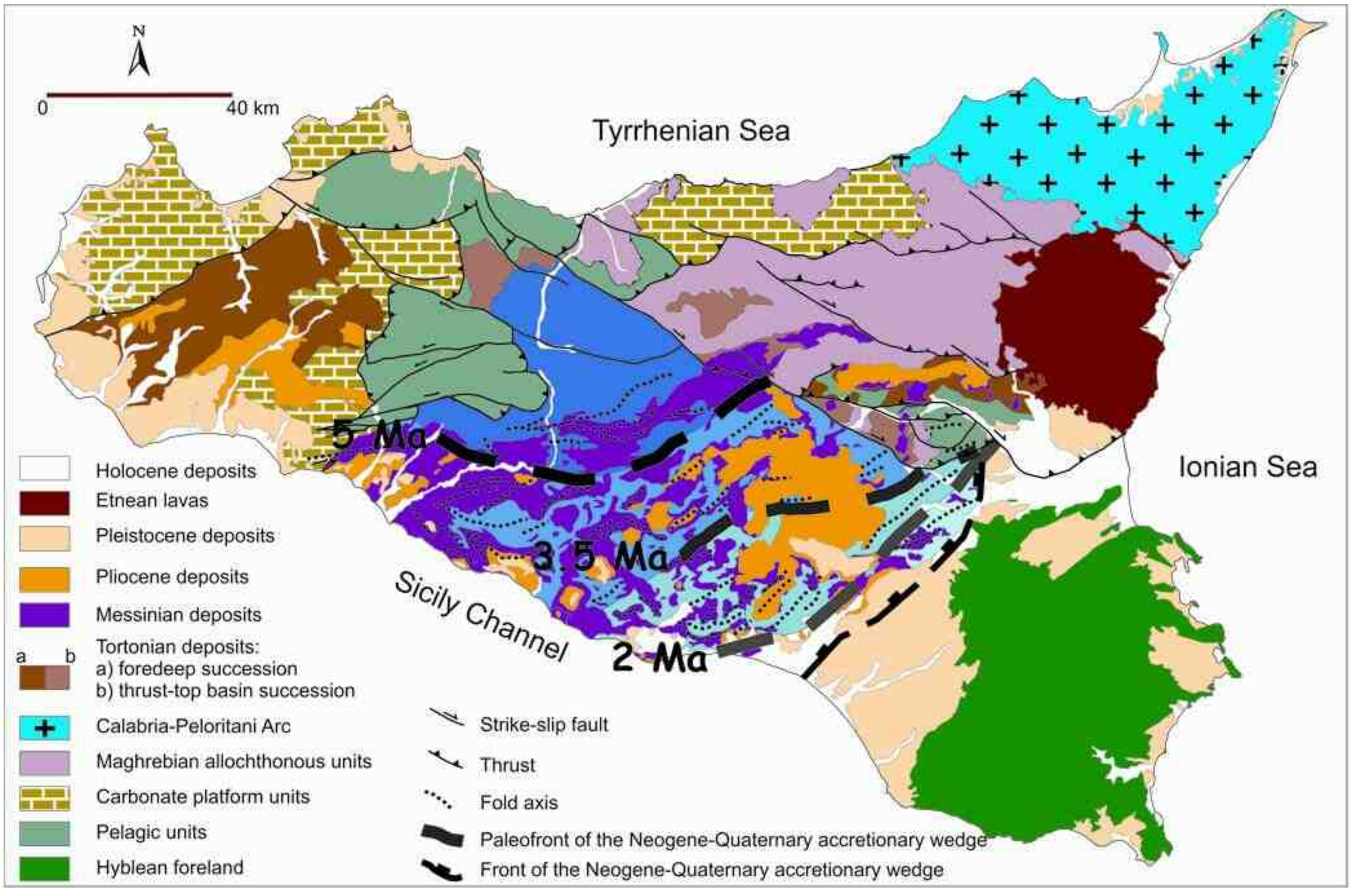

Fig. 1 – Tectonic map of Sicily

deposition of distinct unconformable clastic successions within the thrust-top basins. In the northeastern sector of the island, most of the lineaments of the orogen are indeed pre-Tortonian in age and the externalmost front of the allochthonous units is concealed by Messinian deposits. In this sector of the orogen, the Plio-Quaternary thrust edifice is absent and the Miocene tectonic features are directly juxtaposed to the Quaternary Catania Foredeep, along NW-SE dextral shear zones located in the area to the south of Mt. Etna. In the whole northeastern sector of Sicily, in fact, the Late Miocene-Quaternary thrust deformation essentially produced a diffuse breaching of the piled-up units, related to motion along E-W oriented oblique (dextral) ramps.

The major WNW-ESE oriented shear-zone, separating the two adjacent sectors of the island, accommodated the huge difference of cumulative Plio-Quaternary shortening, many times larger to the south than to the north. Nevertheless, the resulting dextral motion along the NW-SE tectonic boundary, suggests a faster SE-ward shifting of the northern part of the island that, in the last 5 Ma, produced about 120 km of offset. This value can be obtained, taking into account the location of the Messinian thrust front on the two sides of the shear zone (Fig. 2). As a consequence, since the Pliocene, the shear zone has a displacement-rate been of about 2.4 cm/a, not comparable to the active convergence-rate (2.6 mm/a), which has been measured along the Nubia-Eurasia plate boundary across the Sicily, by GPS data (HOLLENSTEIN *et alii*, 2003).

CONCLUSIONS

The analysis of the geometry of the Plio-Quaternary tectonic features of the SE-verging Sicily collision belt has evidenced that the thrust propagation was active only to the southwest of a main WNW-ESE oriented dextral shear zone, while to the north of this tectonic alignment, the Miocene tectonic features have been passively shifted towards the SE (Fig. 2), at rate one order of magnitude higher than the Nubia-Eurasia convergence. The major dextral tectonic feature, extending from the Tyrrhennian coast of Palermo to the Ionian coast to the south of Mt. Etna, bounds the Neo-Tethyan thrust-nappes, to the north, and the Africa-derived thrust belt, to the south. The eastern termination of this tectonic boundary corresponds to the transform zone recognised by CATALANO et alii (2004) to the south of Mt. Etna and represents the prolongation of the WNW-ESE oriented transform zone which separates the buoyant continental Africa crust of the Hyblean Plateau from the subducting thinned crust area of the Ionian Basin, in the off-shore of Mt. Etna region (NICOLICH *et alii*, 2000). All these evidence strongly suggest that the dextral shear zone dissecting the Sicily collision belt actually represents the expression of a transform zone rather than a

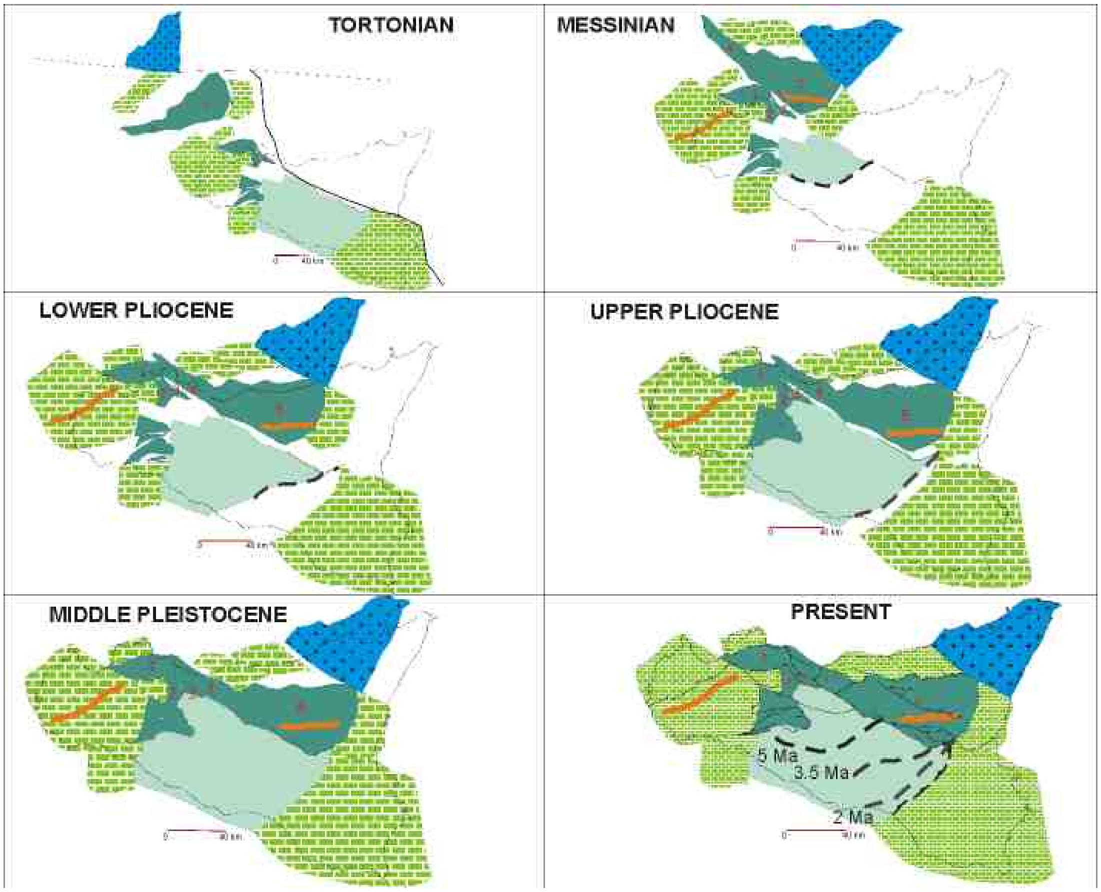

Fig. 2 – Post-Tortonian tectonic evolution of Sicily

transfer fault within the collision belt. According to our reconstruction, this lithospheric feature can be interpreted as the actual southern border of the Calabrian arc that follows at depth the previous African-Ionian boundary that was reactivated by the roll-back of the subducting Ionian crust.

A kinematic model of the Tyrrhenian-Apennine system

TURCO E. (*), SCHETTINO A. (*), MACCHIAVELLI C. (*) & PIERANTONI P.P (*).

Key words: *Tyrrhenian sea, Apennine chain, kinematic models*.

A new model is proposed for the kinematic evolution of the Tyrrhenian extension and the formation of the Apennine belt. The model is compatible with boundary conditions represented by the motion of the large plates involved in the Mediterranean tectonics. The kinematic parameters (Euler rotations) are calculated starting from a morpho-tectonic and geologic analysis of the Tyrrhenian sea and the Apennine belt. The morpho-tectonic analysis of the Tyrrhenian multibeam bathymetry and SRTM images of the emerged part of the chain have been used to identify the principal tectonic structures of the Tyrrhenian-Apennine system. This analysis allowed to distinguish four sectors within the Apennine belt: northern Apennine, central Apennine (including the Umbria-Marche Apennine), southern Apennine, and Calabrian Arc. For each sector an Euler pole of rotation relative to the Sardinia-Corsica block was determined starting from the identified morpho-structures. The temporal range associated to each stage pole and the rotation angles were determined on the basis of geologic constraints and closure of the kinematic circuit. The model is presented through a series of reconstructions illustrating the genesis of the structures bounding the Apennine sectors, which were associated with different directions of extension within the Tyrrhenian basin. The main geologic implications of the model are represented by the compatibility of the tectonic structures predicted along the boundaries of the Apennine sectors during the rotation and the lateral structural variations that can be observed along the belt. Extension results from diverging directions of migration between two sectors, whereas compression is associated with converging directions. In this model extension along a sector boundary is responsible for the transverse structures which are known as “Anti-Apennine faults”, for the formation of transverse wedge-top basins, for low-angle faulting not compatible with the Tyrrhenian directions of extension, and for the exhumation of deep parts of thrust belts. Conversely, converging directions of migration between the central and southern sectors of the Apennine chain, which are associated with the kinematic of extension within the Vavilov Basin, form the contractional structures that can be observed along the Ancona-Anzio and Volturno-Sangro lineaments.

Burial history of the southern portion of the Tuscan Nappe (Northern Apennines) constrained by means of organic and inorganic paleo-thermal indicators: implications for the orogenic wedge evolution

C. CARICCHI (*), S. CORRADO (*) & L. ALDEGA (**)

Key words: *Illite/smectite mixed layers, Northern Apennines, thermal modelling, Tuscan Nappe, vitrinite reflectance.*

INTRODUCTION

The reconstruction of the evolution of the Northern Apennines orogenic wedge has been generally approached by means of classical structural and stratigraphic investigations. In this framework special regard has been devoted to the understanding of the tectonic evolution and geometry of the Ligurian Nappe, the low strength and uppermost structural unit of the orogenic wedge now partially or totally eroded.

The main models that describe the emplacement of Ligurian Unit can be summarized as follows (FESTA *et alii*, 2010, and references therein):

- sedimentary processes: gravity-driven slope failure, sediment transport and deposition of unconsolidated sediments (mass-wasting) and rocks (mass transport bodies)

- tectonic processes: simple shear processes along a subduction zone with embricate structure formation and obduction of ‘oceanic’ nappe translation.

As a matter of fact there are two key topics that are still matter of great debate:

- the mechanism of emplacement and areal distribution of the uppermost units constituting the thrust pile, at present locally preserved in the wedge (e.g. Ligurian and Sub-ligurian units).
- the relative timing of deformation of this units with respect to the lower structural units involved into orogenic deformation (e.g., the Tuscan and Umbia-Romagna-Marche Domains).

When these interpretative ambiguities persist in the literature mainly as a result of the incomplete record preserved in the field, it is crucial to attempt the reconstruction of regional cross sections that take into account reliable evaluations of the missing portions of the sections that have been eroded and/or removed by tectonics (e.g., ZATTIN *et alii*, 2002; MIRABELLA *et alii*, 2011). This approach allows to substantially reduce the number of acceptable geometric and kinematic models on the base of the amount of exhumation and maximum burial that characterize different areas of the wedge.

In order to provide quantitative data on burial (due both to sedimentation and thrusting) that occurs during the wedge building, thermal modeling of sedimentary successions constrained by means of paleo-thermal and low temperature thermo-chonological indicators has been frequently performed in the external areas of fold-and-thrust belts (see ROURE *et alii*, 2010 for a review) with several examples for the Apennines and Sicily (see, CORRADO *et alii*, 2010 for a review; ALDEGA *et alii*, 2011; DI PAOLO *et alii*, 2012). Nevertheless in the area to the south of the alignment Val Sillaro and to the North of the peri-tyrrhenian volcanic complexes cropping out in Southern Tuscany-Northern Latium, these kinds of data are very scarce as well as the outcrops of the uppermost low strength units overriding the wedge (Ligurian and Sub-ligurian units). In this contribution we present a series of thermal models performed along four geological cross-section across the Tuscan Nappe in an area comprised between Chianti Mts, Cetona Mt to the SW and the Trasimeno Lake and the Mugello depression to the NE. These models allowed to reconstruct the areal distribution of the upper structural units and to draw the thrust sequence in Neogene times.

GEOLOGICAL SETTING

The Northern Apennines is the result of the development of the east to northeast orogenic wedge, above the subduction of remnant Ligure-Piemontese ocean. This process was followed by continental collision between European plate (Corsica-Sardinia block) and Adriatic microplate (of African affinity) and the opening of the Tyrrhenian Sea back-arc basin (DEWEY *et alii*, 1989; MALINVERNO & RYAN, 1986; BOCCALETTI *et alii*, 1990; FACCENNA *et alii*, 2004). Since Oligocene, after the continental collision, the evolution consists of intra-continental deformation with a progressive migration toward east of the orogenic system.

(*) Dipartimento di Scienze Geologiche, Università degli Studi “Roma Tre”, 00146 Roma E-mail: ccaricchi @uniroma3.it

(**)Dipartimento di Scienze della Terra, Università degli Studi “Sapienza”, 00193 Roma.

This process of deformation of the ocean and passive margin paleogeographic domains brought to the enucleation of different tectonic units (BARCHI *et alii*, 1998a). Thrust and fold belt geometry was modified by extentional tectonics, that began in the Tortonian times and is still active (BARCHI *et alii*, 1998b). The Northern Apennines are composed of a series of stacked tectonic units: the innermost and uppermost tectonostratigraphic unit is the Ligurian unit (ETLER,1975). It constists of the remnants of the Ligurian Ocean and is made up of a mix of ophiolite, sedimentary rocks and continentally derived flysch deposits ("Helmintohoid flysch") (ETLER, 1975; FESTA *et alii*, 2010). Onto the Ligurian unit, the Epiligurian unit unconformably lies. It deposited in marine thrust-top piggy back basins (BARCHI *et alii* 2001). Deposition of Epiligurian unit occurred simultaneously with the east and northeast migration of the thrust and fold belt (FESTA *et alii*, 2010). Underlying the Ligurian unit there is a Sub-ligurian unit, made up of Paleocene Eocene shales and limestones (BORTOLOTTI *et alii*, 2001) and thick early Oligocene siliciclastic turbidite rocks. During the continental collision Ligurian nappe were obducted on to the western Adriatic margin, and to the other accreted structural units (RICCI LUCCHI, 1986; BOCCALETTI *et alii*, 1990). These are characterized by a similar stratigraphic succession, that consist of a Paleozoic basement unconformably overlain by Mesozoic evaporitic and carbonate deposits. These sequences are covered by Oligocene-Miocene thick syn-orogenic foredeep deposits. These deposits were deposited in an estward-migrating foredeep basin at the front of avalanching Ligurian nappe and progressively incorporated in the evolving fold-and-thrust system (VENTURA *et al.,* 2001).

METHODS AND MATERIALS

A multi-method investigation (organic matter optical analyses and XRD analyses on clay minerals) has been performed to constrain thermal modeling of the Tuscan Nappe sedimentary succession.

We performed two kinds of analyses:

- Vitrinite Reflectance (Ro%) of organic matter dispersed in sediments, using a Zeiss Axioplan microscope, under oil immersion in reflected monochromatic non-polarised light;

- Qualitative and semi-quantitative analyses of the < 2µm grain-size fraction performed by Scintag X1 X-ray diffractogram system (CuKa radiation, solid state detector, spinning sample).

The obtained indicators of maximum thermal exposures were used to calibrate 1D thermal models of the studied successions by means of the software BASIN MOD.

More than one hundred samples for organic matter and clay mineralogy analyses were collected from pelitic-siltitic beds of *Scaglia Toscana* Fm and siliciclastic foredeep turbidites of *Macigno* Fm belonging to the Tuscan Nappe that represents the regional footwall of the Ligurian and Sub-ligurian units.

PRELIMINARY RESULTS

Organic matter dispersed in the *Macigno* Fm is generally abundant, homogeneous and mainly made up of well-preserved huminite-vitrinite macerals. Distribution of reflectance in each sample generally shows one main cluster of measurements with a Gaussian distribution which represents the indigenous population of macerals. The mean values calculated for each sample (Ro%) indicate a general decrease of organic matter maturity moving from eastern area of the *Val di Chiana* toward the external part of Tuscan Nappe where it thrusts on to the Umbria-Romagna Domain. In detail, Ro% values of internal sector range from 0.6 to 0.9% indicating early-mid mature stages of hydrocarbon generation. Moving toward the external areas of fold-and-thrust belt values range from 0.3% to 0.5% indicating the immature stage.

Quantitative analyses of < 2 µm grain-size fraction identify the presence of illite/smectite (I/S) and chlorite/smectite (C/S) mixed layers in most of samples. A decrease of illite content (from 89% to 38%) and a structural change in mixed layers ordering (from R3 to R0) have been detected moving from the inner to the outer part of Tuscan unit, in agreement with thermal maturity distribution derived from Ro% data.

Following the method proposed by Hillier (1995), a low heating rate, typical of foredeep basins, has been obtained from the comparison between Ro% and I% in I/S mixed layers. A geothermal gradient of about 23°C/Km is derived, combining calculated heating and burial rates and used for thermal modelling.

According to performed models, maximum burial and thermal maturity of the Tuscan Nappe succession decrease from internal toward external sector with a corresponding reduction of the eroded thicknesses (ranging from 3.7 to 2.3 Km). Local anomalies in this general trend testify younger thrusting deforming the Tuscan unit with respect to the emplacement of the Ligurian and Sub-ligurian units.

CONCLUSIONS

This study provides new constraints to understanding the thermal and structural evolution of the more internal sector of the Northern Apennines (Tuscan Nappe).

In the investigated successions paleothermal data show a general eastward decrease of thermal maturity, from hinterland to foreland: the *Macigno* and *Scaglia Toscana* Fms reach an early-middle mature and immature stages of hydrocarbon generation moving from W to E. Thermal models suggest that the investigated successions at the footwall of the Ligurian and Sub-ligurian units underwent a differential tectono-sedimetary load (lower in the external portion compared to the internal one). This decrease is related to the reduction of the wedge thickness toward the external sector of the Ligurian wedge, later on dissected by structurally lower and younger up-thrusts deforming the Tuscan Nappe.

ACKOWLEDGEMENTS

Flavia Botti is acknowledged for facilitating our fieldwork and for helping clarify several points. This study has been performed in the framework of PRIN project 'Modello geologico 4D di un sistema estensionale guidato da una faglia diretta a basso angolo da dati di superficie e di sottosuolo: la faglia Altotiberina, Apennino settentrionale'. Supported by Università degli studi di Roma Tre (SDIGAR PhD school and ex 60% Corrado funds) and by Università degli studi di Perugia (PRIN 2009, coord. M.R. Barchi).

Late orogenic deformation of the shallowest portion of an orogenic wedge: coeval activity of extensional and compressional tectonics in the western Northern Apennines (Italy)

MIRKO CARLINI (*), ANDREA ARTONI (*), PAOLO VESCOVI (*), MASSIMO BERNINI (*), FRANCESCA REMITTI (**), GIUSEPPE BETTELLI (**), PAOLA VANNUCCHI (***), LUCA ALDEGA (°), MARIA LAURA BALESTRIERI (°°), SVEVA CORRADO (°°°), LUIGI TORELLI (*)

Key words: orogenic wedge, Northern Apennines, Miocene, late orogenic structures, extension-compression.

INTRODUZIONE

In the Northern Apennines of Italy the Ligurian and Subligurian Units (LSU) were involved, since the Late Cretaceous, in the accretionary and orogenic processes related to the convergence between Europe and Adria. Since early Miocene the Ligurian Units completely overthrusted the Subligurian Units (REMITTI *et alii*, 2011) and both units stacked together (i.e. the LSU) translated towards NE, above the Tuscan-Umbrian foredeep deposits, until they reached the present-day topographic front in the NW portion of the Northern Apennines.

In the NE-facing side of the western Northern Apennines the present-day geometry of the LSU does not reflect neither the shape of the late Cretaceous-middle Eocene oceanic accretionary wedge (MOLLI, 2008 and references therein) nor the shape acquired during the late Oligocene, when the early orogenic collisional phases produced a wedge whose geometry tapered out towards the foreland area, i.e. to the E-NE. In fact, at present, geologic evidences indicate that the LSU have a shape whose thickness ranges from less than 1 km at the main ridge zone (SW) up to more than 3,5 km along the NE slope of the chain and then tips out again few km N of the Northern Apennines topographic front, underneath the Pleistocene-to Recent sediments of the Po Plain foredeep. Therefore, the LSU thickness increases towards its NE external tip and tapers out again in the subsurface of the Po Plain. These data imply the activation of thinning processes in the inner portion of LSU and thickening processes in the central portion of LSU; these thinning and thickening processes have to be related to the post-early Miocene progressive emplacement of the LSU over the foredeep units and to the late orogenic extensional and compressional tectonics affecting the Northern Apennines (ARGNANI *et alii*, 2003, BOCCALETTI *et alii*, 2011). In particular, the thinning processes have been identified as being of tectonic nature in the innermost portion (mainly low- and high-angle normal faults: ARTONI *et alii*, 2006, BETTELLI *et alii*, 2002, VANNUCCHI *et alii* - 2008) and of sedimentary nature (mass-wasting deposits) (ARTONI *et alii*, 2010, PAPANI *et alii*, 1987, REMITTI *et alii*, 2011) in the outermost portion of the study area. The observed thickening in the central portion of the LSU body has been interpreted as a tectonic doubling caused by the late Miocene-Recent (?) thrusting which affected the whole Apennine orogenic wedge (CAMURRI *et alii*, 2001; CARLINI *et alii*, submitted) or, alternatively, as an accumulation zone of large scale and deep-seated gravitational processes (ARTONI *et alii*, 2006).

In order to put new constraints on the timing and modes of thinning and thickening of the LSU we focussed on the western portion of the Northern Apennines, comprised between the main ridge, the Ceno and the Secchia rivers and the Apenninic topographic front. Here we adopted a multidisciplinary approach taking into account field evidences, low temperature thermal and thermochronological data (i.e. vitrinite reflectance, clay mineral analyses, apatite fission-tracks), numerical modelling of the cooling ages through the use of Pecube finite element code (BRAUN, 2003), results from recently published works on the evolution of the external slope of the chain, and a new interpretation of seismic lines and boreholes data.

This multidisciplinary approach allowed us to: 1) build a 3D representation of the LSU present-day geometry; 2) constrain to the late Miocene-early Pliocene (in the innermost portion) and to the late Miocene-Pleistocene (?) (at the Apenninic front) the thinning of the LSU; 3) identify the tectonic exhumation and consequent denudation of the foredeep units as one of the main causes which triggered the thinning processes since late Miocene; 4) define first estimates of exhumation rates affecting the LSU and the underlying foredeep units.

These results allow us to give new insights, temporal and spatial constraints on the interplay between shallow (< 4 km) and deep (< 20 km), compressional and extensional tectonics

Transformation of smectite in I/S mixed layers: Solid-State Transformation or Dissolution-Crystallization? Preliminary data

FRANCESCO CAVALCANTE (*), CLAUDIA BELVISO (*) & SAVERIO FIORE (*)

RIASSUNTO

Illitizzazione della smectite: trasformazione allo stato solido o dissoluzione e cristallizzazione? Dati preliminari

Illite/smectite rappresenta il più abbondante minerale argilloso interstratificato presente nei sedimenti terrigeni. La sua formazione per progressiva illitizzazione della smectite durante la diagenesi è stata ampiamente documentata in letteratura. Il processo di illitizzazione della smectite dipende da numerosi fattori: disponibilità di potassio nel sistema, tempo, chimismo dei fluidi circolanti, natura dei sedimenti, pressione e temperatura a cui possono essere sottoposti. I meccanismi di illitizzazione della smectite vengono generalmente classificati in due categorie: trasformazione allo stato solido (Solid-State Transformation, SST) e dissoluzione e cristallizzazione (Dissolution and Crystallization, DC). Il primo prevede la trasformazione della smectite in illite con il coinvolgimento di fluidi e senza distruggere la struttura silicatica originaria. Il meccanismo DC avviene invece per completa dissoluzione della smectite, cui fa seguito una nucleazione e crescita di fasi illitiche. Nel corso di questa trasformazione la struttura dei minerali originari viene completamente persa. In questo studio, abbiamo analizzato il meccanismo di illitizzazione nelle Argille Varicolori di Calanche di età cretacea affioranti nei pressi di Campomaggiore (Basilicata- Italia). I dati acquisiti indicano una trasformazione allo stato solido della smectite in illite. Infatti dalle decine di analisi micro-diffrattometriche effettuate su diversi campioni risulta che tra le fasi precipitate all'interno dei gusci dei radiolari non è stata mai rinvenuta la presenza di illite discreta o di interstratificati illite-smectite mentre si riscontra clorite.

Key words: *Argille Varicolori of Calanche, Dissolution-Crystallization, I/S mixed layers, Solid-State Transformation*

INTRODUCTION

The smectite to illite transformation, termed "smectite illitization", is an important reaction and it is frequently used as a geothermometer to allow the reconstructions of thermal and tectonic history of sedimentary basins (Collo et al., 2011; Cuadros, 2006; Pollastro, 1989; Weaver and Beck, 1971). Smectite illitization proceeds through mixed-layer illite/smectite (I/S) intermediates in which the percentage of illite interlayers increases with temperature (Hower et al. 1976; Pollastro, 1993), geological time (Pytte and Reynolds, 1989) and K concentration (Huang et al., 1993). As I/S becomes illite, the interlayers arrangements change from random (R0) to ordered (R1) and then to long-range ordered (R3). Reaction of smectite illitization can be divided into two main mechanisms: a) Solid-State Transformation (SST) and b) Dissolution and Crystallization (DC). SST mechanisms involve gradual replacement of starting mineral (smectite) by a sort of daughter mineral (illite) in close contact without changing the original structure. DC mechanisms, instead, involve complete dissolution of parent mineral followed by nucleation and growth of the daughter mineral as separate grain.
In this paper, data on the smectite illitization in the sediments of Argille Varicolori of Calanche (Basilicata, Italy) was reported.

SAMPLING AND METHOD

Eleven samples of clay minerals were collected from Cretaceous stratigraphic intervals of the meso-cenozoic of the Sannio succession (Cavalcante et al., 2011 and referee therein) exposed near Campomaggiore (Fig. 1). This sucession shows a low diagenetic grade (Cavalcante et al., 2003; Sabato et al., 2007).

Mineralogical analysis of the bulk samples and clay fraction were performed by X-ray powder diffraction using a Rigaku Rint/2200 diffractometer with curved graphite secondary monochromator. Cukα radiation was used and the applied voltage was 40 kV with a 30 mA current.

Mineralogical study on selected radiolarians shelles was carried out by micro X-ray diffraction using D/max RAPID Rigaku instrument.

The radiolarians were separated by hand-picking and thin sectioned (Fig. 2).

RESULTS AND DISCUSSION

The XRD patterns of bulk samples show the presence of clay minerals, quartz, feldspars, and hematite. Mn-Fe carbonates are present only in two samples. The clay fraction is characterized by the presence of I/S with a low content of illite

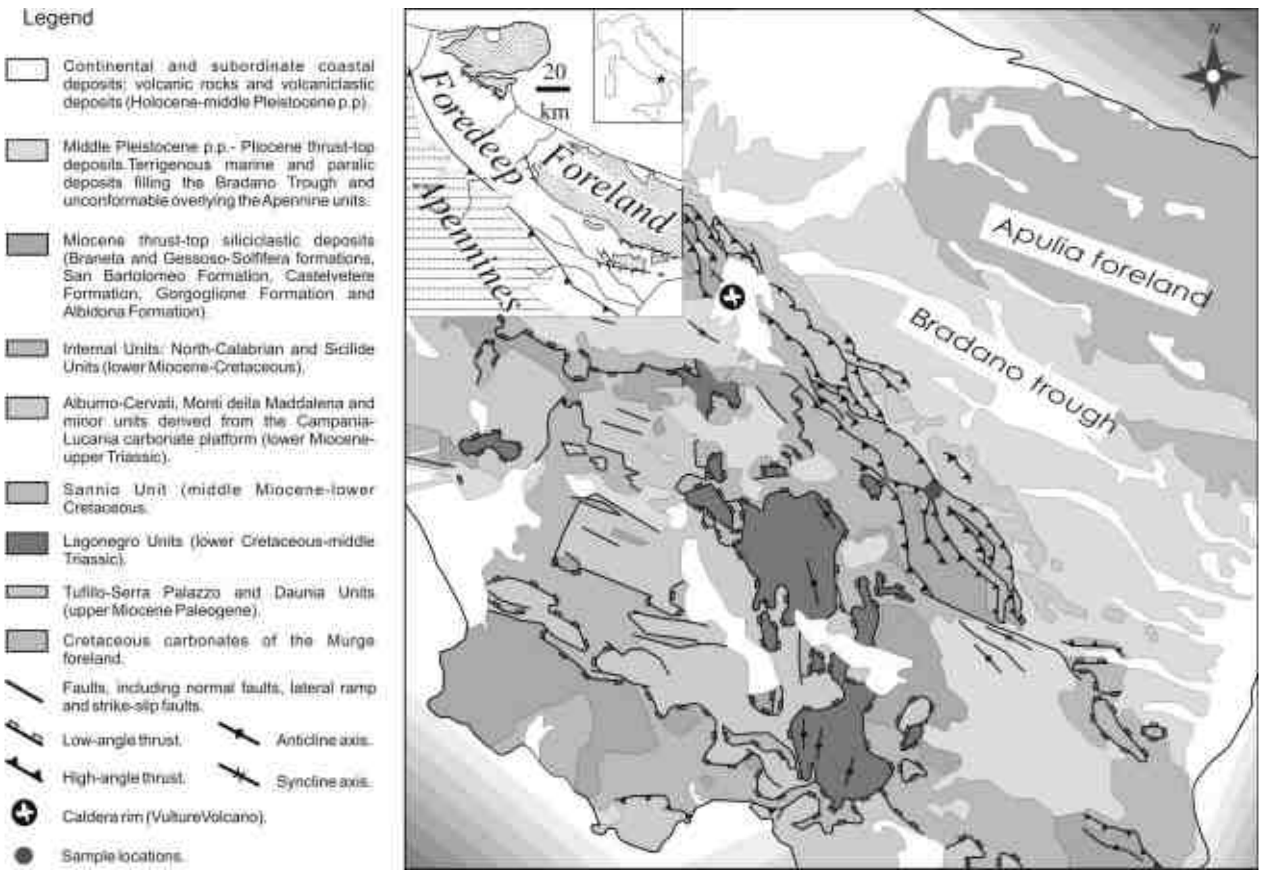

Figure 1 – Geological sketch map of Southern Apennine with indication of studied area (from Patacca and Scandone, 2007).

(30-50 %) and R0 staking order, kaolinite and subordinately chlorite and discrete illite. The presence of I/S R0 indicates a low diagenetic degree in accordance with literature data. The micro XRD analyses of radiolarian shows the presence quartz (due to the radiolarian shell) and chlorite as precipitated phases inside the shell (Fig. 3). The absence of discrete illite and illite/smectite mixed layers and the presence of chlorite suggest the Solid-State Transformation mechanism for the smectite illitization at low diagenetic degree.

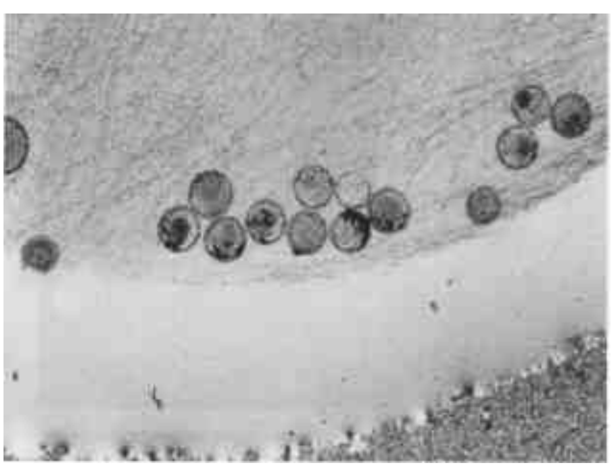

Figure 2 – Thin section of Radiolarians.

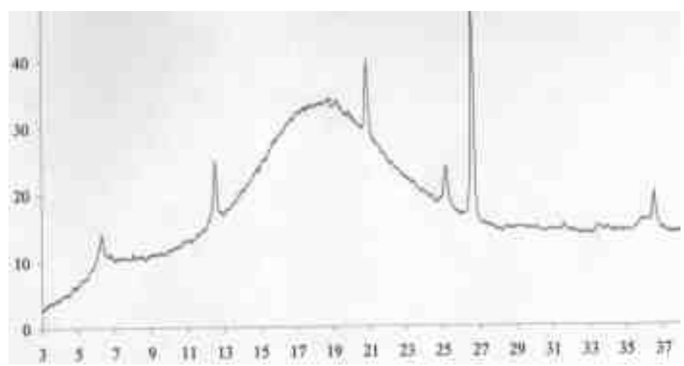

Figure 3 – micro XRD pattern of a Radiolarian shell.

Stepwise behavior of the Eastern Sicily thrust belt: propagation vs thickening by means of thermal and thermochronological constraints

L. DI PAOLO (*), S. CORRADO (*), V. OLIVETTI (*), L. ALDEGA (**),
M.L. BALESTRIERI (***) & R. MANISCALCO (****)

Key words: *wedge dynamics, Eastern Sicily thrust belt, thermal and thermochronological constraints*

INTRODUZIONE

The Sicilian wedge, in Eastern Sicily, is part of the collisional system grown in response to Eurasia-Africa convergence.

Previous studies on the Sicilian chain are based on structural and stratigraphic analysis of seismic sections and syn-orogenic deposits (ROURE *et alii*, 1990; ADAM AND REUTHER, 1995; BUTLER AND LICKORISH, 1997; LICKORISH *et alii*, 1999; BELLO *et alii*, 2000; NIGRO AND RENDA, 2000) whereas recent works have unraveled complex burial and exhumation history (THOMSON, 1994; ALDEGA *et alii*, 2007; 2011; CORRADO *et alii*, 2009; OLIVETTI *et alii*, 2010; DI PAOLO *et alii*, 2012).

In this work, published thermal and thermochronological data have been integrated to propose a stepwise evolution of the Sicilian wedge through time.

GEOLOGICAL SETTING

The Eastern Sicily thrust belt is formed by thrust sheets of Mesozoic to Paleogene basin- platform-derived tectono-stratigraphic units overlying the Hyblean foreland. This consists of a thick carbonate platform sequence with interleaved marls and mafic volcanic levels (BIANCHI *et alii*, 1987). The thrust belt is organized into two main structural zones: the Internal Zone to the north and the External Zone to the south.

The Internal Zone consists of south-verging thin crystalline nappes of the Peloritani Mts. (GIUNTA AND NIGRO, 1999; OLIVETTI *et alii*, 2010).

The External Zone is made up of three main tectono-stratigraphic units. The structurally highest units, widely exposed in the Nebrodi Mountains, are represented by the remnants of the Neotethyan accretionary wedge (CORRADO *et alii*, 2009), made up of a portion of the Sicilide Accretionary Complex (OGNIBEN, 1960) consisting of an upper Cretaceous to lower Miocene pelagic succession and by the Oligocene-Langhian foredeep deposits of the Numidian Flysch (CARBONE *et alii*, 1990; CATALANO *et alii*, 1996). Tectonically beneath these units, the more external Imerese-Sicano Unit forms an imbricate thrust system with a regional backthrust cropping out in the centre of Sicily (MANISCALCO *et alii*, 2010), and to the south a series of thrusts with top-to-the-South sense of transport. The succession is made up of mainly pelagic basin Mesozoic carbonates with radiolarian cherts, overlain by Paleogene marly limestones and younger clastic deposits (BIANCHI *et alii*, 1987).

METHODS

Analytical inorganic and organic thermal indicators concern:

- Organic matter optical analysis. Random reflectance (VRo%) was measured under oil immersion, with a Zeiss Axioplan microscope, in reflected monochromatic non-polarised light.

- Fourier Transform Infrared Spectroscopy on organic matter. FTIR experiments were carried out at the Indiana Geological Survey using a Nicolet 6700 spectrometer equipped with a DTGS detector. Ground kerogen was mixed with potassium bromide in the proportion of 1 mg/ 100 mg and was analyzed as KBr pellets. Two hundred scans per sample were

Lavoro eseguito nell'ambito del progetto di dottorato "Burial and Exhumation History of the Apenninic-Maghrebian fold-and-thrust belt in Eastern Sicily by means of integrated studies of thermal and thermochronological constrains" con il contributo finanziario dell'Università degli Studi "Roma Tre" (Fondi ex 60% Corrado e Scuola Dottorale in Geologia dell'Ambiente e delle Risorse).

recorded in absorption mode from 500 to 4000 cm−1 with a 4 cm−1 resolution.

- XRD analysis of clay minerals. Qualitative identification and quantification of I-S in the <2 μm grain-size fraction was performed with a Scintag X1 XRD system (CuKα radiation). Oriented air-dried and ethylene-glycol solvated samples were scanned from 1 to 48 °2q and 1 to 30 °2θ with a step size of 0.05 °2q and a count time of 4 s per step at 40 kV and 45 mA, respectively.

- Apatite fission tracks analysis. Apatite fission track ages were calculated using the external-detector and the zeta-calibration methods. The samples were irradiated with thermal neutrons in the Lazy Susan facility of the Triga Mark II reactor of the University of Pavia (Italy).

- (U-Th)/He analysis. Inclusion-free apatite for (U-Th)/He analysis were hand-picked under a high- magnification binocular microscope with cross-polarized light. Helium was extracted by heating the Pt-tubes at 600–700°C for 1–2 min using a laser diode. ^{4}He concentrations were measured by comparison to a calibrated standard ^{4}He using a Hiden HAL3F quadrupole mass spectrometer equipped with an electron multiplier.

THERMAL AND THERMOCHRONOLOGICAL CONSTRAINTS FOR TECTONIC MODEL

Thermal and thermochronogical constraints indicate that the structural and stratigraphic Units constituting the Eastern Sicily fold-and-thrust belt are divisible in two levels of thermal maturity: a less evolved level that records limited sedimentary burial and minor heating and a more evolved level tectonically buried and then exhumed. The lower level of thermal maturity is characterized by (1) R0 mixed layer illite smectite with an illite content <60%, (2) vitrinite reflectance <0.5%, (3) vitrinite reflectance values derived from FTIR analysis <0.5% and (4) no resetting of apatite fission tracks. The higher level of thermal maturity is characterized by (1) R1 and R3 mixed layer illite-smectite with an illite content in the range of 60-85%, (2) vitrinite reflectance values between 0.61 and 0.96% and (3) AFT ages ranging between 35 and 6 Ma either totally or partially annealed.

Thermal and structural history of the “colder” Units is linked to phases of propagation of deformation forward in piggy back style through low angle thrusts, whereas the “hotter” Units are linked to tectonic thickening phases of the orogenic wedge in which the deformation concentrates in narrow belts through the formation of duplexes (e.g.., antiformal stacks) and up-thrusts. The two different tectonic styles are localized in different sectors of the FTB, alternate through time and are related to the maintenance of the critical taper linked with eustatic/climatic variations.

ACKNOWLEDGEMENTS

Thanks are due to R. Somma for her help in the field during sampling, to M. Mastalerz and A. Schimmelmann for their support in the kerogen extraction and FTIR lab facilities.

3–D thermokinematic modeling and evolution of topography in the Sila Massif, southern Italy

VALERIO OLIVETTI (*), MARIA LAURA BALESTRIERI (**) & GIORDANO MONTEGROSSI (**)

Key words: *thermochronology, modeling, topography evolution*.

TOPOGRAPHY OF THE SILA

The Sila massif is a portion of the Calabrian orogenic wedge seated on top of a narrow subduction zone. Topography of the Sila results by a polyphase history including crustal thickening, extensional thinning and final regional uplift. The uplift/erosion process likely started at a slow rate in the late Tertiary and underwent a strong acceleration in the middle Pleistocene (Tortorici *et alii*, 2003; Molin *et alii* 2004; Olivetti *et alii*, 2012 and references therein). Indeed, apatite and zircon fission track and Ar-Ar radiometric data show a major exhumation phase from 25 to 15 Ma (Thomson, 1994; Rossetti *et alii*, 2001).

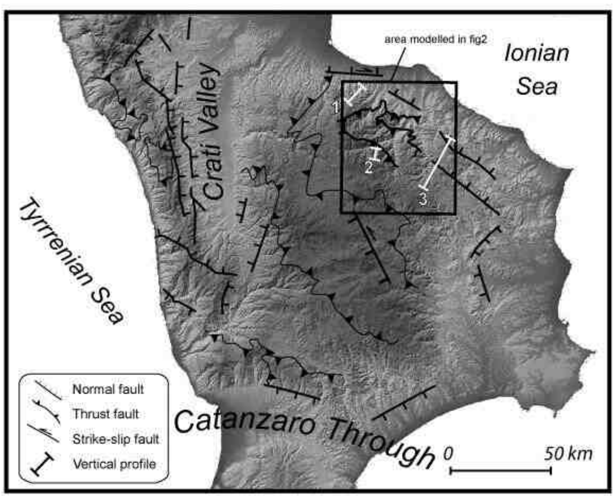

Fig. 1 – Map of the Sila Massif showing main structural features, vertical profiles and studied area.

Present day topography of the Sila Massif is characterized by a low relief upland morphological surface, 40 km wide, standing at an average elevation of 1200 m, and interpreted as a relict of an old landscape developed in stable, base level conditions (Dramis *et alii*, 1992; Molin *et alii*, 2004).

DATA AND MODELING

A set of 14 samples was collected in the Sila basement, in the Longobucco area, in the Ionian side of the Sila massif. They were collected along three vertical sections (Fig. 1). Samples were analyzed with the apatite fission-track (AFT) method in Vignaroli *et alii*., (2012). AFT data showed that most of the different portions of the Sila basement crossed the PAZ between 18 Ma and 13 Ma. Along section 1, a break-in slope in the age-elevation relationship, at ca. 17–18 Ma and ca. 800 m of altitude, was detected. The break-in-slope defines the transition from a time of relative thermal stability to a time of rapid cooling throughout the PAZ. According to these results and published AFT ages from the Sila Massif (Thomson, 1994), the 17–18 Ma can be taken as the age of the inception of the main exhumation phase of the Sila basement in this area. Apatites from the 3 samples of section 1 and from 2 samples from section 2 and 3, respectively, were also analyzed with the (U-Th)/He method. Other samples were collected all along the Ionian side of the Sila massif close to localities were AFT data are available from literature (Thomson, 1994).

In the whole, (U-Th)/He ages results to be slightly younger but close to the AFT age values. This indicate a rapid phase of exhumation followed by an abrupt decrease of the exhumation rate.

We decided to study the evolution of the Sila massif topography through time using the PECUBE code (Braun, 2003). PECUBE is a three-dimensional thermal-kinematic code capable of solving the heat production diffusion-advection equation under a temporally varying surface boundary condition. Pecube predicts thermochronometric ages by tracking the time-temperature histories of rock-particles ending up at the surface and combined with various age-prediction models. It predicts the distribution of thermochronological ages measured at the Earth's surface and the distribution will depend on the imposed erosional scenario. We initially tried to assess, for the Longobucco area only, the effects of changing surface topography and rates of exhumation through time imposing a scenario of rapid exhumation between 18 Ma and 15 Ma followed by topography decline until final uplift. We qualitatively compared the predicted low-temperature thermochronological datasets with real data (fig. 2). We are now performing an inversion of the whole available AFT and (U-

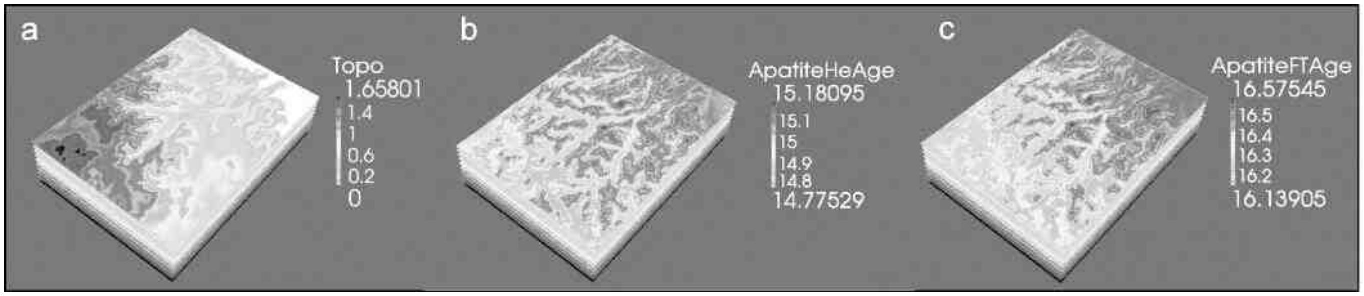

Fig. 2 – a) Present day topography of the Longobucco area, Sila Massif. b) Distribution of the (U-Th)/He ages and apatite fission track ages predicted by Pecube from an imposed erosional scenario (see text for details).

Th)/He dataset: one can envisage to run a large number of predictor model run, each corresponding to a different set of model parameters. By comparing the difference between the predicted ages and the observations, one can define a degree of "goodness of fit" for each model parameter set. Automated methods efficiently search for the minimum misfit which, in turn, should provide the most likely set of model parameters.

Composition, provenance and thermal history of sedimentary successions from the Cilento Group (southern Apennines)

FRANCESCO PERRI (*), ADELE GRECO (*), LUCA ALDEGA (**), SVEVA CORRADO (°),
SALVATORE CRITELLI (*) & LEA DI PAOLO (°)

Key words: *composition, provenance, organic matter, sedimentary succession, Cilento Group*.

INTRODUCTION

The Cilento Group represents the first deep-marine foreland clastic wedge, deposited since the early Langhian, onto deformed oceanic-derived rocks and shallow-water carbonate rocks of the Adria margin. The Cilento Group, is an impressive turbiditic system, which records the earliest collisional phases of the Calabria and Adria microplates in southern Apennines and extends from the Tyrrhenian coast to the NE to the Ionian coast to the SE. The terrains of the Cilento Group unit unconformably overlie carbonate rocks of the apenninic platform to the east and, more extensively, the Liguride and Sicilide oceanic-derived terranes.

The Cilento Group, Langhian to Tortonian in age (AMORE *et alii*, 1988 and many others) 1200-2000 m thick, rests unconformably on the Liguride Complex, and in turn it is unconformably overlain by the upper Tortonian Gorgoglione Formation, and the upper Tortonian to lower Messinian (?) Monte Sacro, Oriolo and Serra Manganile Fms (CRITELLI, 1999; CRITELLI *et alii*, 2011). The Cilento Group consists of different turbidite depositional systems. In addition to siliciclastic turbidite beds, the Cilento Group includes numerous carbonato-clastic megabeds (from a few meters to 65 m thick), olistostrome beds (ten to hundreds of meters thick), and coarse volcaniclastic debris flows and turbidites. It has been divided into four formations: the Pollica FmFm, the San Mauro Fm, the Torrente Bruca FmFm and the Albidona FmFm, from the northwest to the southeast (Fig. 1).

Generally, the Cilento Group is an upward-coarsening megasequence where thick sections are exposed. The lower part of the Cilento Group section (Monte della Stella locality) consists of a deep-sea fan. The lower part of the Pollica Formation is characterized by a section of intensely folded fine sandy-shaly turbidite beds over 300 m thick. The upper part of the Pollica Formation (undeformed or slightly deformed) consists of 250 m of coarse-grained sandstones locally interbedded with conglomerates of the inner-fan turbidite facies association.

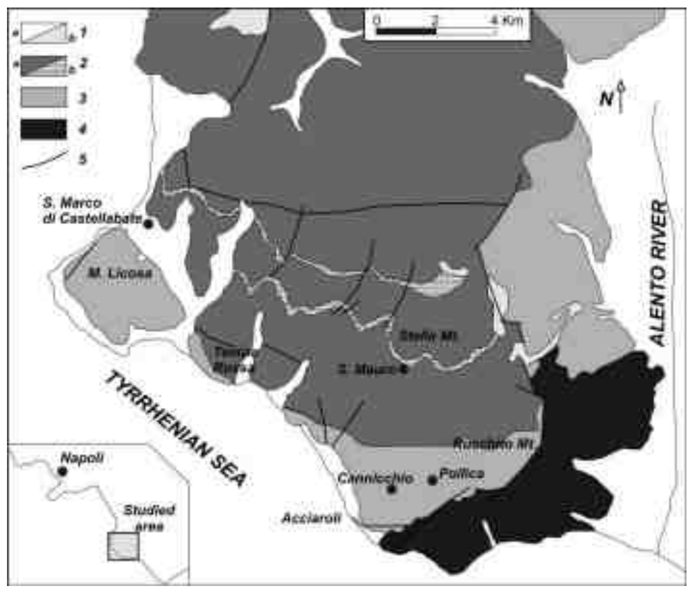

Fig. 1 – Geological map of the study area (modified from CRITELLI, 1999). 1. Holocene-Pleistocene deposits; 2. San Mauro FmFm; 3. Pollica FmFm; 4. Santa Venere Fm; 5. Faults.

The San Mauro and Torrente Bruca formations are the upper portions of the Cilento Group. They occur widely in the Monte della Stella (San Mauro FmFm) and in the Monte Sacro (Torrente Bruca FmFm) structures. The San Mauro Fm consists of 1400-1600 m of the outer-fan, middle-fan, and inner-fan turbidite facies association. In the Mote Sacro section, the Torrente Bruca Fm exhibits good exposures and a complete lateral and vertical outcrops. It includes the same turbidite facies association of the San Mauro Fm, including the two thick carbonate megaturbidite beds. The only significant peculiarity of the Torrente Bruca Fm, is the presence, in the upper portions of very thick olistostrome beds (more than 100 m in thickness), including olistholiths and broken formations of variegated shales, chert and ophiolitiferous rocks. The Albidona Fm outcrops along the Ionian margin between Calabria and Lucania. The thickness of the entire

(°) Dipartimento di Scienze Geologiche, Università degli Studi "Roma Tre", 00146 Roma.

succession cropping out in this area is about 1000-1200 m. This turbiditic succession represents the infilling of thrust-top or foredeep basins which developed on the frontal part of the accretionary wedge of the Apenninic Chain during its Middle-Late Miocene northeastwards migration.

COMPOSITION AND PROVENANCE

Sandstones of the Cilento Group are quartzolithic, volcanolithic and quartzofeldspathic (CRITELLI & LE PERA, 1994). Hybrid arenites and calcarenites characterize the carbonatoclastic megabeds. Sandstone strata of the lower portions are metamorphiclastic quartzolithic and quartzofeldspathic, resting on quartzolithic sandstones of the Liguride Complex. Volcanic and plutonic lithics increase upward in the upper Pollica Formation and lower San Mauro, Torrente Bruca and Albidona formations. A volcaniclastic interval in the lower San Mauro Formation includes abundant felsic (rhyodacite to rhyolite) calcalkaline volcanic clasts (CRITELLI & LE PERA, 1994). Sandstones of the upper Cilento Group are plutoniclastic quartzofeldspathic, and consist of abundant phanerites of plutonic and metamorphic fragments. In the upper Cilento Group, thick carbonatoclastic and olistostroma megabeds record major tectonic events in the active thrust belt and the forebulge (e.g. CRITELLI & LE PERA, 1994). Carbonatoclastic megabeds record huge volumes of sand-sized and mud derived from the flexed Adria margin.

The mudstones are characterized by narrow compositional changes for Al_2O_3, K_2O, Fe_2O_3 and MgO which have concentrations higher than UCC (Upper Continental Crust; MCLENNAN *et alii*, 2006). SiO_2, Na_2O and P_2O_5 are strongly depleted relative to UCC. The distribution of Al, Ca, Na and K used to estimate the degree of alteration of source areas (e.g., CIA index; NESBITT & YOUNG, 1982), suggests a low to moderate weathered sources. Palaeoweathering conditions can be also determined by the K_2O-Fe_2O_3-Al_2O_3 ternary diagram (WRONKIEWICZ & CONDIE 1990). The studied samples fall between the illite-muscovite and chlorite field related to a low to moderate weathered sources, according to the CIA values. This chemical composition reflects the mineralogical data obtained on the studied mudstones, showing <2 μm grain-size fraction characterized by illite, mixed layers illite-smectite, chlorite and kaolinite.

Element geochemical proxies (e.g., MONGELLI *et alii*, 2006; PERRI *et alii*, 2012 and references therein) suggest that the source-areas have a predominantly felsic composition. Evolution of detrital modes is directly related to thrust-sheet emplacement of metasedimentary/granitoid units of the frontal thrusts of the northeastern Calabrian Arc (CRITELLI, 1999) and, to the north of the Sangineto-Pollino Line, of crystalline seamounts of the Tyrrhenian Sea. These areas evolved from metasedimentary (phyllite, fine-grained schist) to granitic-gneissic units. The compositional changes from metamorphyclastic to plutoniclastic sandstones in the Cilento Group are affected by thrust-sheet emplacement of the granitoid nappe. The studied sediments recorded a progressive increase of volcanic-plutonic supply. These compositional variations may be related to eastward displacement of the Calabrian arc and complete separation of the Calabrian terrane from the Sardinia block. The intrabasinal carbonatoclastic petrofacies (6) may be related to the abrupt flexure of the Alburno-Cervati-Pollino forebulge platform unit as response of the increasing tectonic load of the plutonic-high-grade metamorphic thrust unit (CRITELLI, 1999).

THERMAL HISTORY

A multi-method investigation (organic matter optical analyses and XRD analyses of clay minerals) has been performed to constrain 1D thermal modeling of the Cilento Group, cropping out along the Tyrrhenian margin in the Cilento promontory, among Castellabate, Pollica and Agropoli villages.

We performed two kinds of analyses:

- Vitrinite Reflectance (Ro%) of organic matter dispersed in sediments, using a Zeiss Axioplan microscope, under oil immersion in reflected monochromatic non-polarised light;
- Qualitative and semi-quantitative analyses of the < 2μm grain fraction (equivalent spherical diameter) performed by Scintag X1 X-ray diffraction system (CuKa radiation).

The thermal indicators obtained were used to calibrate 1D thermal models of the studied successions by means of the BASIN MOD software.

Samples for organic matter and X-ray diffraction analyses were collected from both Pollica and S. Mauro Fms. In addition, a few samples derive from the pelagic substratum (Crete Nere Fm).

Preliminary results of analysis on organic matter dispersed in sediments indicate that fragments of coalified woody tissues are generally very abundant throughout the entire synorogenic section. They are mainly made up of well-preserved macerals, extremely inhomogeneous in origin and preservation state. They indicate an effective reworking from thermally more mature sources and intense pre-burial oxidation. Furthermore the thermal signal due to well preserved macerals of the huminite-vitrinite group, coeval with the basin evolution, indicates the mature stage of hydrocarbon generation.

Quantitative analyses of < 2μm grain-size fraction show long-range ordered mixed layers illite-smectite indicating deep diagentic conditions in satisfactory agreement with organic matter maturity data.

According to the thermal modeling the maximum burial and thermal maturity experienced by the Cilento group decrease from older to younger stratigraphic units with an important erosional phase, at least, at the top of San Mauro Fm.

CONCLUDING REMARKS

The clastic compositions of the southern Apennines foreland basin strata reflect the thrust belt evolution through time, recording the accretion history of the Calabria microplate over the Adria margin. The Cilento Group records the main geodynamic events during the earliest collisional phase of the southern Apennines orogenic belt, and stratigraphic, compositional and thermal analyses may represent a quantitative tool for understanding the evolution history of collisional events in the central Mediterranean region.

Chemical-mineralogical and geological features of siliciclastic deposits from Mesozoic succession (western Calabria, Southern Italy): regional implications

FRANCESCO PERRI (*), FRANCESCO MUTO (**) & CLAUDUA BELVISO (°)

Key words: *composition, Mesozoic, mudstone, palaeoweathering, recycling, western Calabria*.

INTRODUCTION

In the Alpine orogenic belts, developed along the central-western Mediterranean region from the Betic Cordilleras to Apenninic Chain, clastic sediments preserve informations of the Mesozoic Pangea supercontinent break-up, the Tethyan Ocean rifting and its closure during Tertiary orogenesis. The interpretations of the history of these sediments can be used to test palaeogeographic and palaeotectonic reconstructions during the key orogenic phases and can be of relevance for evaluating global changes (e.g., PERRONE *et alii*, 2006).

The continental rift-valley phase and the proto-oceanic phase of the Tethyan rifting in the western-central Mediterranean region occurred during the Late Triassic to Early Jurassic, and in many tectonic units of the Alpine orogenic belts, continental redbeds, which mark the base of the Meso-Cenozoic covers, are interpreted as deposited during the rift-valley phase. The domain of these redbeds was located around small mountain areas, from which alluvial depositional systems provided siliciclastic supply to neighbouring nascent continental sedimentary basins formed during Triassic rifting (e.g., PERRONE *et alii*, 2006; CRITELLI *et alii*, 2008; ZAGHLOUL *et alii*, 2010 and references therein).

In this paper we clear up the complex history of a set of mudstone siliciclastic samples from a Mesozoic selected section outcrops along the western Calabria (Amantea section, Stilo Unit), using mineralogical, geochemical and geological tools. The history of these sediments, which include source area weathering, provenance, composition, recycling and burial, records an important phase during the geological evolution of the Western-Mediterranean Internal Domains.

GEOLOGICAL AND STRATIGRAPHIC SETTING

The Stilo Unit represents the uppermost tectonic unit of the complex calabrian thrust belt. The entire sheet has been involved in tertiary sheared blocks in oblique tectonic movement and results as remains of the basement and their Mesozoic cover. Sporadic and limited blocks outcrop in some uplifted areas, elongated in NW-SE trending ridges, where the Neogene to Quaternary cover has been eroded. The thickness of the whole succession changes notably among different outcrops. A continuous stratigraphic section is present in the western side of Calabria, between the Amantea village and Grassullo Mt. The mudstone samples (Mesozoic siliciclastic redbed deposits) have been collected along this stratigraphic section that unconformably rest on the hercynian basement (Fig. 1A). The last is made of calcschists, metapelites, granite and granodiorite that intrude Devonian shales.

The studied stratigraphic section consists of a lower siliciclastic sequence and an upper carbonate-dominated sequence. The siliciclastic deposits are made of quartz-rich conglomerates, that are generally massive and clast-supported. They are followed by sandstones and mudstones (siltstones and claystones) with red colours (mainly from purple red to orange red, but also yellowish, or whitish, Figs. 1A-B), coarse-grained arenites, greyish and brown, alternated to reddish and brown mudstones ('redbeds'). The sandstone beds are laterally continuous, although some beds laterally thin and wedge out to adapt to synsedimentary normal faults (Figs. 1A-C). The sequence passes upward to transitional conglomerates with carbonate clasts, yellowish and whitish calcareous sandstone, dolostone and breccias (Figs. 1C-D). This sedimentary evolution from siliciclastic continental redbeds to carbonate deposits, through transitional deposits, is quite similar to those of Peloritani Mt. and Calabria-Peloritani Arc (MONGELLI *et alii*, 2006; PERRI *et alii*, 2008, 2011), Sierra Espuña section (Betic Cordillera, Spain) and Ghomaride Nappes (Internal Rif Chain, Morocco) (PERRI, 2006; CRITELLI *et alii*, 2008;; ZAGHLOUL *et alii*, 2010).

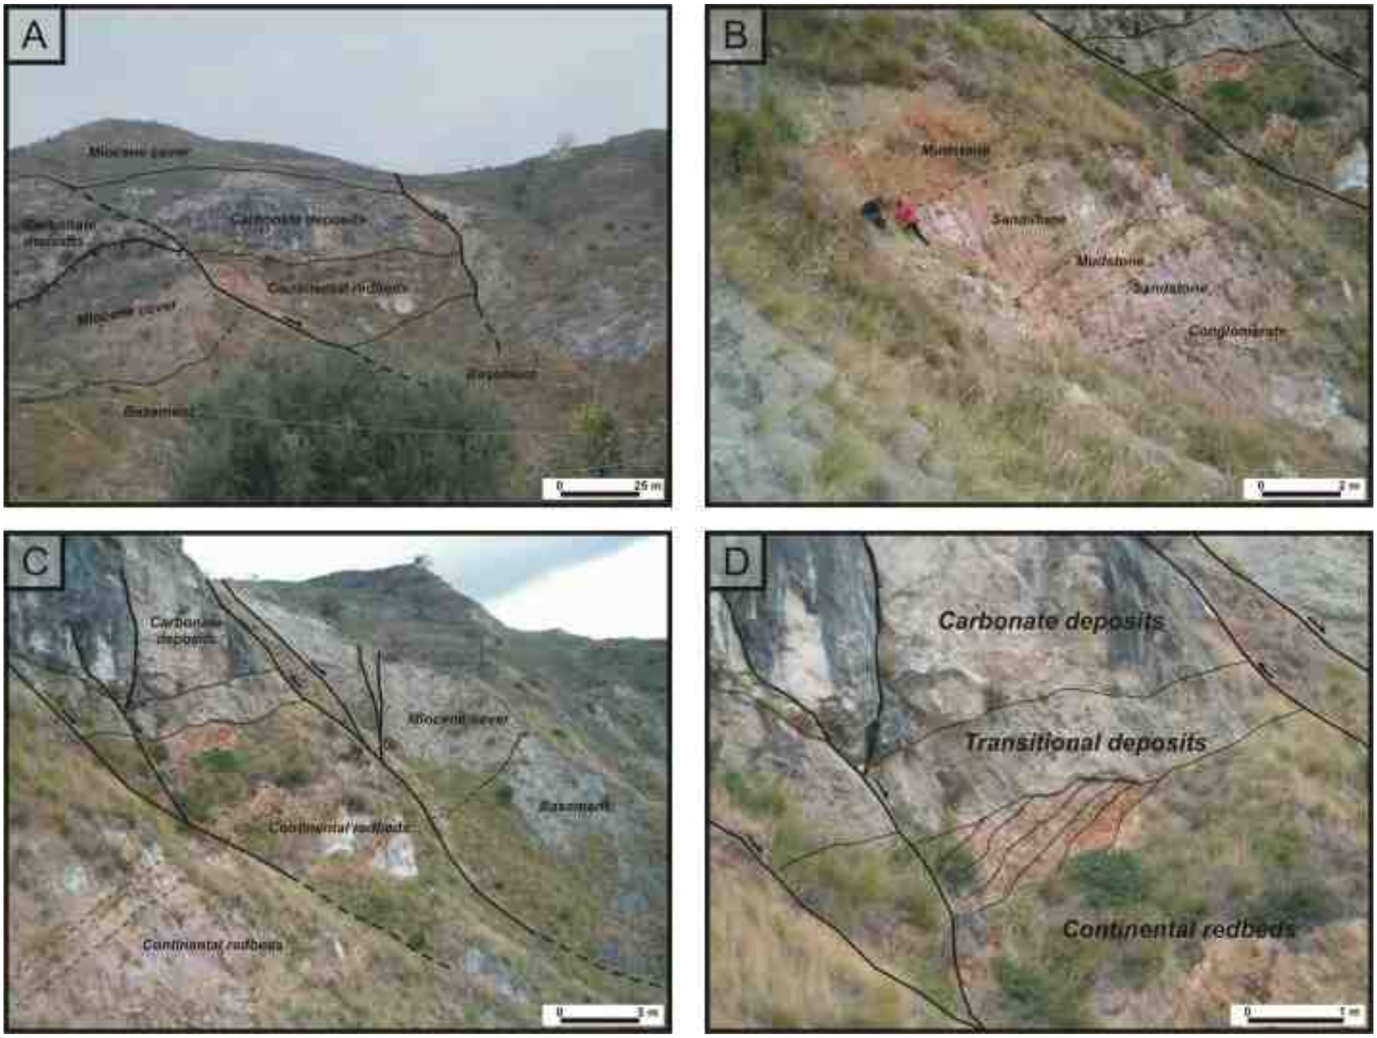

Fig. 1 – Exposure of key lithofacies of the Stilo Unit. (A) Panoramic view of the studied stratigraphic section along the Grassullo Mt. (western side of Calabria, Southern Italy). (B) Detail of the studied siliciclastic continental redbeds. (C) Upper part of the studied section showing the unconformable contact among siliciclastic continental redbeds, hercynian basement and Miocene cover. (D) Detail of the stratigraphic contact among continental redbeds, transitional deposits and carbonate deposits.

The siliciclastic deposits pass upward to the Jurassic carbonate sequence made up of white limestones separated by an evident angular unconformity and an erosional surface. Limestone thickness range from 30 metres to few metres in thickeness. The top of limestone is truncated by the Upper Miocene transgressive deposits or by the actual topographic surface (Fig. 1A-D). The succession is affected by a synsedimentary deformation testifying the Mesozoic tectonic phase, partially obliterated by the Tertiary tectonic evolution, as also showed in many Alpine Chain of the central-western Mediterranean region (e.g., PERRONE *et alii*, 2006; CRITELLI *et alii*, 2008). Post sedimentary low-angle faults are documented in the succession and result dislocated by Miocene-to-Quaternary faults. During this period the central calabrian arc experienced a crustal trascurrent tectonic phase that involved the neogene deposits and reactivated, in some case, the oldest faults. This phase is responsible of the reorientation of the ancient tectonic assemblage of the Stilo Unit involved in an oblique sheared crustal belt.

DISCUSSION AND CONCLUDING REMARKS

The Mesozoic continental redbeds of the Stilo Unit (northern sector of the Calabria-Peloritani Arc) has been described for its stratigraphical, mineralogical and chemical features. The CIA index and the A-CN-K plot, coupled with a mineralogical assemblage dominated by illite and illite/smectite mixed layers, suggests post-depositional K-enrichment. Recycling and sorting effects are showed by the $15Al_2O_3$-$300TiO_2$-Zr diagram and the Th/Sc vs Zr/Sc plot.

The clay-mineral features (Tab. 1) and mineralogy of authigenic interstitial components suggest that the studied samples experienced temperatures in the range of 130-160°C and, based on a geothermal gradient of about 25-30°C/km, a lithostatic/tectonic loading at least of 4-6 km (e.g., MONGELLI *et alii*, 2006; CRITELLI *et alii*, 2008; PERRI, 2008; PERRI *et alii*, 2008).

The close similarity in composition, diagenetic features and tectono-sedimentary evolution, as above-mentioned, between the studied sediments and the continental redbeds of different sectors

of the circum-Mediterranean orogens (Pseudoverrucano sub-domain; Perrone *et alii*, 2006), suggests a common deposition and evolution in a distinctive Mesozoic domain (Fig. 2, Mesomediterranean Terrane; GUERRERA *et alii*, 2005 and reference therein). This exotic terrane (M.T., Fig. 2), independent of the Africa-Adria and Europe-Iberia Plates, was separated from

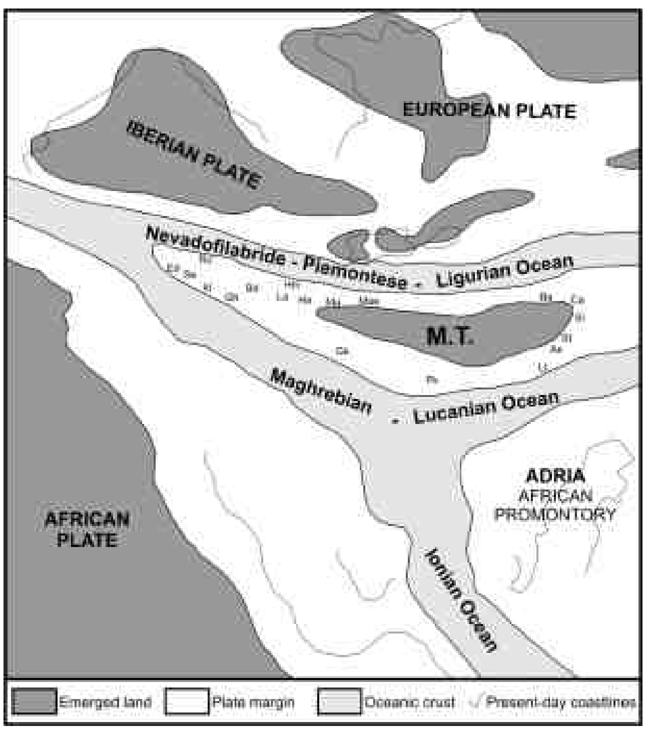

Fig. 2 – Early Cretaceous palaeogeography of the Central-Western Mediterranean Region and distribution of the oceanic basins around the Mesomediterranean Terrane (modified from GUERRERA *et alii*, 2005). Key - Mesomediterranean Terrane (M.T.): Rifian External 'Dorsale' (Ed); Rifian Internal 'Dorsale' (Id); Rondaides (Ro); Higher Mulhacen (Hm); Sebtides (Se); Lower Alpujarrides (La); Higher Alpujarrides (Ha); Betic Internal 'Dorsale' (Bd); Ghomarides (Gh); Malaguides (Ma); Malaguides-Espuña (Mae); Grande Kabylie (Gk); Petite Kabylie (Pk); Bagni (Ba); Castagna (Ca); Sila (Si); Aspromonte (As); Stilo (St); Longi-Taormina (Lt).

them by oceanic basins and transform zones, that connected the Proto-Atlantic Ocean with Central Tethys (Fig. 2). Thus, the studied sediments coupled to the continental redbeds preserved in rifted-margin prisms of many tectonic units (Internal Domains of the Apenninic, Maghrebian and Betic chains; PERRONE *et alii*, 2006) have palaeogeographical and palaeotectonic significance at the scale of the central-western Mediterranean area.

Miocene thrusting in the eastern Sila Massif: constraints from structural and AFT data

GIANLUCA VIGNAROLI (*), LILIANA MINELLI (**), MARIA LAURA BALESTRIERI (°), FEDERICO ROSSETTI (*) & CLAUDIO FACCENNA (*)

Key words: *AFT thermochronology, structural geology, Calabria-Peloritani Arc.*

INTRODUCTION

A common characteristic in evolution of the Alpine orogens in the central Mediterranean is the concomitance between the forward propagation of the frontal thrusts in the foreland domain regions and the activation of extensional structures in the back-arc regions (e.g., DEWEY *et alii*, 1989; PATACCA *et alii*, 1990; JOLIVET & FACCENNA, 2000).

The occurrence of the shortening-extension pair in the Calabria-Peloritani Arc (CPA) has been already proposed (e.g. WALLIS *et alii*, 1993; ROSSETTI *et alii*, 2004; IANNACE *et alii*, 2007; HEYMES *et alii*, 2010) and linked to the dynamics of the Apennine trench (e.g., JOLIVET *et alii*, 2003; ROSENBAUM & LISTER, 2004).

The eastern Sila Massif corresponds to the frontal sector of the CPA (Fig. 1), where basement units were involved in the orogenic construction (e.g., BONARDI *et alii*, 2001 and references therein). In this study, by combining structural dataset (off-shore and on-shore) with apatite fission-track (AFT) thermochronology applied to the Sila basement rocks of the Longobucco area, we document the Early Miocene age of the frontal thrusting in the CPA. These new data are then used to propose a unitary tectonic scenario for the Early Miocene evolution of the Calabria orogenic wedge.

DATA AND DISCUSSION

The first order structures in the Longobucco area are NW-SE striking thrust systems that mark the contacts between the Sila basement (Hercynian high-grade metamorphic and intrusive rocks), the Longobucco cover, and the Paludi Formation.

(**) Istituto Nazionale di Geofisica e Vulcanologia

(°)CNR, Istituto di Geoscienze e Georisorse

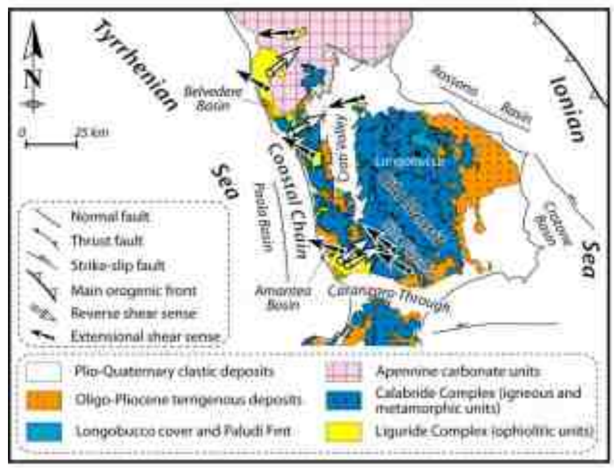

Fig. 1 – Schematic geological map of the Calabria-Peloritani Arc showing the main ductile and brittle tectonic features described in both metamorphic and non-metamorphic domain.

The Sila basement forms a major antiformal structure, with a westward gently-dipping western flank and a steeply-dipping eastern flank along the overthrusting contact with the underlying Longobucco cover sequence. The structural style in the Longobucco cover resembles a fold-thrust-belt geometry, consisting of ENE-imbricated thrust slices and ENE-verging fold trains. Thrust deformation also involves the Paludi Formation, with thrust surfaces, generally striking NW-SE and dipping SW. Fold vergence and shear fabrics systematically document a top-to-the-NE sense of shear. The Middle Miocene deposits of the Rossano Basin unconformably lie above the contact between the Paludi Formation and the Sila basement along an E/NE shallowly dipping contact.

The analysis of available well log data generally confirms the stratigraphic-structural relationships among the above mentioned units. The Sila basement and the Longobucco cover are characterised by imbricate thrust sheets that also involve the flyschoid sequence of the Paludi Formation. These allochthonous sheets are bounded by southwestern dipping thrust surfaces that show a top-to-the-ENE sense of shear.

A set of 14 samples for apatite fission-track thermochronology was collected from the granitoid rocks belonging to the Sila basement that constitutes the hangingwall of the frontal thrust system. Sampling followed three NE-SW

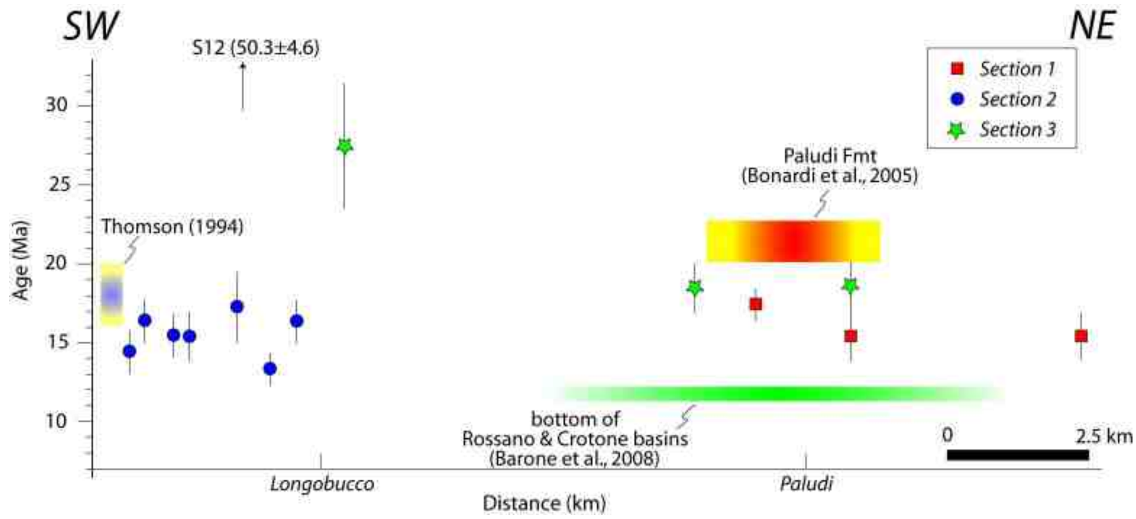

Fig. 2 – Stratigraphic and geochronological dataset across the eastern Sila Massif.

vertical profiles that ran roughly parallel to the tectonic transport direction. The samples show unimodal length distributions with relatively long mean lengths and small standard deviations that are indicative of moderate-to-rapid cooling across the partial annealing zone (PAZ). Our AFT data show that the Sila basement crossed throughout the PAZ between 18 Ma and 13 Ma (Fig. 2). A reconstructed break-in-slope at ca. 17–18 Ma defines the transition from a time of relative thermal stability to a time of rapid cooling throughout the PAZ. According to published AFT ages from the Sila Massif (THOMSON, 1994), the 17–18 Ma age can be attributed to the main exhumation and cooling phases of the Sila basement in the study area. Evidence arising from the geological survey constrains the age of the thrusting phase bracketed within (i) the age of the Paludi Formation (Aquitanian, BONARDI *et alii*, 2005) involved in the thrusting tectonics, and (ii) the onset of the sedimentation in the Rossano and Crotone basins (Serravallian-Tortonian) considered as wedge-top basins related to orogenic accretion and uplift/erosion in the CPA (BARONE *et alii*, 2008) (Fig. 2). Therefore, our structural and thermochronological dataset constrains the age of the thrusting event in the region.

The exhumation in the eastern Sila Massif was accomplished by erosion promoted by upward motion of thrust-bounded blocks during the Longobucco thrusting event, following the typical scenario of the mountain profile denudation in convergent settings (e.g., RING *et alii*, 1999). The Africa-verging shearing recognised in the eastern Sila Massif is compatible with the compressional tectonics, regionally distributed in the CPA (see HEYMES *et alii*, 2010; VIGNAROLI *et alii*, 2012). The Miocene shortening of the outer units of the CPA was synchronous with ductile-to-brittle extensional tectonics leading to crustal thinning in the orogenic hinterland (ROSSETTI *et alii*, 2004; CIFELLI *et alii*, 2007). Our model suggests that the concomitance of foreland shortening and hinterland extension can be associated with the dynamics of the CPA orogenic wedge concomitant with the progressive Apennine slab retreat since at least Oligocene onward.

The transition from continental to oceanic subduction across the Southern Apennines - Calabrian Arc boundary: insights from Receiver Function Analysis

NICOLA PIANA AGOSTINETTI (*), LUCIA MARGHERITI (*), CLAUDIO CHIARABBA (*)

Key words: *Southern Apennines, Calabrian Arc, continental subduction, oceanic subduction.*

Along-strike variations in the subducted lithosphere (i.e. oceanic vs. continental) have been well-documented in the Apennines-Calabria subduction zone, where we observe strong changes in crustal wedge materials, subduction rates, earthquakes distribution, subduction-related volcanisms, trench-retreat rates and overriding plate extension, from North to South. However, the transition from one to the other lithospheric domain has not been deeply investigated, such that a clear location of the former, subducted ocean-continent boundary is still missing. In this study, we focus on the transition between Southern Apennines (SA) and the Calabrian arc (CA). While the former have been developed from the crustal wedge of the subduction of the Adria microplate margin (i.e. the subduction of a continental shelf), the latter is a widely-recognized, "classical" subduction of an oceanic plate (i.e. the Ionian ocean). The differences in the two subduction regimes are striking (i.e. SA subduction is almost stopped, while CA subduction is still active), but the strongly 3D nature of the subduction zone (i.e. the arc curvature), did not allow to clearly recognize the two plates at depth (e.g. from the deep earthquake distribution, which should characterize oceanic subduction). Here, we use teleseismic receiver function, i.e. the analysis of the P-to-s converted phases from the slab interfaces, to constrain the nature of the subducted lithosphere along the Tyrrhenian coast from the southern edge of the SA orogens to the central portion of the CA. Seismic data were recorded by 15 stations, both permanent and temporary, deployed between 2004 and 2010 along the Tyrrhenian coast of the SA and CA. We analyse about 1000 teleseismic events from which we select about 100 high S/N receiver function (RF) for each stations. RF are inverted using a Neighbourhood Algorithm, a global search method based on geometrical concepts. We apply a method for harmonic decomposition of the RF data-set, to investigate both isotropic and anisotropic properties of the materials investigated and imagine the different stages of metamorphisms of the subducted crust. Also, anisotropic structure of the mantle wedge is reconstructed and linked to the possible asthenospheric mantle flow driven by slab rollback.

Preliminary results point out a number of interesting differences in the lithospheric structure, between SA and CA. First, the subducted crust beneath the SA displays strong anisotropy with respect to the subducted crust beneath CA, which confirms the different nature of the materials subducted. The subducted crust beneath SA is thicker with respect to CA, as expected from widely accepted model of continental subduction. The horizontal projection of the anisotropic axis in the mantle wedge displays a coherent trench-normal pattern, which can be related to the mantle flow in front of a retreating slab. Finally, a low S-velocity layer is likely above the slab surface, beneath SA. Such layer could represent the mantle wedge hydrated from the fluids released by the progressive metamorphism of the subducted crust.

Are the source models of the M 7.1 1908 Messina Straits earthquake reliable? Insights from a novel inversion and a sensitivity analysis of Loperfido (1909) leveling data

MARCO ALOISI (*), VALENTINA BRUNO (*), FLAVIO CANNAVÒ (*), LUIGI FERRANTI (**), MARIO MATTIA (*), CARMELO MONACO (°), MIMMO PALANO (*)

Key words: *Messina Straits, 1908 earthquake, inversion of leveling data, morphotectonics.*

INTRODUCTION

Intense Quaternary extensional tectonics, coupled to coastal uplift, are well documented in the Messina Straits (Fig. 1), a highly seismic area in the Central Mediterranean orogen struck on December 28th, 1908 by a M 7.1 earthquake and ensuing devastating tsunami (BARATTA, 1910*;* SCHICK, 1977). This structural depression is bounded by active normal faults, marked by well-preserved scarps, which displace Pleistocene marine terraces and Holocene shorelines (GHISETTI, 1981; VALENSISE & PANTOSTI, 1992; TORTORICI *et alii*, 1995; FERRANTI *et alii*, 2007; SCICCHITANO *et alii*, 2011).

The lack of recognition of clear surface faulting made it difficult to determine the source of the 1908 earthquake. However, the coseismic displacement caused a predominant down-throw of the narrower part of the Straits, and minor coastal uplift away from it, as documented by leveling surveys performed one year before and immediately after the earthquake (LOPERFIDO, 1909). By inverting the leveling data, different sources have been modeled, all concurring with dominant normal faulting on planes trending nearly parallel to the Messina Straits, albeit with different locations and dip (see VALENSISE & PANTOSTI, 1992; AMORUSO et alii, 2002 and references therein). Because geological and seismological arguments pose weak constraints and have led to conflicting interpretation of the causative source, leveling data are still advocated as the basis for the correct model (see review in PINO *et alii*, 2009). Contrary to this common thinking, we retain that the still lingering debate on the source highlights potential pitfalls in the use of leveling data as model constraints. This possibility motivated us to carry out a novel inversion of the original data collected by LOPERFIDO (1909) with the aim of defining their limits and usefulness. The main focus of our study was the analysis of the reliability of the leveling data as a useful tool toward an undisputed certainty about the fault source of the 1908 earthquake. We demonstrate that no definite conclusions can be drawn on the basis of the leveling data alone and more robust geodetic and morphotectonic constraints are necessary to contribute to solving this conundrum. With the aim of providing a meaningful contribution to the debate on the 1908 earthquake source, we also review and implement morphotectonic, geodetic and geophysical observations on the Armo fault in Calabria, which is proposed as being part of the 1908 seismogenic source.

MAIN RESULTS

In order to test the possible fault models for the Messina Straits 1908 earthquake, a novel inversion and a sensitivity analysis of LOPERFIDO (1909) leveling data has been carried out using two well-known and robust search techniques: the GAs and successively the Pattern Search applied on the obtained Gas minimum. In summary, our analysis highlights that there is no model, among those proposed so far, which is able to fully explain the data, and the available data themselves are not able to strongly constrain a model solution. The main result of our analysis is that the differential leveling data do not differentiate between a west-dipping fault on the Calabrian side from an east dipping fault on the Sicilian side of the Straits. This result contradicts the mainstream conclusion that the data favor the latter, and places a possible candidate seismogenic source of the 1908 earthquake near to the Armo fault (Fig.1).

Seismicity, geodetic (MATTIA *et alii*, 2009; SERPELLONI *et alii*, 2010) and new morphotectonic data collected in the area of the western-dipping modelled source suggest its recent geologic activity and that it is presently accumulating strain. The small instrumental seismicity illuminates the whole array of en-echelon faults, a possible upper crustal expression of a longer fault at depth, which is compatible with the required size for the earthquake source. Seismic tomography images indicate that this west-dipping structure extends to 18-20 km depth, and thus represents the main crustal structure in the Messina Straits area (SCARFÌ *et alii*, 2009; NERI *et alii*, 2012).

Integrated data appraisal corroborates the possibility that the Armo and other en-echelon on-land and submerged faults (ARGNANI *et alii*, 2009) are the locus of major deformation in the region, and possibly slipped during the 1908 earthquake, causing

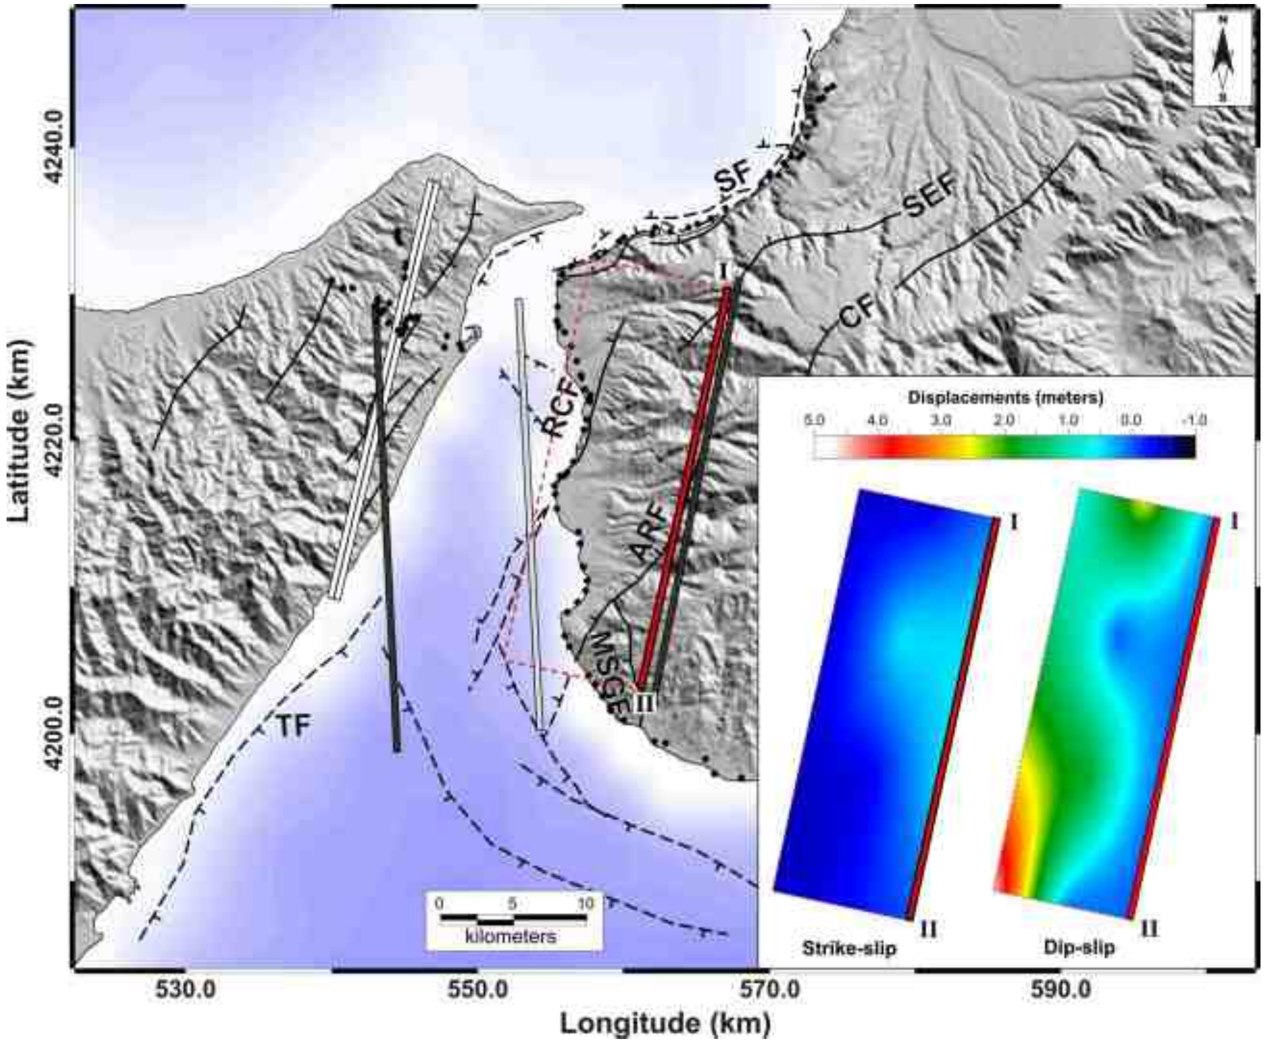

Fig. 1 – Schematic map of the faults modelled for the Messina Straits 1908 earthquake. Solid lines indicate the intersection between the fault planes and the ground surface: the white double line represents the summary model proposed by BRANCALEONI *et alii* (2009); the dark grey single lines represent two equivalent solutions obtained without constraints on the fault parameters; the light grey and red single lines represent the two equivalent solutions obtained fixing the dip angle to the value of 60°. Black lines indicate the geological fault traces (dashed where inferred or submerged, ticks on the downthrown block; ARF: Armo Fault, CF: Cittanova Fault, MSGF, Motta San Giovanni Fault; RCF, Reggio Calabria Fault; SEF, S. Eufemia Fault; SF, Scilla Fault). Black circles indicate the leveling point measured by LOPERFIDO (1909). Inset shows strike-slip and the dip-slip component for the Armo fault modelled with the dip fixed to 60° (the red line), calculated dividing the dislocation surface into a grid of uniformly sized blocks of 7×7 km. The results are projected on the ground surface. The projection is UTM-WGS84.

near-surface ruptures and westerly down-stepping of leveling benchmarks. This proposition has important engineering implications for the planning of the ~3 km long single-span bridge between Sicily and mainland Italy.

The Southern Tyrrhenian subduction zone: an upgraded view from seismological studies

CLAUDIO CHIARABBA (*), NICOLA PIANA AGOSTINETTI (*), IRENE BIANCHI (**)
GENNY GIACOMUZZI (*)

Key words: *Southern Thyrrenian subduction, seismological studies*

The southern Tyrrhenian subduction is known since more than thirty years. A Benioff plane defined by intermediate depth and deep earthquakes was early proposed in 1970. From the first intuition to the current representation of the Ionian subduction several decades were passed and numerous contributions published. In this review, we present our knowledge of the system obtained by integrating earthquakes distributions within the Ionian slab, seismic tomography (Vp, Vs, Qp models) and receiver function (RF) results.

The joint analysis of RF and tomography allow us to reconstruct both the elastic properties and the geometry of the components of the subduction zone. The first method clearly delineates the geometry of the shallow structures from the bottom of the Tyrrhenian crust to the upper portion of the downgoing ionian plate. Tomographic models from local earthquakes and teleseismic events show almost consistently the regions of high to low speeds associable to oceanic portion of the slab and to the asthenosphere flowing through tears of the slab.

In particular, RF images clearly depict the discontinuity of the subduction interface between the Southern Apennines and the Calabrian arc, supporting the hypothesis of the segmentation of the Ionian slab during its subduction beneath the Tyrrhenian sea. Such discontinuity can be related to the transition between the oceanic slab, still subducting beneath the southern Calabria, and the continental margin, which entered the subduction trench a few Myr ago, promoting the slow decrease of the subduction rate in Southern Apennines. Harmonic decomposition of the RF data-set points out both the isotropic and the anisotropic structure of the subducted crust and allow to recognize the different elastic properties of the materials subducted beneath Southern Apennines and the Calabrian Arc. Such differences could be related both to the different origin of the subducted crust (Continental vs Oceanic) and to the different "style" of their metamorphisms.

Our data show that the subduction of the Ionian slab was a rather discontinuous event. The progressive incoming of continental margins and complexity of the oceanic plate account for a complex scenario during which accelerating phase of subduction, back arc opening, slab tearing and detachments took place over the past 16 Myr. Presently the oceanic slab is narrow and restricted to southern Calabria.

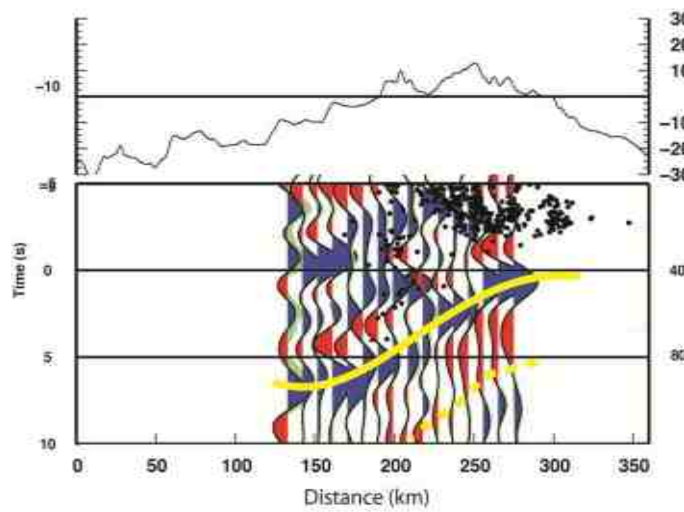

Fig. 1 - The figure shows the geometry of the subducting slab underneath the Sila Mt., as defined by Rfs and earthquake locations. Blue and red pulses stand for high and low velocity material, respectively. The yellow lines are the thin lithosphere, probably of continental origin. The NW-dipping stripe of seismicity occurs within low Vs material, the subducted portion of the crust.

Site effect in Messina and Reggio Calabria Area using HVSR technique

DE ROSE C. (*), GUERRA I. (**), GERVASI A. (**,***), TAFARO A. F. (°) & MUCCIARELLI M. (°°)

Key words: *HVSR technique , 1908 earthquake.*

INTRODUCTION

The Messina Strait is one of the most seismically active areas of the Southern Italy; in fact, since 1783, 7 earthquakes with M ranging between 6.0 and 7.2, are reported with extensive damages and induced coseismic environmental effects well described. The most remarkable phenomena were massive landslides (with consequent obstruction of the valleys), small lakes formation, watercourses deviation, slumps, soil fracturing and liquefaction; in the urban area many of the coesismic effects were without doubt due to the settlement of loose sediments and artificial filling (e.g., Messina and Reggio Calabria dock areas).

The aim of this work is to understand whether the site effect (generated by resonance phenomena in the upper sediments layers) could affect, at least partially, the distribution of urban damage after the 1908 earthquake. In fact the existence of detailed damage information for this earthquake, collected by one of the most relevant seismologist of that time (BARATTA, 1910), provides the opportunity of making a comparison between observed damage and the natural frequency of the foundation soil.

For this purpose a geophysical survey was carried out in the two main cities of the Straits, and the HVSR method was adopted to identify areas subject to amplification effects and delineate the geometry of sedimentary bodies.

The microtremor HVSR method (originally proposed by NOGOSHI AND IGARASHI (1970) and later diffused by NAKAMURA (1989) widely used for site effect study provides a direct estimate of the resonance frequencies of sedimentary cover, which tend to amplify soil motion in the case of earthquake.

HVSR MEASUREMENT

For the site effects study in Reggio Calabria and Messina HVSR (horizontal over vertical spectral ratio, or H/V method) technique had been used. A complete review on the method and a critical approach can be found in MUCCIARELLI (1998), BARD (1999), and MUCCIARELLI & GALLIPOLI (2001).

A total of 80 records of ambient noise were collected at ground surface in Reggio Calabria and in Messina in the period between May and September 2008 (fig.1).

At each site, seismic noise was sampled for 10, 20 or 30 minutes at 256 Hz sampling rate and acquired trough an ultralight tool (Tromino, tromograph, www.tromino.eu) specifically designed to accomplish this task; the instrument was North oriented during all the measurements.

All measurements were carried out on outcropping of natural soil avoiding artificial covering that may strongly affect HVSR curves (CASTELLARO & MULARGIA, 2009); in addition, no recordings were carried out in windy days because noise induced by wind can affect the significance of the HVSR curves.

Data analysis was performed using Grilla software (www.tromino.it): H/V curves were calculated by averaging the H/V obtained dividing the signal into non-overlapping windows of 20 s. For each windows, the signal was de-trended, tapered with a Bartelett windows, padded with zero and FF transformed. The spectra of each windows are smoothed with a Konno and Homachi (1998) smoothing function f with b =30 , and the horizontal to vertical spectral ratio is computed at each frequency, for each window. When transient noises were identified, the portions of signal were rejected and excluded from further computation.

The final HVSR function at each frequency is given by the average of the HVSR of each window with the relevant 95% confidence interval.

All the curves were submitted to the SESAME (European Project 2005) test to validate the meaningful of the HVSR peak; all peaks fit exactly the SESAME (2005) criteria are considered to be significant and usefully in our analysis.

Due the different effects observed by Baratta in the two cities, a different approach in planning measures in each city was adopted.

Fig. 1 –Location of record sites in Reggio Calabria and Messina.

Records in Reggio Calabria were performed mainly in an approximate 800×800m grid; other sites of measurement were chosen along the main rivers (*fiumare*) that cross the town (Annunziata, Calopinace e Sant'Agata).

In the city of Messina measurements were carried out mainly in the historical center, in areas reported by Baratta (1910) between the most and the least damaged.

The first include the Duomo, the Church of the Catalans, the Monte di Pietà, the Porta Imperiale, Boccetta , the city Port, etc.., the second comprise Fort Gonzaga F, Montepiselli, Scoppo, etc..

Other measurements were performed in the Ganzirri area.

RESULTS IN REGGIO CALABRIA

Measurements in Reggio Calabria can be grouped in three principal trends:

Measurements performed close to the coastline show significant peaks at very low frequencies (between 0.3 and 0.8 Hz) ;

Measurements in the inland area characterized by peaks with higher frequency (1.5-2 hz), with a frequency increase for increasing distance to the coastline.

Measurement along the rivers show a chaotic distribution of the HV peaks, but also in this case it is possible observe the same phenomenon of "migration of the peaks" towards higher frequencies away from the coast line.

Significant HVSR peaks at low frequencies can be attributed to the presence of a deep contact between the crystalline bedrock and the terraced marine sediments that cover the area. The well observed "migration phenomenon" instead could be related to the progressive decrease of the sedimentary cover thickness towards the internal areas.

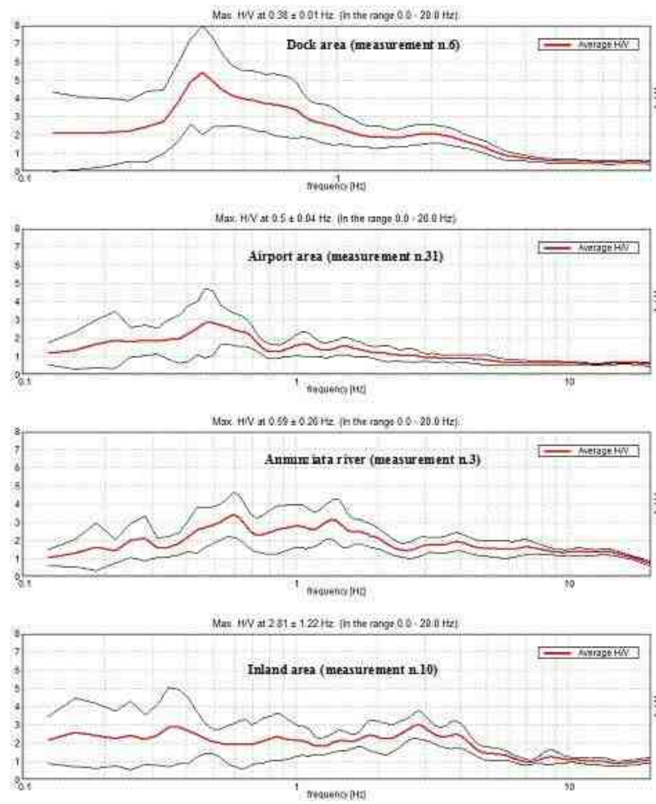

Fig. 2 – Same HV curves in Reggio Calabria area. In the dock and in the airport area are present clear and significant peaks a low frequencies. Along Annunziata river curves are chaotic. the HV curves in the inland show peaks a higher frequencies.

RESULTS IN MESSINA AND "LAGHI DI GANZIRRI"

In the historical center of the city (Cathedral, Town Hall Square, Church of the Catalans) peaks of amplification around 1 Hz and with a maximum at 2 Hz are observed.

Along Viale San Martino we observe significant peaks following a trend comparable to the data surveyed in Reggio where the HV ratio increase moving away from the coastline.

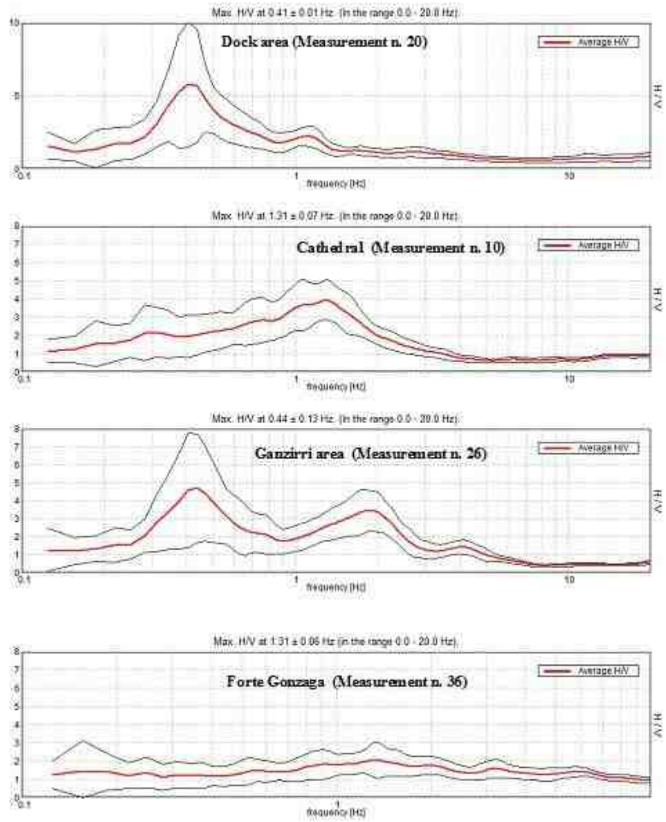

Fig. 3 – Same HV curves in Messina area. In the dock is well visible a peaks a low frequencies. Near the cathedral the HV curve show a maximum around 1. In the Ganzirri area double peaks are visible whereas in the Forte Gonzaga any peak is present.

In the docks area frequencies are low (about 0.5 Hz) with values comparable to those found in both in Ganzirri and in areas closer to the coast of Reggio Calabria.

In the Ganzirri area, in the north of Messina, is possible observe two peaks: the first characterized by large amplitude and low frequency (ca. 0.45 Hz); the second, contrariwise, showing lowest amplitudes values and frequency ranging between 2 and 4 Hz.

A remarkable result in this case is the directivity of HVSR, which shows a preferred direction N60E, approximately parallel to the coastline and the main tectonic structures of the area.

Finally, for measurement performed in the inner area where Baratta (1910) observed the minor damages in Messina (Forte Gonzaga, where the measurement was made on the bedrock, Montepiselli and Scoppo, placed on consolidated sandstone), no significant amplification is detected.

On the active tectonics along the Messina Strait

CARLO DOGLIONI (*), MARCO LIGI (°), DAVIDE SCROCCA (°°), SABINA BIGI (*), GIOVANNI BORTOLUZZI (°), EUGENIO CARMINATI (*), MARCO CUFFARO (°), FILIPPO D'ORIANO (**), VITTORIA FORLEO (*), FILIPPO MUCCINI (^) & FEDERICA RIGUZZI (^^)

Key words: *Messina Strait, seismic hazard, coexisting independent tectonic settings*

The world's longest and tallest one-span bridge has been planned to connect peninsular Italy to Sicily across the Messina Strait. This is one of the most seismically active areas of the Mediterranean, located along the transfer zone between the faster SE ward retreating Calabria subduction zone and Sicily.

Considering this historical background and the geological evidence of active deformation in the area, it should be discussed whether the bridge is compatible with our knowledge of the area. Since the regional tectonics is still unclear and the network of active faults not yet framed in a comprehensible structural model, we explored the area by a multichannel seismic reflection survey (TIR10, cruise report available at http://www.ismar.cnr.it). New regional cross sections allow to image the upper crust of the area, and to add information for the evaluation of the seismic risk.

The following main features have been observed: i) the NW-trending Capo Peloro fault, running parallel to the coast of northeastern Sicily, offsetting the sea-floor, steeply southward dipping, and interpreted as a right-lateral transpressive system; ii) a 12 km wide, NE-trending crustal anticline deforming the sea-floor, en-échelon to the Capo Peloro fault, located at the eastern tip line of the fault itself in the southeastern Tyrrhenian Sea, just north of the Messina Strait; iii) a normal fault propagation-related actively growing syncline, buried in the ENE-trending segment of the Messina Strait, with a blind normal fault.

Relative to fixed Eurasia, the GPS sites in Sicily move toward NNW, whereas those in Calabria are NE-trending, at slower rate. This implies a faster northward component of motion of Sicily with respect to Calabria, and E-W stretching between Sicily and Calabria. Therefore, the boundary between Sicily and Calabria is diffuse and is deforming by right-lateral transtension. Most of the right lateral motion and the extensional component appears to be concentrated onshore Sicily, along the northern prolongation of the Malta Escarpment in the central-western part of the Peloritani mountains (e.g., the Tindari fault). The strain rate indicates that the Messina Strait itself is presently not the most actively moving area, suggesting tectonic loading, i.e., the faults are locked and the elastic energy is accumulating more than elsewhere, making them more prone to rupture. Along the ENE-trend, the Messina Strait is expected to behave as a graben, possibly with a minor left-lateral transtensional component. Along the N-S trend of the strait, moving S-ward into the Ionian Sea, the Messina Strait is interpreted as a right-lateral transtensional fault system, merging into the Malta Escarpment. Therefore, the area represents the transfer zone between two geodynamic settings being characterized by the coexistence of extension and N-S dextral transtension in the southern Messina Strait, adjacent to an area of roughly E-W transpression along the Capo Peloro fault along the northern Sicilian offshore.

Based on conservative estimates of the Capo Peloro fault length and vertical offset, and size of the upper crustal-scale anticline, a magnitude higher than the 1908 Messina earthquake (M 7.1) cannot be ruled out.

Geometry and modeling of an active offshore thrust-related fold system: the Amendolara Ridge, Ionian Sea, southern Italy

LUIGI FERRANTI (*°), FABRIZIO PEPE (**), PIERFRANCESCO BURRATO (***), ENRICO SANTORO (*), MARIA ENRICA MAZZELLA (*), DANILO MORELLI (****), SALVATORE PASSARO (*****), GIANFRANCO VANNUCCI (******)

Key words: active fault-propagation folds, blind fault segment modeling, seismotectonics, southern Italy.

On the Ionian Sea coast of southern Italy, spanning the transition from the Calabrian Arc to the Apennines, NE-directed motion of the thin-skinned frontal thrust belt of the Apennines toward the Apulian foreland reportedly ceased during the Early-Middle Pleistocene (PATACCA & SCANDONE, 2007). Deformation since then was dominated by the regional uplift of the Calabrian Arc (WESTAWAY, 1993; CUCCI & CINTI, 1998). However, detailed structural and geomorphologic analysis has revealed that uplift of Middle Pleistocene and younger marine terraces not only ensues from a regional-scale process, but also reflects a smaller-wavelength component of shortening which is attributed to recent, deeper activity of blind thrust and transpressional structures (FERRANTI *et alii*, 2009; CAPUTO *et alii*, 2010). Thus, shortening in this sector of the Apennines may still be ongoing although at a very slow rate and with a subdue morphological signature. The latter limitations have led to the common thinking that this sector of the Apennines is inactive.

The submarine extension of the frontal thrust belt is represented by the Amendolara ridge, which stretches for over 80 km to the SE beneath the Taranto Gulf, the northern embayment of the Ionian Sea (Fig. 1, inset). Although it was suggested, based on existing multichannel seismic profile analysis, that the ridge has grown as a result of transpressional displacement (DEL BEN *et alii*, 2007; FERRANTI *et alii*, 2009), detailed images of the structural architecture as well as robust constraints on the timing of recent deformation were lacking.

High-resolution marine geophysical data collected on the Amendolara ridge during the TEATIOCA_2011 cruise provided unequivocal constraints to assert active fault-related fold growth. Single-channel seismic (sparker) and acoustic CHIRP profiles, corroborated by multibeam mapping and shallow coring, form the novel dataset to constrain the near-bottom evolution. The new data were benchmarked to the crustal geometry by means of interpretation of existing multichannel seismic profiles.

The integrated dataset analysis revealed that the NW-SE trending ridge has grown during Late Pliocene-Quaternary as a result of motion above an array of blind thrusts grouped into the Amendolara Thrust-Fold System

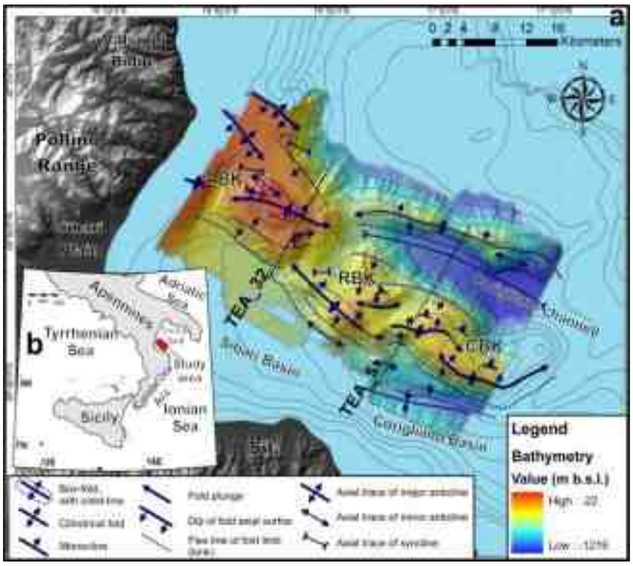

Fig. 1 – Structural map of the Amendolara Ridge based on analysis of Sparker profiles. Base is the multibeam dataset acquired during the TEATIOCA_2011 cruise. Inset b is location of study area. ABK, Amendolara Bank; RBK, Rossano Bank; CBK, Cariati Bank.

(ATFS). Strikingly, the ATFS has displacement to the southwest toward land, and represents a backthrust belt in the regional reference frame.

The stratigraphic signature of recent (Middle-Late Quaternary) fold growth is recorded by syn-tectonic depositional sequences within ponded basins and on the flanks of the ridge, and is represented by tectonically-stacked packages, and by widespread debris flows and slumping (Figs. 2, 3). Along the whole southwest margin of the ridge, the Middle-Late Quaternary depositional packages are ostensibly folded in response to southwest-

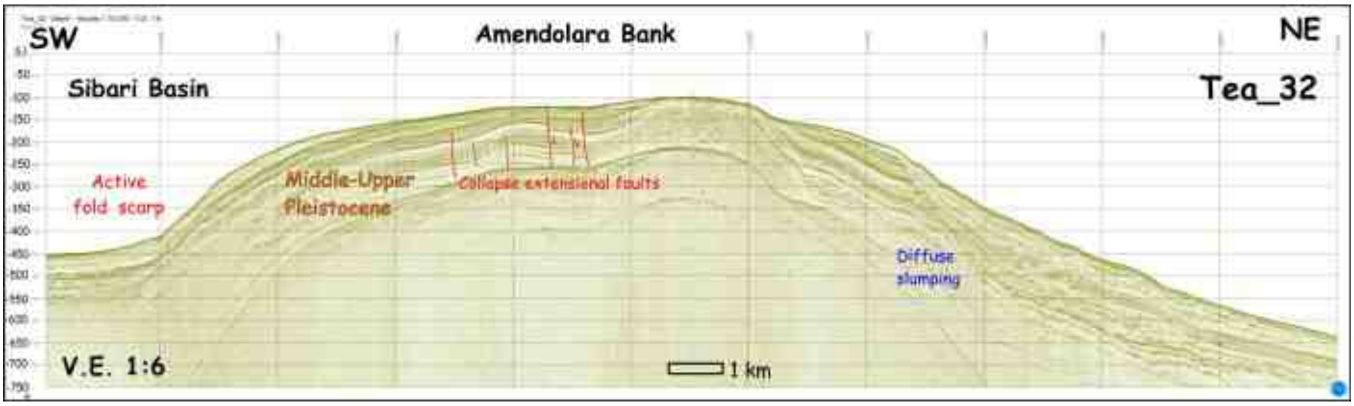

Fig. 2 – Depth-converted line TEA_32 across the Amendolara bank, western part of the Amendolara ridge (location in Fig. 1).

directed displacement, as documented by fold asymmetry (Figs. 2, 3).

Morpho-bathymetry data and seismic profiling show contrasting geometries and structural styles among the three ~15 to 20 km long and right-laterally offset banks which form the top of the Amendolara Ridge (Fig. 1). These banks are floored by the folded sediments and locally by lower Pleistocene or older bedrock. Whereas the Amendolara and Rossano banks are floored by an asymmetric fold (Fig. 2) the structure of the Cariati bank is represented by a north-dipping monocline with a train of minor frontal folds (Fig. 3). Based on the different geometry and morpho-structure, we argue that the banks are the expression of as many en-echelon blind fault segments.

Based on the pattern of folded reflectors, the eastern and central segments (Cariati and Rossano, respectively) display evidence of more recent activity (Fig. 3). To the north of the Amendolara bank , a NE-verging system of two anticlines (Fig. 2), which are the offshore prosecution of the Valsinni ridge on-land (one of the recent most uplifted ridge of the Southern Apennines, PATACCA & SCANDONE, 2007), fold the basal unconformity of the last glacial sequence.

Appraisal of the crustal seismic reflection profiles calibrated with exploratory wells reveals that the ATFS controlled deposition of an up to ~3 km thick syn-tectonic Late Pliocene-Quaternary sedimentary sequence in the Sibari and Corigliano basins, which flanks the ridge to the southwest (Fig. 1).

Numeric modeling of Middle Pleistocene markers extracted from the sparker, and of older markers derived from the multichannel seismic dataset suggests that the three steep blind segments, which are the deep expression of the folded or tilted sediments in the banks, are rooted at ~10 km depth into a low-angle dipping detachment ramp extending to ~20 km depth. This deeper ramp is responsible for the overall NE-tilt of the ridge (Fig. 3) and development of a larger-wavelength fold involving the ridge as a whole.

Documentation of active fold growth beneath the Amendolara Ridge carries important seismotectonic implications. This part of southern Italy is characterized by a low level of historical and instrumental seismicity. Indeed, the region suffered from moderate but locally damaging earthquakes caused by yet unknown or debated sources.

The strongest earthquakes in the area are the 1836, April 25 (M= 6.2), the 1917, June 12, (M=5.25) and the 1988, April 13 (M=5) (data from CPTI11, ROVIDA *et alii*., 2011). The 1917 and 1988 events are located offshore, and our new analysis supports the contention that they spatially coincide with the central-eastern segments of the ATFS, where the evidence of more recent activity is found (Fig. 3). On the other hand, evidences show that the 1836 event is located inland, near the northern coast of the Sila (GALLI *et alii*, 2010). We also investigated the tsunami occurred during the 1836 event (TINTI *et alii*, 2004) and the alternative hypothesis between earthquake or submarine landside.

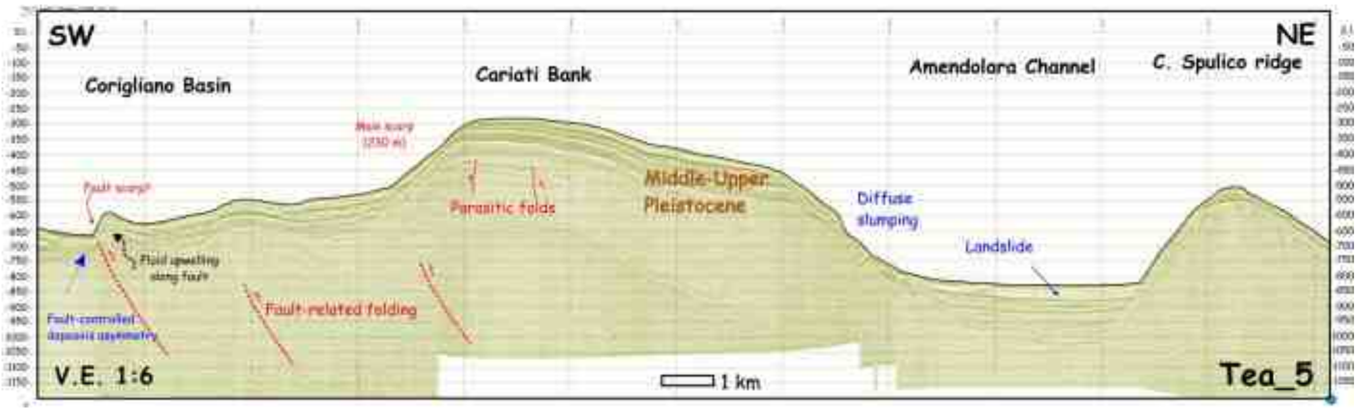

Fig. 3 – Depth-converted line TEA_5 across the Cariati bank, central part of the Amendolara ridge (location in Fig. 1).

Today, the ATFS shows a moderate seismic activity expressed by Mw<4.7 thrust and transpressional earthquakes (Fig. 4), which apparently originate at the branching zone between shallow ramp segments and deep detachment. The incremental shortening axis resolved onto the mean strike of the ATFS indicates left-oblique to reverse motion. Based on the size of fault segments and the modeled depth of micro-seismicity, we argue that the ATFS may be capable of moderate (M~6) earthquakes.

Growth of the Amendolara Ridge temporally coincides with cessation of the Southern Apennines thin-skin thrust belt motion, when collision between southern Adria and Europe overwhelmed retreat of the Apulian-Ionian slab, that had dominated the structural evolution of the central Mediterranean orogen since the Oligocene. The localization of the transpressional belt was controlled by an inherited mechanical interface between the thick Apulian crust and the attenuated Ionian crust.

Paleomagnetic evidence for a post-1.2 Ma disruption of the Calabria terrane: Consequences of slab break-off on orogenic wedge tectonics

P. MACRI' (*), F. SPERANZA (*) , D. RIO (**), E. FORNACIARI (**) & C. CONSOLARO (**)

Key words: *Calabria, Calabro-Peloritan block, Crotone basin, paleomagnetism, rotations.*

ABSTRACT

In the last few years, a wealth of paleomagnetic data gathered from Neogene sediments consistently showed that since ~10 Ma the Calabria terrane coherently drifted ~500 km ESE-ward from the Sardinian margin, and rotated 15°-20° clockwise (CW) as a rigid microplate between 2 and 1 Ma. Here we report on a high-resolution paleomagnetic investigation of the Crotone fore-arc basin of northern Calabria. The integrated calcareous plankton biostratigraphy indicates Early Pliocene (Zanclean) to late Early Pleistocene (Calabrian) ages for 29 successful paleomagnetic sites/sections. Unexpectedly, four domains undergoing distinct rotations are documented. Two blocks have undergone a CW rotation statistically

undistinguishable, for both timing and magnitude, from the rigid Calabria rotation documented in the past. Two additional ~10 km wide blocks yielded a 30.8°±22.5° and 32.0°±9.2° post-1.2 Ma counterclockwise rotation, likely due to left-lateral shear along two NW-SE fault zones. We infer that since advanced Early Pleistocene times, after the end of the uniform CW rotation, left-lateral strike-slip tectonics disrupted the Calabria terrane, overwhelming a widespread extensional regime accompanying the Calabria drift since late Miocene times. Seismological evidence reveals that only the southern part of the Ionian slab subducting below Calabria is continuous, while beneath northern Calabria a slab window between 100 and 200 km depth is apparent. We suggest that the partial break-off of the Ionian slab after 1 Ma induced the fragmentation of the Calabria wedge, and that strike-slip faults from the Crotone basin decoupled "inactive" northern Calabria from southern Calabria, still drifting towards the trench.

RESULTS

Paleomagnetic data from the Crotone basin document four domains undergoing rotations of opposite sign (Fig. 2). Apart from the Catanzaro domain, each rotational block is defined by at least six sites/sections yielding a rotation of same sign. The Catanzaro and Marcedusa-Zinga domain are rotated CW by 7.6°±7.0° and 27.0°±18.9° (respectively), while the Botricello and Strongoli-Neto domains yield a counterclockwise (CCW)

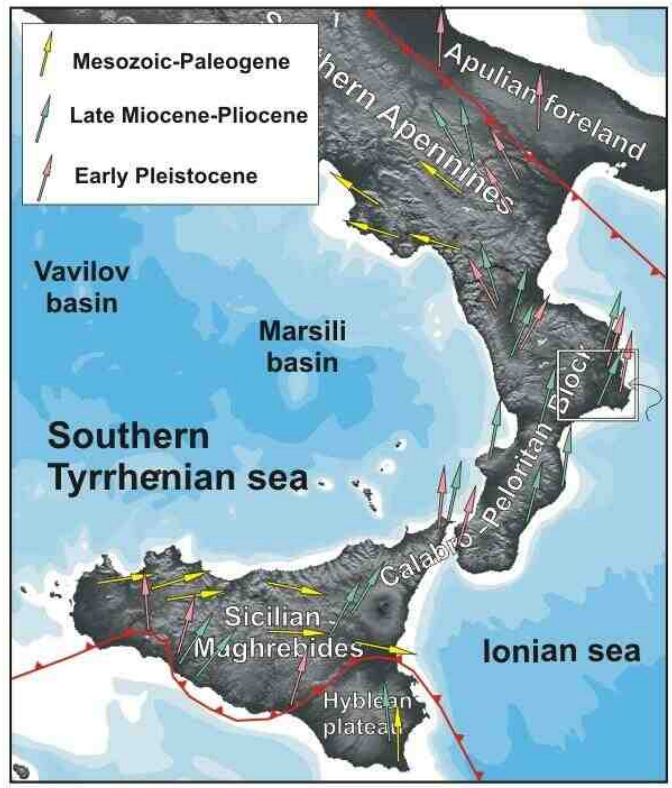

Fig. 1 – Digital elevation model of the southern Tyrrhenian domain and paleomagnetic rotations with respect to Africa recorded by different age rocks (e.g. Cifelli et al., 2007).

rotation of 30.8°±22.5° and 32.0°±9.2°, respectively (one site/section showing a very different rotation was discarded from each of these three latter domains). All domains include almost coeval Lower-Middle Pliocene sediments, thus documenting a real block rotation, instead of a uniform rotational evolution versus time. The CW rotation observed in the Catanzaro and Marcedusa-Zinga domains is statistically indistinguishable from the 15°-20° CW rotation observed elsewhere in Calabria. The youngest Lower Pleistocene section (13, 1.24-1.1 Ma) among those yielding a significant CW rotation would suggest that the regional CW rotation of

(*) Istituto Nazionale di Geofisica e Vulcanologia, Via di Vigna Murata 605, Roma, Italy

(**) Dipartimento di Geologia, Paleontologia e Geofisica, Università di Padova, Via Giotto 1, Padova, Italy

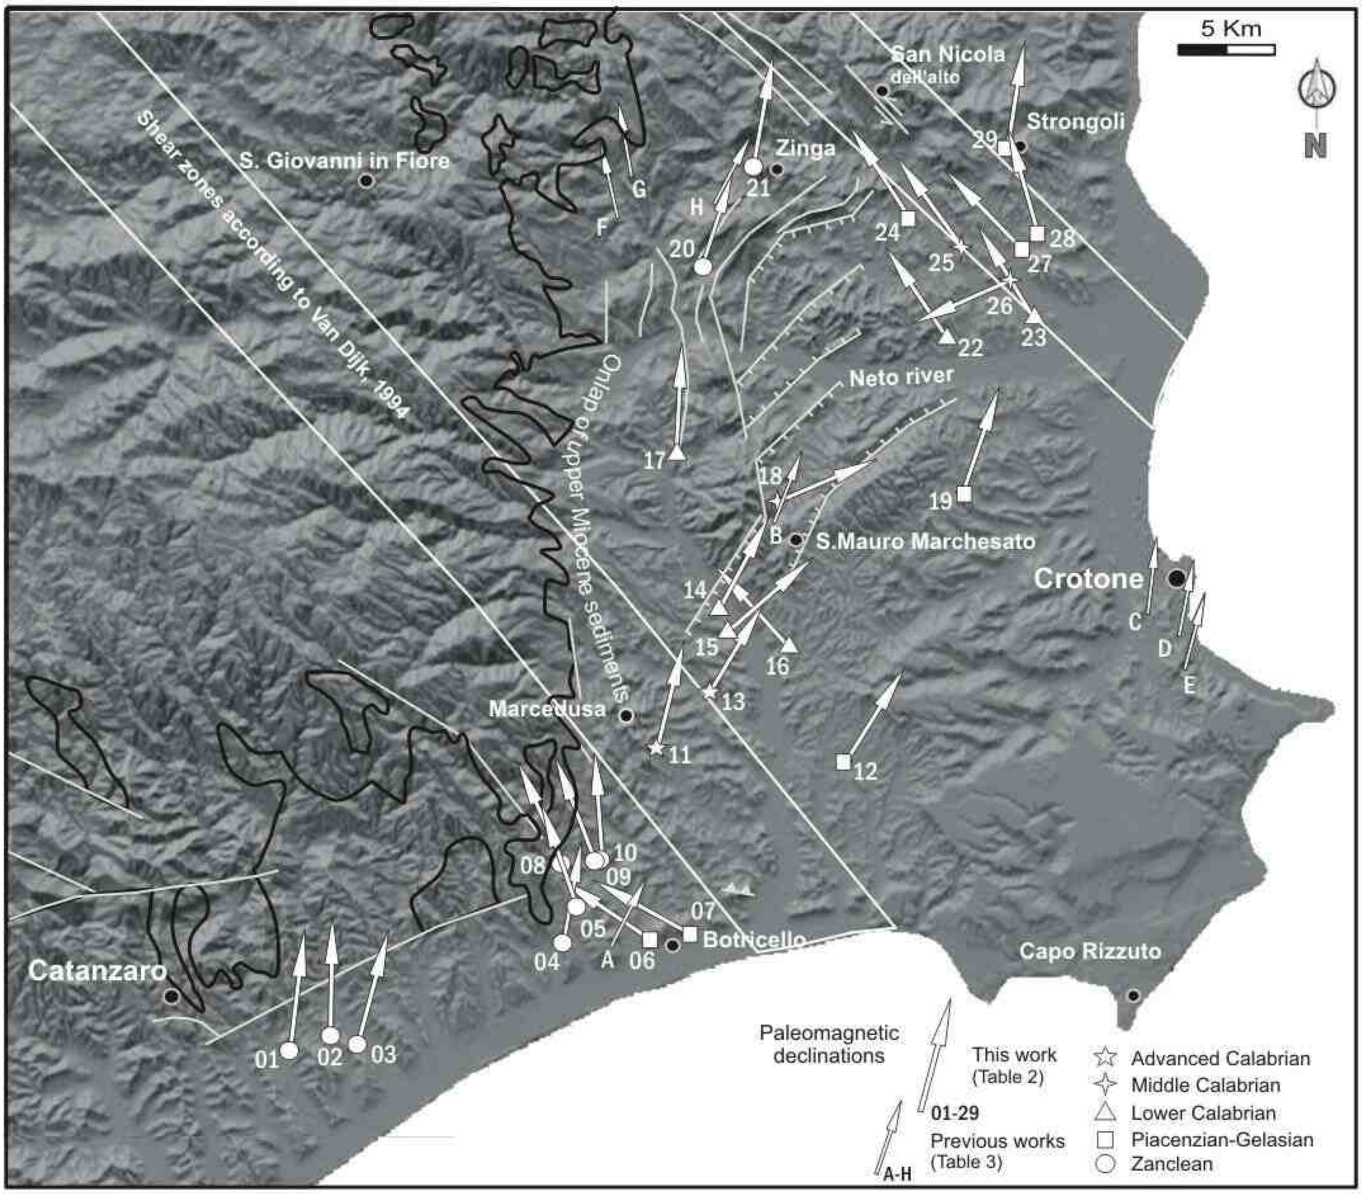

Fig. 2 – Paleomagnetic declinations from the Crotone basin.

Calabria has not ended before 1.0 Ma, in agreement with Cifelli et al. (2007). However, the large-magnitude rotation (66.6°±6.2°) from site 18 (1.46-1.23 Ma) strongly suggests a local block-rotation effect, which would bias the value of data from the Marcedusa-Zinga domain to address the timing of the regional Calabria rotation. The youngest CCW rotated sites (25 and 26) from the Strongoli-Neto domain document a 36.1°±10.0° and 114.4°±11.2° rotation (respectively), occurring as recently as after 1.46-1.23 Ma. Though the great rotation of site 26 may be related to slip along an adjacent fault, overall these data prove that CCW rotations in the Crotone basin are synchronous and/or younger than the regional CW rotation of the Calabria block.

3D modeling of an active offshore thrust-related fold system: the Amendolara Ridge, Ionian Sea, southern Italy

MARIA ENRICA MAZZELLA (*), LUIGI FERRANTI (*°), CHIARA D'AMBROGI (**)

Key words: *3D modeling, retro-deformation history, Amendolara Ridge, southern Italy*

The increase of massive computerization of deep geological data and the recent diffusion of high-performance software for bi- and tridimensional modeling provide geologists with a valid instrument for crustal deformation and deep structure analysis, as well as with an alternative approach for the analysis of geographically inaccessible, tectonically complex and quite aseismic areas.

This is the case presented in this study, where a dedicated 3D modeling software (Move 2010.1 MVE Ltd.) has allowed the management and processing of geologic data in the southern Taranto Gulf and offered a better visualization of geometries and volumes, making their analysis easier.

Processing and analysis of a tridimensional model in the offshore of the northern Calabrian coast has enabled to enlarge the knowledge of a submarine, quite aseismic area, in a key sector of the Southern Apennines front, that marks the boundary between an extensional deformation province to the west, and a transpressional deformation province to the east.

Regional geophysical studies (CATALANO *et alii*, 2001 and references therein) show that the deep transition from the Adriatic continental crust to the Ionian thinned continental or oceanic crust is settled just beneath the Calabrian area taken into consideration here.

More in detail, recent studies (FERRANTI *et alii*, 2009; SANTORO *et alii*, 2009; CAPUTO *et alii*, 2010) have shown that uplift of marine terraces from the middle Pleistocene onward along the coast of the southern Taranto Gulf, is not only due to a regional scale process but also reflects a local smaller-wavelength component of shortening which is attributed to recent activity of blind thrust and transpressional structures.

Among these, the Amendolara Fault Zone (AMFZ), represents the major thrust system that bounds and generates the Amendolara, Rossano and Cariati anticlines, the three of them arraying along a NW-SE direction along the Amendolara Ridge (for more details see FERRANTI *et alii*, this congress). The AMFZ displaces to the SW and represents a backthrust in the regional reference frame.

The southern Taranto Gulf shows a complex morphology composed of an alternation of basin and ridges whose growth is linked to the Neogene-Quaternary geodynamic evolution of the tectonically active offshore margin of the Southern Apennines.

Recent geophysical studies have recognized in this area the main submarine morphotectonic features (Fig. 1), such as the Sibari and Amendolara basins, that bound the Amendolara Ridge, and the shear zones that border and control these elements (DEL BEN *et alii*, 2007; FERRANTI *et alii*, 2009).

The aim of this work is to reconstruct a tridimensional model of the area on a regional scale that helps to understand: i) the stratigraphic and tectonic relations between the Neogene-Quaternary formations; ii) the geometry and kinematics of known structures, in particular for what concern the deep back-thrust and their superficial splays; iii) the displacement magnitude, along these structures, of the Neogene horizons; and iv) the evolution history of the Amendolara, Cariati and Rossano ridges, using the retro deformation algorithm.

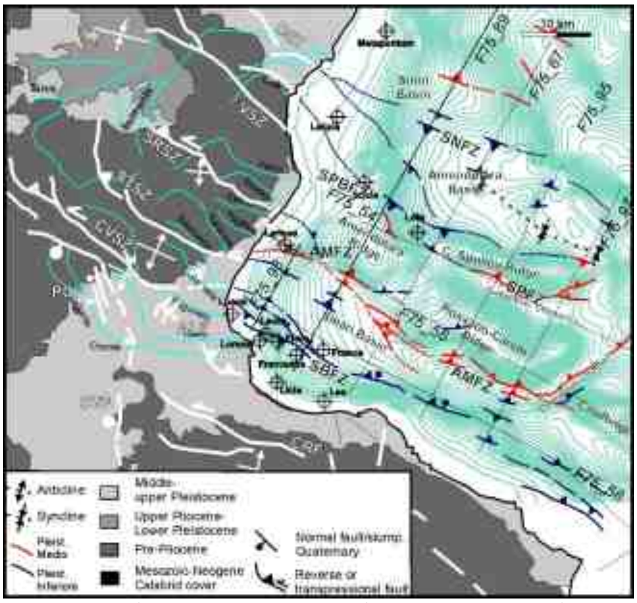

Fig. 1 – Map of the southern Taranto Gulf showing the traces of seismic reflection profiles, wells, and main faults.Onland faults: CVSZ: Civita shear zone; STSZ: Satanasso shear zone; SRSZ: Saraceno shear zone; VSZ: Valsinni shear zone; CSZ: Canna shear zone; CRF: Faglia di Corigliano-Rossano; CVF:Faglia di Civita; PCF: Faglia Pollino-Castrovillari; ALF: Faglia Avena-Lauropoli. Offshore faults: SBFZ: Sibari fault zone; AMFZ: Amendolara fault zone; SPFZ: Capo Spulico fault zone; SPBFZ: Capo Spulico basin fault zone; SNFZ: Sinni fault zone. (Modificata da Ferranti et al., 2009).

Toward this aim, we analyzed 8 multi-channel seismic reflection profiles, which are available online (http://www.socgeol.info/pozzi/index.asp), from areas D and F of the Taranto Gulf. The profileare arranged in a grid of 5x3 (Fig. 1): five SW-NE striking profiles (F75_93; F75_89; F75_87; F75_95; F75_97) and three NW-SE striking profiles (F75_58, F75_56; F75_54). Profile calibration was obtained using 13 well logs provided by I.S.P.R.A, which provided thickness and age of drilled deposits and, where available, the strata attitude.
The fundamental prerequisite for the tridimensional modeling is the input and digitalization of the seismic data interpretation into the 2D software. The two main processes are: the time-depth conversion and the picking of horizons recognized using the well log data constrains. Then, the eight sections were imported in the 3D Move platform, and the dataset was simplified according to our objectives, taking into account the more recent chrono-stratigraphic horizons and the main thrusts of the Amendolara bank.
With the 3D Move algorithms, we elaborated the representative surface of the top of 4 main horizons: Middle Pleistocene, lower Pleistocene (Emilian stage), lower Pliocene and Messinian, as well as the most representative structural elements that cut, bound and uplift the anticline ridge. At last, we modeled an inferred deep detachment surface beneath the ridge (Fig. 2).

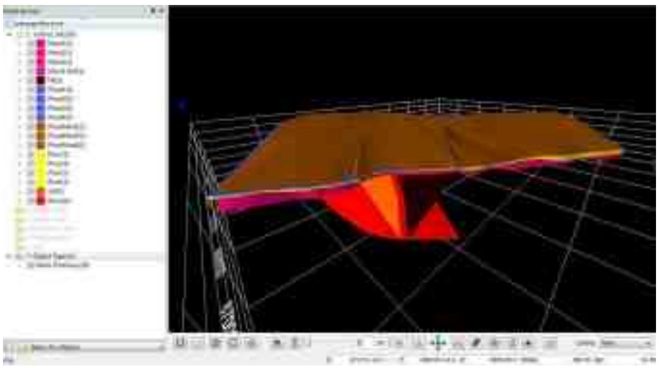

Fig. 2 – 3-D Model of the four surfaces (brown: top Middle Pleistocene; blue: infra lower Pleistocene; yellow: top lower Pliocene; pink: top Messinian) and of the three main faults (red).

Analysis of the modeled surfaces with the 3DMove tools, allowed detecting changes of average attitudes through time. Specifically, during the middle Pleistocene the dip of marker horizons changed from NNW to NE (Fig. 3).
Furthermore, thickness analysis between two sequential surfaces show a general decreasing through time and a general shift of the uplift from south to north along the anticline system.
Once we obtained the 3D model, we tested the software in the retro deformation operation using a standard processing workflow (MAESANO *et alii*, 2010; 2011) for reiterate decompaction and restoration of slip on faults.

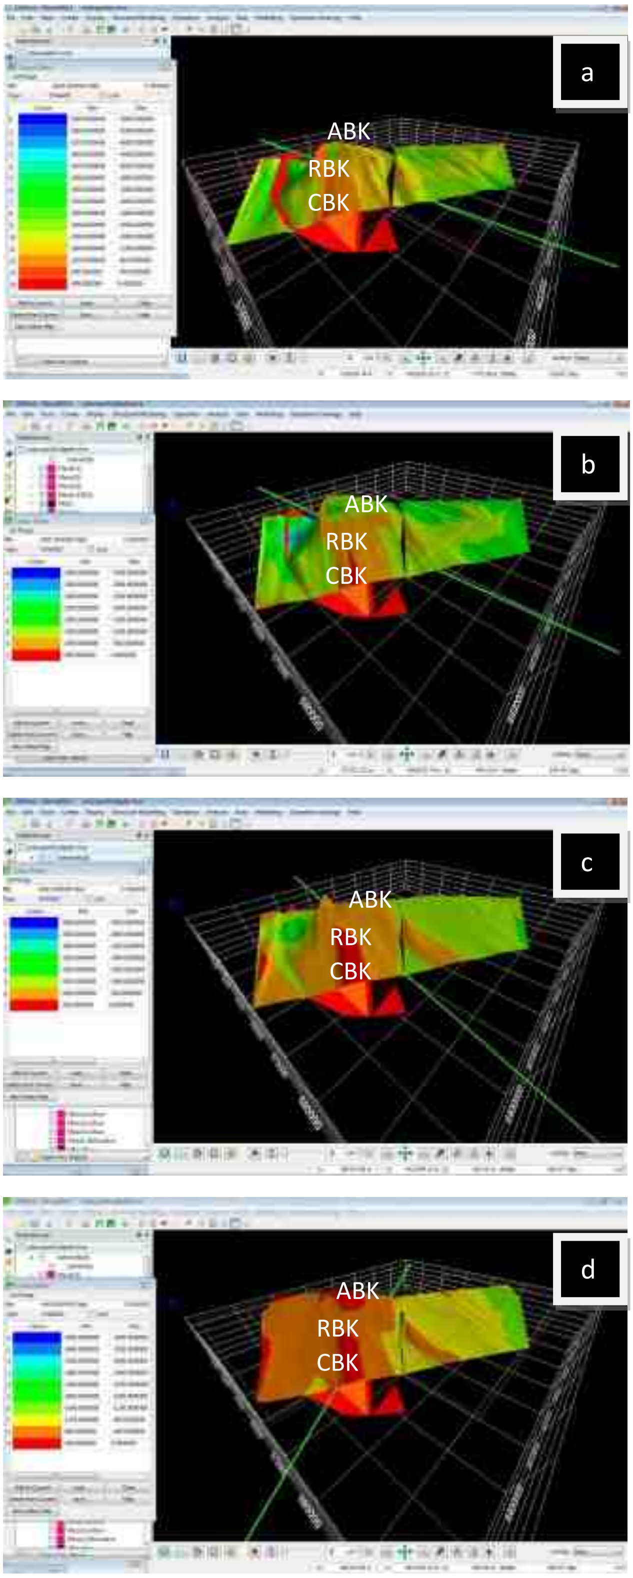

Fig. 3 – Chromatic visualization of four modeled surfaces: a) top Messinian; b) lower Pliocene; c) lower Pleistocene; d) Middle Pleistocene according to depth. The depocenter zones in the footwall of SW and NE thrusts (green areas) and the anticline culminations in the hanging-wall of the same thrusts are well evidenced. The green line is the average strike for each horizon. SB: Sibari Basin; AM: Amendolara Ridge; RC: Rossano-Cariati Ridge; CSB: Capo Spulico Basin; CS: Capo Spulico Ridge.

In such a manner we calculated the theoretical slip rate along the main structure for each temporal interval chosen for the model. The slip rate pattern show, from a qualitative point of view, development of a larger activity of these structures through time, as we already inferred from the punctual well log data. The average slip rate obtained for the upper Miocene is 0.05 mm/a, for the Pliocene is 0.06 and for the lower Pleistocene is 0.08.
More in detail, this result holds true for the Amendolara bank, but is the exact opposite for the Rossano and Cariati ridges, where the slip rate gradually decrease in time (Fig. 4). This observation is consistent with shifting of the maximum Pleistocene deformation toward the northwestern part of the region.
It is worth noting that, in this approach, these results cannot be taken into account as representative of the regional geodynamic of the region because of the extreme simplification of the model, but allowed us to reconstruct with a certain approximation the structural evolution of the Amendolara ridge.

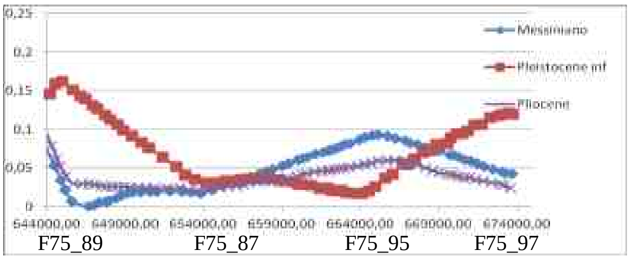

Fig. 4 – Pre-retro-deformation slip rates computed through the "Allan lines" for the Messinian, Pliocene and lower Pleistocene horizons, shown as a function of longitude (distance from the coast, which is on the left side of diagram). Shown is the position of seismic profiles.

At last, we tried to obtain information about the strength of the decompaction of lithostatic load on the marker horizons, and calculated to which percentage this process can influence the slip rate along the faults.
It is important to stress that the approximation of these values is due to the difficulties that the decompaction tool has shown in some areas, for example nearby the tectonic discontinuities, where the slip rate calculation is affected by distortion. To avoid this, we moved away from the fault line and calculated the slip rate differences in the maximum depocenters,that are located at the hanging-wall and at the footwall of the thrust system, respectively.
In these areas these values seems to be reasonable, so we obtain a variation of 16% of the lower Pleistocene slip rate value, due to the removal of the lithostatic load of the sedimentary package above it. For the Pliocene slip-rate, we calculated a variation of 20% with the removal of the sedimentary load until the middle Pleistocene and of 55% if we remove also the lower Pleistocene package.
The same result occurs with the Messinian slip rate that decreases of 25% with the decompaction of the Middle Pleistocene horizons, and increases up to 50% with removal of the whole package above the Messinian surface.

Off-shore gravity investigation across the Calabrian Arc

FILIPPO MUCCINI (*), LUCA COCCHI (*), ALINA POLONIA (**) & COSMO CARMISCIANO (*)

Key words: *gravity data, Calabrian Arc, Ionian Sea.*

INTRODUCTION

The subduction complex of the Calabrian Arc (CA) is one of the principal arcuate structures formed in the general context of convergence between African and Eurasian plates and it is one of the most seismically active regions in Italy.

The CA subduction complex is partially submerged in the Ionian Sea that has been described as a segment of oceanic crust being subducted in the central Mediterranean (FACCENNA *et alii*, 2004; DE VOOGDT *et alii*, 1992). This reconstruction is in agreement with the Bouguer gravity map of the Ionian Sea presented by CATALANO *et alii* (2001) showing values in the abyssal plain ranging from 130 to 250 mGal that decrease underneath Calabria to 20 and 30 mGal due to the subduction of the Ionian lithosphere. The CA subduction complex is about 400 Km wide and it is bounded by the Apulia and Malta escarpments (figure 1), considered by CATALANO *et alii* (2001) passive margins of the Ionian basin.

Subduction of the Ionian lithosphere beneath the CA, roll back processes and associated back-arc extension in the Tyrrhenian Sea (PATACCA *et alii*, 1990; FACCENNA *et alii*, 2001) drove the evolution of this area during the last 25 Myr. The regional geometry of the CA in the Ionian Sea has been described by several authors through the analysis of seismic data (ROSSI & SARTORI, 1981; FINETTI, 1982; DOGLIONI *et alii*, 1999; MINELLI & FACCENNA, 2010, POLONIA *et alii*, 2011). Very few information exists on the deep structure of the subduction complex and relationship between the nature of the crust, tectonic processes and structural development.

During the CALAMARE (CAlabrian Arc MARine geophysical Experiment – study of active deformation and seismic hazard assessment) project a scientific cruise (CALAMARE08) was carried out in the Ionian Sea (POLONIA *et alii*, 2008) with the Italian oceanographic research vessel CNR-Urania. During the 30 days long cruise, different kind of geophysical data at different resolutions were acquired (multibeam, multichannel seismic profiles, CHIRP, magnetic and gravity data).

We collected about 7000 km of regional gravity lines using a MicroG AirSea gravity meter installed onboard the R/V Urania. The gravity meter has sensibility of 0.01 mGal providing a resolution in the order of 1 mGal. Differential GPS navigation data furnished by the Fugro Omnistar GPS system assured the correct positioning and the possibility to have a good estimation of the Eotvos effect.

The gravity profiles were collected during multichannel seismic data acquisition along track lines orthogonal to the main structural trends both across the frontal part of the subduction system and across its western lateral boundary (i.e. the Malta escarpment).

A set of 3 NW-SE trending and about 200 km long lines have been acquired orthogonal to the deformation front across the transition between the abyssal plain and the accretionary wedge and between the salt bearing complex and the pre-Messianian wedge. A second set of gravity profiles have been acquired orthogonal to the Malta escarpment across the set of transtensive faults segmenting along strike the continental margin, such as the Malta STEP (Slab Transfer Edge Propagator) fault system (POLONIA *et alii*, 2012).

The gravity profiles collected during the Calamare cruise have been integrated with the satellite derived gravity field (SANDWELL & SMITH, 1997) that has been particularly useful for lateral correlation of gravity data acquired in the different structural domains. The high resolution of our gravity data allow to study in detail the relationships between gravity anomalies and the first order structural pattern within the subduction complex.

These new gravity data can furnish new insights about the deep assessment of CA and provide new constrains to support the tectonic evolution of this area.

Pre-stack depth migrated (PSDM) seismic transects across the Calabrian Arc: a Miocene-Pleistocene arcuate complex accretionary wedge in the Ionian sea

MUSSONI P. (*), TORELLI L. (*), POLONIA A. (**), GASPERINI L. (**), ARTONI A. (*), KLAESCHEN D. (***)

Key words*: Accretionary wedge, Ionian sea, Seismic reflection, Tectonic evolution.*

The Calabrian Arc (CA) is the most impressive arcuate feature of the Central Mediterranean sea and connects the E-W trending Sicilian Maghrebian belt with the NW-SE trending Southern Apennines defining the African-Eurasian plate boundary in the Ionian sea. The CA attained its geometry mostly in the interval between Middle-Late Miocene to Pleistocene and its evolution is related to the opening of the back-arc Tyrrhenian basin, in response to the SE retreat of the subduction zone caused by the sinking of the Mesozoic Ionian oceanic lithosphere along a steeply inclined Benioff plane.

In this geodynamic frame, the submerged portion of the CA is a key area to study subduction and collisional processes in detail. We reconstructed the regional architecture of the accretionary complex from MS-OGS lines and CROP deep seismic profiles acquired during 70s and 90s in the Ionian Sea. We preliminary re-processed MCS seismic data at ISMAR-BO, through a sequence that involves velocity analysis, Dip Move Out (DMO), velocity analysis after DMO, stack and time migration. Three CROP seismic lines were further processed at the Marine Geodynamics Department of the IFM-GEOMAR (Kiel) in the frame of the European EC-IHP project. We obtained full pre-stack depth-migrated (PSDM) seismic sections through an iterative migration procedure (The SIRIUS/GTX, Migpack software package) that uses seismic velocities constrained by focusing analysis and common reflection point gathers. We have thus obtained a very accurate velocity model that includes both lateral and vertical velocity variations in agreement with interpreted geological cross-sections.

(**) ISMAR-CNR, Bologna.

(***) IFM-GEOMAR, Kiel, Germania.

The offshore external part of the CA is represented by a 300 km wide accretionary wedge, bordered by the Malta and Apulia Escarpments. Its active front extends southward close to the Medina Bank and is dissected by a prominent NNW-SSE striking tear fault located about 50 km E of the Malta Escarpment. The accretionary wedge, whose geometry and evolution are driven by the slow convergence between the African and the Eurasian Plates (estimated in 5 mm/yr or even <5 mm/yr), is characterized by a sub-horizontal décollement, and consists of African Plate sediments, scraped off from the thick (up to 10 km) Mesozoic and Cenozoic sedimentary cover of the descending plate and piled up along low angle thrust faults. The surface of the accretionary complex is marked by a gentle and irregular slope that sinks the water depth down to more than 4000 m. The outer portion of the slope (approximately from 3000 m to 4000 m of water depth down to the Ionian abyssal Plain) displays shallow strong deformation triggered by the presence of a very thick sequence of Messinian evaporites that have been accreted since Messinian. In this outer zone, the contractional deformation is driven by a detachment surface located at the base of the evaporites. The inner portion of the slope (approximately from 2000 m to 3000 m depth) exhibits a steeper topographic gradients associated with pronounced gravity anomalies and is the site of the pre-Messinian accretionary wedge. Here, the basal detachment cuts to deeper levels leading to the formation of complex thrust system, chaotic units and mud volcanoes. This region seems to be devoid of evaporites but thick accumulation of Messinian deposits occurs in restricted basins on top of the pre-Messinian wedge. Landward, between the upper slope and the onland Calabria (approximately at depths less than 2000 m or in the inner plateau of the CA), a backstop, made of Calabrian-affinity nappes, is partly overlain by back-thrust units of the pre-Messinian wedge and by the NE-SW trending Crotone-Spartivento fore-arc basin. Beneath most of the accretionary wedge the Mesozoic subducting crust is 18-20 km thick and seems to have an oceanic character, but quite anomalous if compared to typical oceanic crust because of velocity profiles and locally-preserved features typical of a passive margin.

An effort addressed to integration of geophysical evidences and new seismological data in the Calabrian Arc subduction area

BARBARA ORECCHIO (*)

Key words: *Calabrian Arc, subduction slab, STEP fault.*

The question on whether and eventually where the subduction slab is still continuous in depth or is already detached beneath the Calabrian Arc has been a primary subject of debate in the recent literature concerning the geodynamics of the Western Mediterranean. The most recent history of this region has been modeled in terms of southeast-ward rollback of the subducting slab and progressive detachment of the deepest portion of it. Detachment is believed to have occurred with a tear process propagating from the edges of the subducting structure to the center of it, corresponding to the central part of the Calabrian Arc. Teleseismic data tomographic inversions and hypocenter locations at mantle depths (see, e.g., SPAKMAN & WORTEL, 2004; MONTUORI *et alii*, 2007; GIACOMUZZI *et alii*, 2010) have furnished regional- to continental-scale pictures of the subduction system while regional tomographies of body wave velocities at intermediate depths (CHIARABBA *et alii*, 2008; MONNA & DAHM, 2009, NERI *et alii*, 2009) have better detailed the key sector of the Calabrian Arc. A review of these results and of the most recent geophysical investigations (see e.g., D'AGOSTINO *et alii*, 2011; FACCENNA *et alii*, 2011; POLONIA *et alii*, 2011; SPERANZA *et alii*, 2011; NERI *et alii*, 2012) seems to suggest that the local geodynamic scenario is characterized by residual rollback of the Ionian subducting slab and very slow trench retreat only in the central part of the Arc (southern Calabria), with the lateral borders of this central sector located close to NW-trending seismogenic faults of northeastern Sicily (i.e. the Tindari zone) and northern Calabria (i.e., Crotone Basin). According to the model introduced by GOVERS & WORTEL (2005) for describing the dynamics at the borders of retreating subduction slabs these seismogenic faults have been indicated by several authors as possible STEP (Subduction-Transform Edge Propagator) fault zones. New estimates of focal mechanisms and hypocenter locations of recent shallow to deep earthquakes have been performed in order to better detail the main geometrical and kinematic features of these potential STEP fault zones. The spatial distribution of earthquakes and their source kinematics framed in the local geodynamic scenario and jointly evaluated with the above mentioned geophysical data give new insights on the subduction system structure and dynamics.

GPS velocity and strain fields in Sicily and southern Calabria, Italy: updated geodetic constraints on tectonic block interaction in the central Mediterranean

MIMMO PALANO(*), LUIGI FERRANTI (**), CARMELO MONACO (°), MARIO MATTIA (*), MARCO ALOISI (*), VALENTINA BRUNO (*), FLAVIO CANNAVÒ (*), GIUSEPPE SILIGATO (°°)

Key words: *Geodynamics, GPS velocity fields, Sicily, Calabria*.

ABSTRACT

We present an improved rendition of the geodetic velocity and strain fields in Sicily and southern Calabria obtained through the analysis of 18 years of GPS observations from networks of continuous and survey stations. The dense spatial coverage of geodetic data provides precise quantitative estimates of previously established first-order active kinematic features, including: i) a narrow east-west-elongated belt of contraction (~1-1.5 mm/yr) extending offshore northern Sicily from Ustica to Stromboli across the Aeolian Islands; ii) a narrow east-west-trending contractional belt (shortening occurs at ~4.4 mm/yr) located along the northern rim of the Hyblean Plateau in southern Sicily; iii) transpression and transtension partitioned across discrete sectors of the Aeolian-Tindari-Letojanni fault (ATLF) system, a main shear zone extending from the Aeolian Islands to the Ionian coast of Sicily; iv) transtension (~1 mm/yr) across the Sicily Channel between Sicily and North Africa. We use geodetic observations coupled to geological constraints to better elucidate the interplay of crustal blocks revealed in the investigated area.

In particular, we focus on the ATLF, which forms the primary boundary between the Sicilian and Calabrian blocks. The ATLF juxtaposes north-south contraction between Sicily and the Tyrrhenian block with NW-SE extension in north-eastern Sicily and Calabria. Contraction between Sicily and Tyrrhenian blocks probably arises from the main Europe-Nubia convergence, although Sicily has a component of lateral escape from Nubia. We found that convergence is not restricted to the northern offshore, as commonly believed, but is largely accommodated between the frontal belt and the northern rim of the Hyblean foreland in southern Sicily. Geodetic data also indicate that active right shear on the ATLF (~3.6 mm/yr) occurs to the southeast of the mapped fault array, suggesting the fault cut through Sicily till its Ionian coast. The small geodetic divergence between the Hyblean and Apulian blocks rimming on both sides the Calabria accretionary prism, coupled with marine geophysical evidences in the Ionian Sea lends credit to the proposed deep root of the ATLF and to a fragmentation of the Ionian domain.

MAIN RESULTS

The complex tectonic puzzle highlighted by geodetic data, is characterized by the presence of three distinct deformation domains separating the Tyrrhenian, Sicilian-Hyblean and Calabrian blocks, which join in north-eastern Sicily (Fig. 1).

Deformation between the Sicilian-Hyblean and Tyrrhenian blocks is segregated between two distinct belts in the northern Sicily offshore and at the northern rim of the Hyblean plateau (LAVECCHIA *et alii*, 2007). Deformation is instead diffuse in the extensional belt from north-eastern Sicily to southern Apennines, as suggested by seismicity, especially in southern Calabria (MONACO & TORTORICI, 2000). Conversely, deformation is more concentrated along the ATLF oblique strike-slip zone extending between the Aeolian Islands and the Ionian coast of Sicily (BILLI *et alii*, 2006). In this context, the ATLF system juxtaposes NNW-SSE contraction between Sicily and the Tyrrhenian blocks with NW-SE extension along the CPA. To the south, transtension occurs on the ATLF extending along the Ionian offshore of Sicily.

The ATLF has probably formed as a consequence of the Middle Pleistocene tectonic reorganization in the south-central Mediterranean, characterized by slowing or cessation of Calabrian roll-back and subduction and back-arc Tyrrhenian extension (WESTAWAY, 1993; WORTEL & SPAKMAN, 2000; GOES *et alii*., 2004). This process has also caused i) the partial jumping

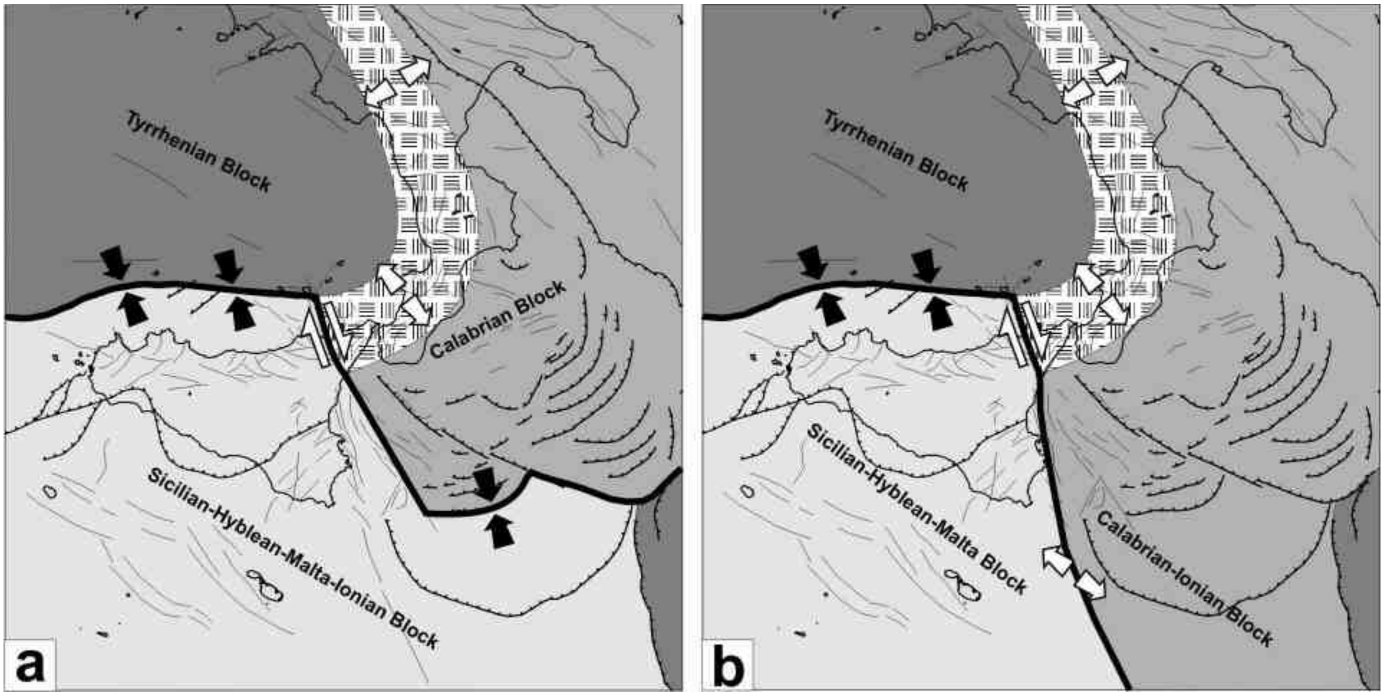

Fig. 1 – Schematic maps of the different tectonic scenarios suggested in this work. a) in this scenario, the Ionian domain is rigidly connected with the Hyblean-Malta block: this scenario suggests that the current convergence along the Calabrian trench should adsorb a large part of the horizontal motion measured across the ATLF which is currently connecting the north Sicilian contractional belt to the arc front located on the Ionian basin. b) in this scenario the Ionian domain diverge from the Hyblean-Malta block, moving to the north-east with respect to Europe similarly to the Calabrian block. This scenario although still compatible with convergence along the Calabrian trench, would imply the prolongation of the ATLF way to the south, as far as the North Africa, with the involvement of the HMEF and the Sicily Channel rifting.

of the Sicilian thrusting from the front to the rear of the chain (southern Tyrrhenian contractional belt); ii) the reactivation of the extensional belt in western Calabria and north-eastern Sicily; iii) the chemistry change of magmatic products on the eastern Aeolian Islands (DE ASTIS *et alii*, 2000); iv) the triggering of Mt. Etna volcanism (GVIRTZMAN & NUR, 1999; DOGLIONI *et alii*, 2001). In this context, a problem is the role played by the Ionian domain (see also D'AGOSTINO & SELVAGGI, 2004) that *i*) could still be a rigid part of the Hyblean-Malta block or *ii*) alternatively diverge from the Hyblean-Malta block, moving to the north-east with respect to Europe together with the Apulian block. The first scenario (Fig. 1) implies that the ATLF only connects the north Sicilian contractional belt to the arc front located on the Ionian basin, accommodating differential movements within the contractional belt (GOES *et alii*, 2004; JENNY *et alii*, 2006; BILLI *et alii*, 2006). Recent GPS analysis (D'AGOSTINO *et alii*, 2011) proposes that shortening between Calabria and Apulia is still active (~2 mm/yr southeastward motion of eastern Calabria) and associated to 1.4 mm/yr extension of the forearc. This scenario suggests that the current convergence along the Calabrian trench should adsorb a large part of the horizontal motion measured across the ATLF.

The second scenario (Figure 5b), although still compatible with convergence along the Calabrian trench, implies the prolongation of the ATLF way to the south, as far as North Africa (WESTAWAY, 1990), with the involvement of HMEF and possibly other, sub-parallel faults located further east in the Ionian Sea, which cut the Ionian crust beneath the Calabria wedge (ARGNANI & BONAZZI, 2005; POLONIA *et alii*, 2011; NERI *et alii*, 2012)

Taking into account the apparent lithospheric nature of transtensional and normal faults occurring along the eastern Sicily offshore (NICOLICH *et al.*, 2000), the small geodetic divergence between the Hyblean and Apulian blocks further east lends credit to the southward extension of the ATLF system and a deep fragmentation of the Ionian domain. However, the lack of islands in the rigid Ionian domain precludes the use of GPS to verify the independent motion of this domain. Further data (*i.e.* tomographic and reflection profiling experiments, GPS measurements on North Africa) are necessary to better constrain the geometrical and tectonic characters of the crustal block occurring and interacting in this active region of the Mediterranean.

Mud volcanoes along the inner deformation front of the Calabrian Arc accretionary wedge (Ionian Sea)

GIULIANA PANIERI (*), ALINA POLONIA (*), RENATA GIULIA LUCCHI (**) & LUIGI TORELLI (°)

Key words: *Accretionary wedge, Calabrian Arc, mud volcano, mud breccia, fluid emissions.*

INTRODUCTION AND GEOLOGICAL SETTING

The Calabrian Arc (CA) is part of the eastward migrating Apennine subduction system and represents the Africa/Eurasia plate boundary in the Ionaina Sea. The external part of the arc (Figure 1) is represented by a subduction complex that reaches both the Ionian abyssal plain and the Mediterranean Ridge and is bordered by two major structural features, the Malta escarpment to the southwest and the Apulia escarpment to the northeast.

The convergence between the Africa and Eurasia plates, has generated a 10-km thick accretionary wedge in the Calabrian Arc (CA) subduction complex due to offscraping of the thick sedimentary section resting on the lower African plate.

Compared with the Mediterranean Ridge, from which wealth of data have been collected, the Calabria Arc in the Ionian Sea has been less intensively investigated in the past. Evidences of allochthonous material were reported by Rossi and Sartori (1981) and Barbieri et al. (1982) who interpreted the chaotic deposits as the result of mass flows accompanying and/or following underthrusting of unconsolidated sediments. The presence of mud volcanoes were suspected few years later by Fusi and Kanyon (1996) and Sartori (2003). Only recently, Praeg et al. (2009), reported a province of mud volcanoes ("Madonna dello Ionio" and "Pythagoras") in the inner accretionary prism of the Calabrian Arc while topographic mounds in the inner plateau offshore the Squillace basin have been related to salt diapirism and/or argilokinetic processes (Polonia et al., 2011).

The aim of this study is to gain new insights on the occurrence and nature of mud volcanism in the CA and study the relationships between mud volcanism, fluid flow and tectonics in the inner domains of the subduction complex.

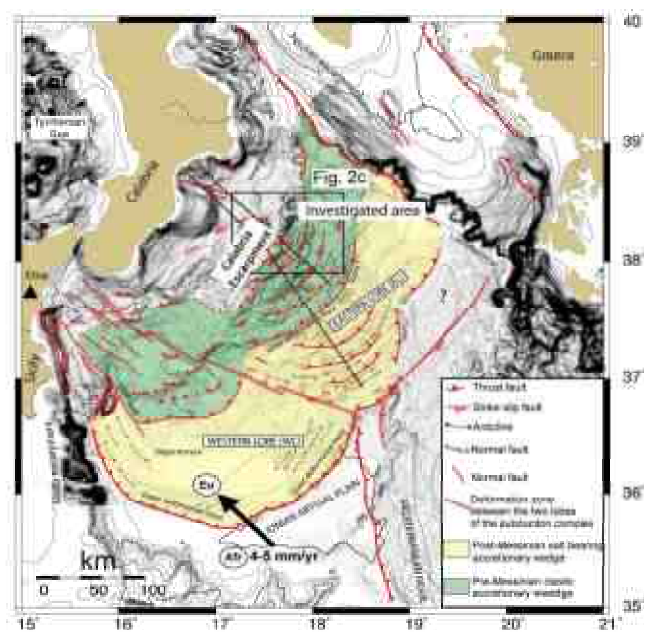

Fig. 1 – Tectonic map of the Calabrian Arc subduction complex (modified form Polonia et al., 2011) with the study area.

METHODOLOGY

A multidisciplinary approach involving the analysis of geophysical data at different resolutions and targeted ground truthing has been used to unravel fluid flow processes and the interplay between tectonics and mud volcanism in the submerged portion of the Calabrian Arc.

The regional architecture of the accretionary complex (Figure 1) was reconstructed from multichannel seismic data (the CNR-ENI Deep Crust Seismic Profiles - CROP and Mediterranean Sea - MS datasets). High-resolution Sparker and sub-bottom CHIRP profiles, as well as multibeam data, integrate deep data and constrain the fine structure of the accretionary wedge as well as the geometry and seismic facies of topographyc mounds in key areas.

Two gravity cores collected during 80's (BARBIERI *et alii*, 1982; MORLOTTI *et alii*, 1982) and core CALA 21 acquired ontop of a topographic swell imaged on Sparker line J-22 (Fig. 2) were studied through micropaleontological, sedimentological, mineralogical and stable isotope geochemical analysis.

RESULTS

The integration of sediment cores analysis with geophysical data permitted to relate tectonic activity and different fluid emissions dynamic in mud volcanoes. Sediment facies description, micropaleontological and stable isotope investigations allowed to distinguish the massive mud breccia facies within two previously collected cores (5 BS81/II and 10 BS81/II; BARBIERI *et alii*, 1982; MORLOTTI *et alii*, 1982). The massive facies is formed by a mixture of differently aged rock fragments (from Cretaceus to Late Miocene, Fig. 3) deriving from deeper stratigraphic intervals that have been mechanically incorporated into a stiff mud matrix by powerful fluid espulsion associated to dynimic of the the accrectionary complex. Clasts include calcareous mudstone (light gray, firm, massive, with sometimes abundant mica, and rounded shape), fossiliferous micrite (light gray, firm, massive, rounded or angular in shape) with occasionally orange-colored altered surfaces.

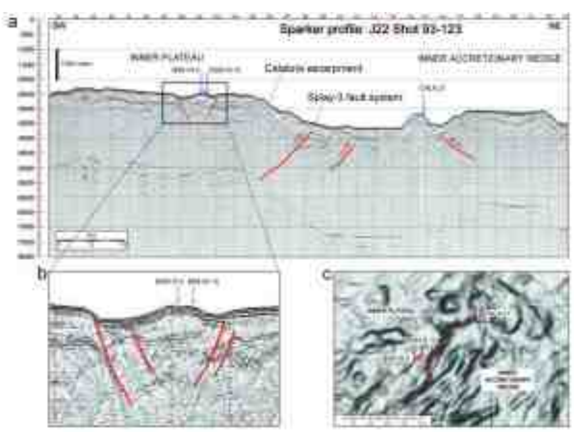

Fig. 2 – a: segment of Sparker seismic profile J-22 parallel to the Calabrian continental margin across the transition between the inner plateau and the inner accretionary wedge. The boundary between the two structural domains corresponds to the splay-3 fault system. The three studied cores are located at the footwall and hangingwall of this major tectonic feature. b: zoom of the seismic line across the mud volcano. c: contour bathymetric map of the study area superimposed on the slope map of the multibeam data (isolines every 200m).

The sedimentological and geochemical analyses on a newly acquired core (CALA 21) collected from the summit of a topographic high of the inner accretionary wedge suggest the presence of mud breccia patchy/cloudy facies (Fig. 3) (*sensu* CITA *et alii*, 1996 and STAFFINI *et alii*, 1993) where sediment disturbance is caused by fluid expulsion. The mud breccia patchy/cloudy is characterized by silty-clay bulk sediments containing irregularly clustered intervals of differently coloured sediments (from dark grey to olive grey clouds and light grey to grey matrix) with several fragmented and vertically dislocated thin sandy/silty turbidites and tephra layers.

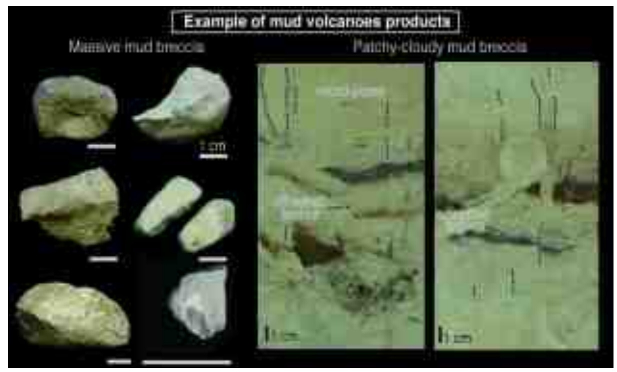

Fig. 3 – Examples of mud volcanoes products in the Calabrian Arc. Massive mud breccia, with clasts found cores 5 BS81/II and 10 BS81/II. Patchu-cloudy mud breccia observed in CALA 21 at different stratigraphic intervals. Dotted line indicate vertical migration structures. Disrupted tephra/terrigenous sandy layers and micro-pipes filled with silt/fine sand transported by fluid escape are evident.

The integration of the entire data set provide information on the formation of mud volcanoes in the accretionary prism where overpressure provided by the Pliocene and Pleistocene sediment accumulation and the evolution of normal fault systems, triggered the fluid circulation and mud volcanoes formation that progressively developed toward the upper slope.

The occurrence of mud volcanic processes appears to be related to major structural features, such as the inner deformation front of the CA subduction complex, a transpressive fault accommodating strain partitioning at the contact between the highly deformed wedge and the continental basement. The lack of evaporitic impermeable cap in the inner wedge, active faulting along the inner deformation front and transverse structures segmenting the subduction complex all favor rising of fluids from the wedge interior and formation of diapiric features.

Dynamics and seismotectonics of NE Sicily

FRANCESCO PAVANO (*), STEFANO CATALANO (*), GINO ROMAGNOLI (*) & GIUSEPPE TORTORICI (*)

Key words: *NE Sicily, Mantle diapir, crustal block.*

INTRODUCTION

The NE Sicily, represents a crustal mobile block (here designed **PMB** – Peloritani Mobile Block), comprising part of the Peloritani-Nebrodi Mountain Belts and the Aeolian Islands. The **PMB** diverges towards the NE, from the rest of the Sicilian collision zone as evidenced by available GPS data (HOLLENSTEIN *et alii*, 2003; D'AGOSTINO & SELVAGGI, 2004 - see inset of Fig. 1). In addition, seismological data (NERI *et alii*, 2005) suggest that this region is characterised by the coexistence of both extensional and compressional dynamics.

New morphostructural studies and detailed geological-structural analyses have been carried out along both the coastal areas of the NE Sicily and the southern Aeolian Archipelago, in order to reconstruct the geometry, the age, the slip-rate and kinematics of the Pleistocene deformation pattern. On the basis of the collected dataset, a new interpretative model of the Late Quaternary deformation of the NE Sicily is here proposed to constrain the active dynamics that control the volcanism and the seismicity of the region.

MORPHOTECTONIC AND SEISMOTECTONIC SETTINGS

The morphostructural analysis carried out in the studied area has evidenced that the **PMB**, since 600 ka B.P., has experienced a 1.1 mm/a tectonic uplifting, higher than in the adjacent Mt. Nebrodi region (<0.8 mm/a) (Fig. 1). As consequence, the 600 ka-old marine deposits have been displaced at an elevation of about 580 m a.s.l..

The southwestern boundary of the **PMB** is evidenced along the Tyrrhenian coast by a sharp decrease in the elevation of the marine terraces, ranging in age from the OIS 15 (570 ka) to the OIS 3 (60 ka). A segment of this tectonic boundary is well exposed to the south of Capo d'Orlando, where it is composed of distinct NW to NNW-oriented, south dipping normal faults, distributed along a WNW trending tectonic alignment. The extensional motions, which are consistent with the geodetic data, have reactivated distinct segments of previous dextral fault zones, with a cumulative vertical displacement of about 40 m. A discrete portion of this extensional belt is marked by southwest-facing fresh bedrock scarps, ranging in height from 3 to 5 m.

Within the mobile block, the active volcanic belt of the Eolian Islands is distributed along two perpendicular alignments. The island of Volcano, Lipari and Salina are located at the main releasing bends along a seismogenic NNW-SSE dextral shear zone, extending from Salina to the Peloritani Mountains (**EPSZ** in Fig. 1). The fault belt is the eastern border of an uplifted sector, along which old (225-150 ka; CRISCI *et alii*, 1991) submarine volcanics are modeled by a flight of Late Pleistocene marine terraces, constraining an uplift-rate of 0.8 mm/a. From Salina to Stromboli, the sea floor topography (FAVALLI *et alii*, 2005) of the southeastern border of the volcanic islands is controlled by NE-SW oriented, southeast facing tectonic scarps. As a whole, the Eolian Island contours a Late Pleistocene collapsed basin. The opposite margin of this basin is represented by the N20-40 oriented, northwestern facing normal faults that bound the Peloritani Mountains, to the northeast of the **EPSZ**. The motions along the Peloritani faults have exactly balanced the regional uplifting, being concentrated on distinct short-lived coast-bounding fault zones. The relation between faults and marine terraces clearly demonstrate the progressive migration of the active fault zone towards the NW (CATALANO & CINQUE, 1995), which caused the emergence of the relict branches of the margin, as well as the deactivated portions of the **EPSZ**. The kinematics on the fault planes located along the margins of the Late Pleistocene collapsed basin indicate the coexistence of two active (NW-SE and NE-SW) directions of extension that, along the **EPSZ**, are associated with a NE-oriented compression, which is consistent with the seismogenic stress field in the area (NERI *et alii*, 2005). The contribution of three different stress fields on remobilizing the active structures is also evidenced by the available seismological data. The main recorded event (e.g. 1978; CELLO *et alii*, 1982) is to relate to dextral motion along the off-shore active segments of the **EPSZ**. The coexistence of the two active direction of extension

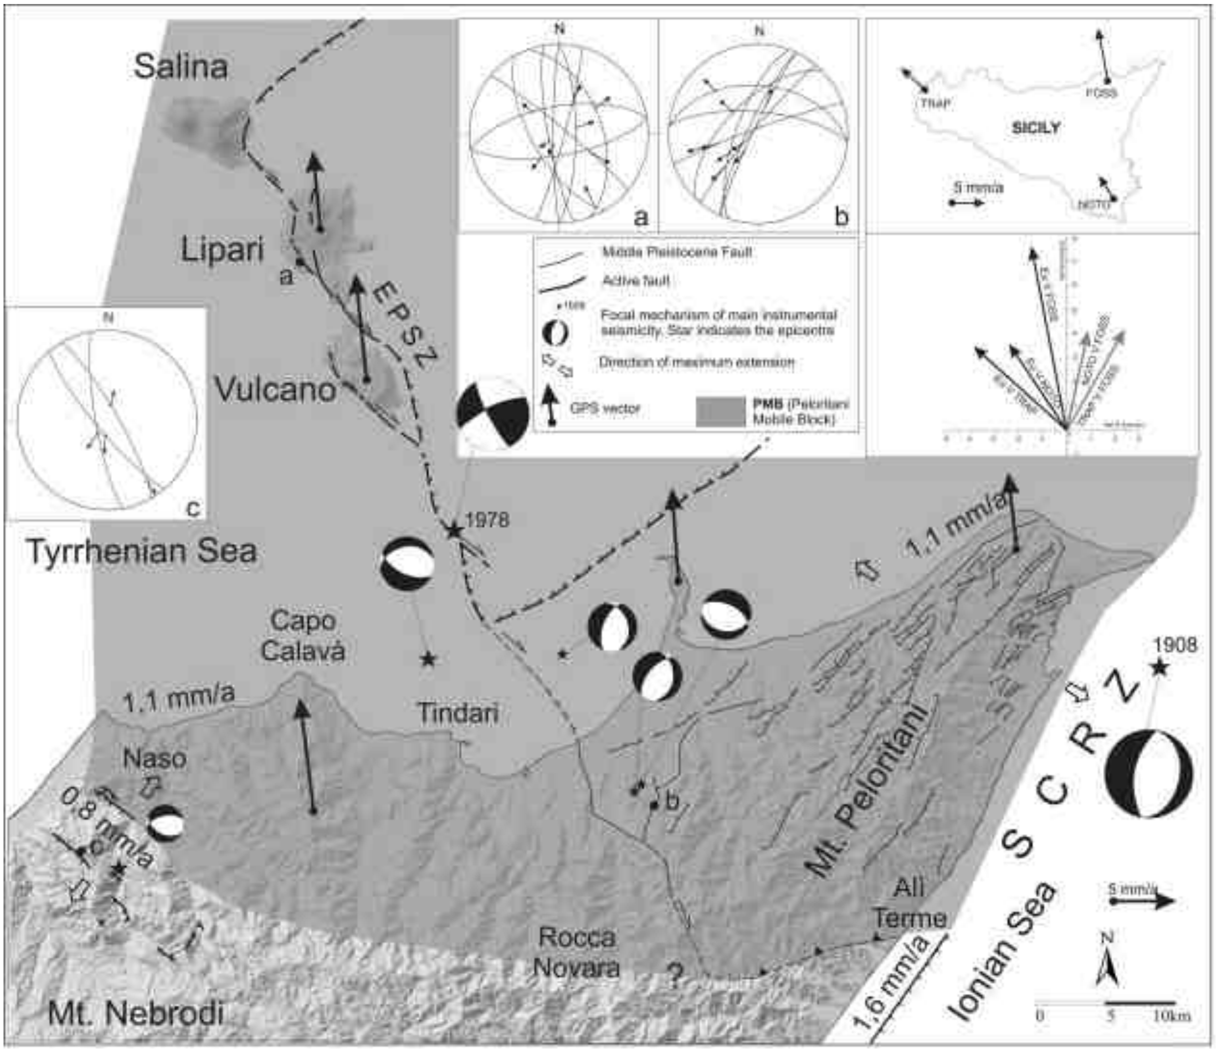

Fig. 1 – tectonic sketch map of the NE Sicily mobile block. The inset a, b refer to the kinematics of the Eolian and Peloritani faults. The inset c regards the southwestern boundary of the mobile block. In the figure, the orientation of the GPS vectors and their composition are reported.

is demonstrated by focal mechanisms related to the low-magnitude events, which are spread over all the Peloritani margin (GIAMMANCO *et alii*, 2008). Finally, the Ionian margin of the **PMB** is represented by the NNE-SSW oriented Taormina Fault that, propagated in the off-shore, since the 125 ka B.P. (CATALANO & DE GUIDI, 2003), represents a normal fault segment of the incipient N-S trending Siculo Calabrian Rift Zone (**SCRZ**; CATALANO *et alii*, 2008).

CONCLUSIONS

The **PMB** shows several peculiarities that provides useful constrains to explain the Late Quaternary deformation of the region: 1) the Late Quaternary uplift faster than the adjacent areas; 2) the development of discrete collapsed basins, parallel to the σ_1 measured within the block; 3) the occurrence of an extensional margin, perpendicular to the σ_1 measured within the block; 4) the absence of a crustal back stop at rear of NNE-ward moving crustal block, as the southwestern extensional tectonic boundary shows Holocene vertical displacement-rate of about 0.3 to 0.5 mm/a that accommodates the entire relative motion between the **PMB** and the adjacent regions; 5) the cumulative displacement along the southwestern margin of the block indicates a Tyrrhenian age of the activation of the structure, which is coeval to the emergence of part of submarine edifices and the onset of the marine terracing in the Eolian island and the development of the collapsed basin.

These evidences suggest that the re-orientation of the σ_1 in this region of north-eastern Sicily is the result of active Mantle diapirism at depth that produced a tectonic wedging in the overlying crust (Fig. 2). The NE-ward shifting and the differential tectonic uplifting of the entire region, associated with the negative tectonic inversion along the southwestern margin of the block and with the diffuse processes of crustal extension and contraction along the same direction, are consistent with a NE-verging intrusion of a the Mantle diapir.

It is to remark that the remobilized crustal block is located at the footwall of the **SCRZ**, in a region affected by pre-existing Mantle upwarp, responsible for the earlier Eolian volcanism. This strongly suggests that the Late Quaternary Mantle

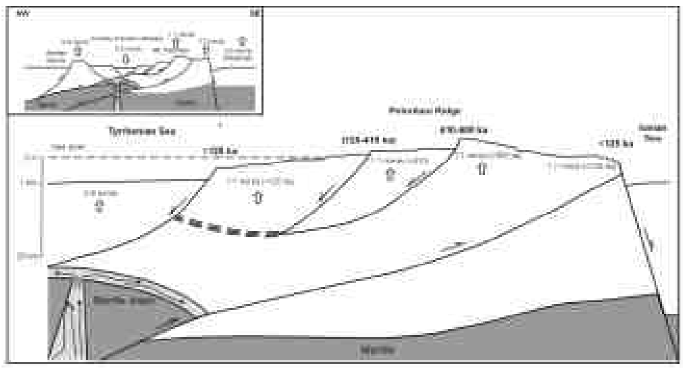

Fig. 2 – Schematic profile located to the north of the major **EPSZ**, showing the Mantle intrusion beneath the **PMB**. The age of the main Late Quaternary tectonic features and the uplift-rates are reported.

intrusion, with the related volcanism, is direct effect of the rift-flank deformation along the **SCRZ**.

The transition between the Marsili oceanic crust and the W Calabria rifted margin: rifting and drifting in the upper plate of the Ionian subduction zone

PEPE F. (*), BERTOTTI G. (^) & SULLI A. (*)

Key words: *W Calabria continental margin, Continent– Ocean Transition; Mantle exhumation; Marsili basin, Marsili volcano, Southern Tyrrhenian Sea.*

The western Calabria continental margin forms the transition between the Late Pliocene to Recent Marsili spreading center and continental Calabria. Integrating high-penetration and -resolution upper crustal seismic images with seafloor morphology, ODP well data and geological/geophysical constraints we provide a detailed reconstruction of the architecture of the distal portion of the W Calabria rifted margin and of the adjacent Marsili "oceanic" domain (Fig. 1) and develop a scheme for the Pliocene to present rifting and drifting of the upper plate of the Ionian subduction zone. Our seismic data document the presence of stretched and thinned continental crust, less than 10 Km thick into the eastern sector of the Marsili abyssal plain previously considered as floored by a three-layer oceanic crust.

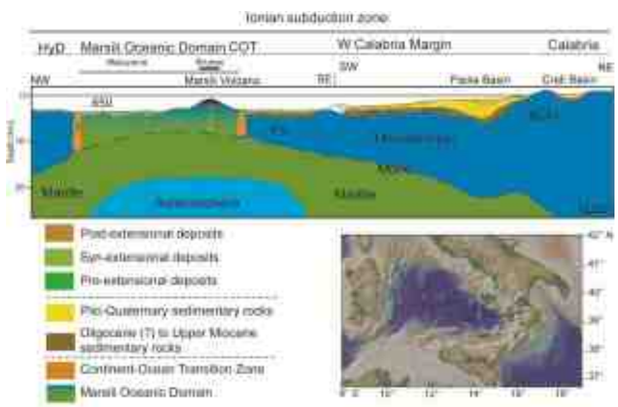

Fig. 1 – Lithospheric cross-section from the hybrid domain between the Marsili and Vavilov basins, across the Marsili Oceanic Domain, the W Calabria continental margin to the Crati Basin (Calabria mainland). HyD, hybrid domain between the Marsili and Vavilov basins; MB, Marsili basin; MV, Marsili Volcano; AA, Aeolian Arc, PB, Paola Basin, CB, Crati Basin; KCU, Kabilian - Calabrian units; TS, thinned and stretched Calabrian continental crust; COT, Continent-Ocean Transition Zone. No vertical exaggeration.

Thinning of the crust is associated with a numbers of 2-4 km wide tilted blocks composed of an acoustic basement and pre- and syn-rift sediments.

Stretching factors between 1.1 and 1.42 (ca. 40% extension) has been obtained assuming a domino-like style of deformation. With few exceptions, the infill completely smoothes out pre-existing topography and explain the flat sea floor in the area surrounding the Marsili volcano. Extensional tectonics began in the Late (?) Pliocene – Early (?) Pleistocene times and ended at ca. 0.5 Ma resulting in the formation of ca. 70 km of "oceanic" domain with an average spreading rate between ca. 5.1 and 5.9 cm/yr. The appearance of vescicular basalts in the Marsili basin was not associated with the end of extension. The post-extensional sedimentary package has fairly constant thicknesses of ca. 350 along the entire Marsili abyssal plain. The Marsili volcano grows close to the western termination of the stretched and thinned W Calabria continental crust, in an asymmetric position with respect to the < 2 Ma Marsili Basin itself.

Measuring magnitude and rate of vertical movements in the offshore Capo Vaticano (W Calabria) using lowstand coastal prisms and wave-built terraces

PEPE F. (*), SACCHI M. (°), BERTOTTI G. (^) & COLLURA A. (*)

Key words: *Capo Vaticano, Vertical movements, Wave-built terrace; Last Glacial Maximum.*

The magnitude and rate of vertical movements have been measured in the offshore Capo Vaticano (western Calabria) for the Late Pleistocene - Holocene on the basis of the depth of submerged coastal prism and associated wave-built terrace formed during the sea-level lowstand of the Last Glacial Maximum (LGM). Uplifted and submerged terraces have proved to be valuable recorders of vertical motion in many locations around the world (e.g. DICKINSON, 2001; WEBSTER *et alii*, 2004) as the depth of their tops appear to be controlled by the sea-level. In the eastern Tyrrhenian margins, depending on the hydraulic energy conditions (i.e. waves and wind-induced currents), the average water depth of terraced surface of lowstand coastal prisms was probably 15-20 m (CHIOCCI & ORLANDO, 1996).

A series of LGM lowstand coastal prisms and associated wave-built terraces were identified on a new set of very high-resolution reflection seismic profiles acquired along the continental shelf and upper slope of the western Calabria continental margin. Data processing included time-depth conversion and the interpretation of the resulting seismic lines was performed using a GIS-based software package.

Seismic interpretation highlight that along the offshore Capo Vaticano the slope-breaks associated with wave-built terraced formed during the LGM deepens from ~130 m (cluster A) to ~170 m (cluster B) below sea level (bsl) as one moves from southwest to the northeast, over a distance of ~21 km (Fig. 1). Farther to the north, along the western flank of the Calabrian Arc, an average depth for the slope-breaks of ~165 m is measured.

(^) Department of GeoSciences and Engineering, Delft University of Technology, The Netherlands

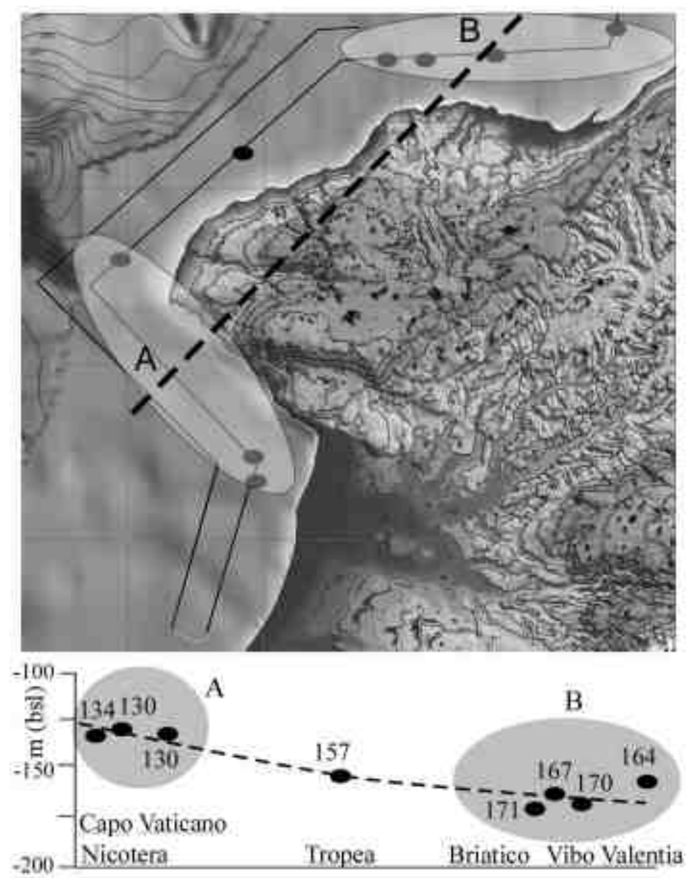

Fig. 1 – Map of the submerged coastal prism and associated wave-built terrace along the offshore Capo Vaticano and their depth profile along a NE-SW vertical section.

Removal of the non tectonic component of vertical changes using an ice-volume equivalent eustatic sea-level compilation (LAMBECK *et alii*, 2011) indicates ~15 (± 5) m of uplift and ~25 (± 5) m of subsidence during the post-LGM for the southern and northern sectors offshore Capo Vaticano, respectively. The resulting average uplift and subsidence rates (both regional and local components) for the last 20 (± 2) k.y. are 0.75 (±0.325) mm/y and 1.25 (±0.375) mm/y, respectively.

The integration of the new data with those available in the literature (e.g. TORTORICI *et alii*, 2003; CUCCI & TERTULLIANI, 2010; FERRANTI *et alii*, 2011) may provide information on fault kinematics and constraints on slip rates of tectonic structures that are relevant for earthquake hazard analysis of western Calabrian margin.

Active Faults, Historical Earthquakes and Turbidites in the Messina Straits Region

ALINA POLONIA (1), LUCA GASPERINI (1), GIULIANA PANIERI (1), LUIGI TORELLI (2),
GIORGIO GASPAROTTO (3), & PAOLA MUSSONI (2)

Key words: *Calabrian Arc, subduction complex, seismogenic faults, earthquakes, tsunamis.*

INTRODUCTION

The Calabrian Arc (CA) subduction system is one of the most seismically active regions in the Mediterranean Sea. It has been struck repeatedly by destructive historical earthquakes (BOTTARI et alii, 1989; JACQUES et alii, 2001; GALLI AND BOSI, 2003; JENNY et alii, 2006), often associated with destructive tsunamis (PIATANESI AND TINTI, 1998; TINTI et alii, 2004); however, source parameters and recurrence time for major events are poorly known, particularly for seismogenic structures extending offshore.

To address the seismogenic behaviour of the CA region and evaluate its seismogenic/tsunamigenic potential, it is essential to unravel the tectonic setting of the submerged portion of the system, reconstruct the fine-scale geometry of single fault strands and relate their kinematics to the overall geodynamic framework of the Central Mediterranean.

STRUCTURAL SETTING

The CA subduction complex is located at the toe of the Eurasian plate in the Ionian Sea where sediments resting on the lower plate have been scraped off and piled up in the accretionary wedge, due to the Africa/Eurasia plate convergence and back arc extension. The external part of the arc is represented by a subduction complex whose overall geometry (i.e., depth of the basal detachment, geometry and structural style of the different tectonic domains) was reconstructed through an integrated approach involving the analysis of geophysical data at different scales (POLONIA et alii, 2011).

Main morpho-structural domains of the subduction complex have been identified on the basis of variations of structural style and seafloor morphology that are related to different tectonic processes such as, frontal accretion, out-of-sequence thrusting, underplating and complex faulting. The pre-collisional tectonic setting of the Calabrian Arc is reflected in the segmentation of the margin along "transfer" faults that reflect recent plate re-organization in the Central Mediterranean. Transfer faults represent boundaries between margin segments with different deformation and uplift rates, structural style and basal detachment depths.

We analysed the fine structure of major tectonic features in the offshore Messina Straits region (Fig. 1), likely to have been sources of past earthquakes including: i) the NNW-SSE trending Malta STEP (Slab Transfer Edge Propagator) fault system, representing a lateral tear of the subduction system; ii) a system of out-of-sequence thrusts (splay faults) at the rear of the salt-bearing outer accretionary wedge; and iii) the Messina Straits fault system, part of the wide deformation zone separating the Western and Eastern lobes of the accretionary wedge.

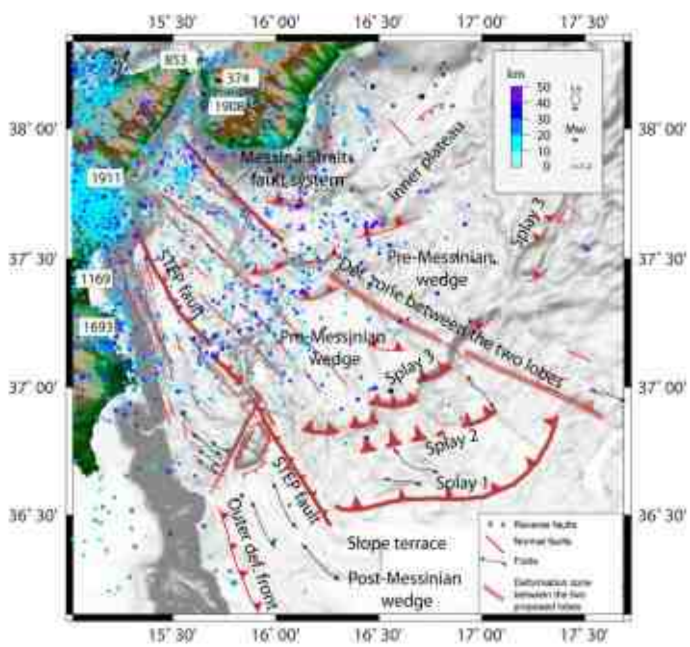

Fig. 1 – Tectonic map of the Messina Straits region (POLONIA *et alii*, 2012) with major seismogenetic structures indicated (STEP, Splay-1, -2, -3, and Messina Straits fault systems). Filled circles mark earthquake epicenters in the region during the period 1981-2011 from two different catalogs, CSI-1.1 (CASTELLO et alii, 2006) and ISIDe (ISIDe Working Group (INGV, 2010), Italian Seismological Instrumental and parametric database: http://iside.rm.ingv.it)..

The Messina Straits fault system, in particular, accommodates differential movements of the Calabrian and the Peloritan portions of CA, and might account for the NW-SE extension observed in the Messina straits, as well as the relative motion between Calabria and NE Sicily. This implies that immediately South of the Messina Straits a steep East-dipping fault is present at depth and satisfies the requirements of the causative fault for the 1908 earthquake (POLONIA et alii, 2012).

TURBIDITE PALEOSEISMOLOGY

Fault activity and recurrence time of major earthquakes have been studied through the analysis of well targeted gravity cores collected in the abyssal plain and slope basins (Fig. 2). Three turbidite beds emplaced during the last Millennia have been studied through a multidisciplinary approach involving sedimentology, biostratigraphy, mineralogy and physical properties. Resedimented units make up more than 80% of sedimentation in the Ionian Sea abyssal plain. The age of each turbidite bed suggests that turbidite emplacement may be correlated to major historical earthquakes in the area (i.e. 1908, 1693 and 1169 events) while micropaleontological associations and mineralogical signatures have been used to infer sediment provenance and probable causative faults in the CA subduction complex (POLONIA *et alii*, submitted).

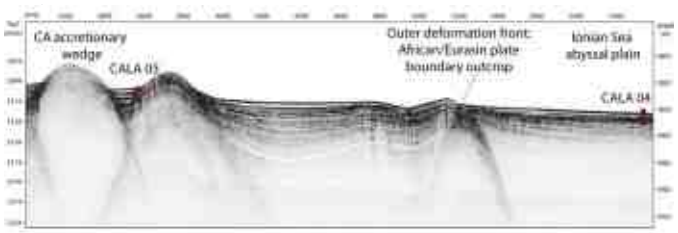

Fig. 2 – CHIRP profile representing shallow stratigraphy of the working area and the location of the two analyzed cores.

These findings have implications for seismic and tsunami hazard, as we compile an inventory of first order active faults that may have produced past seismic events and be source regions for future large magnitude events as they are long, deep and bound sectors of the margin characterized by different deformation and coupling rates on the plate interface. The geological setting of the CA, which shows very high uplift and erosion rates of the mountain range behind the sedimentary basins, increases the possibility of mass failures (POLONIA et alii, submitted). Sediment supply is a fundamental parameter controlling the potential for mass wasting processes in tectonically active regions, and this makes the CA and the Messina Straits region more prone to tsunamigenic risk, because of the intense sediment discharge into the slopes and the occurrence of medium to large earthquakes.

The Calabrian Arc Subduction Complex in the Ionian Sea: Structure, Evolution and Seismic Hazard

ALINA POLONIA (*), LUIGI TORELLI (**) PAOLA MUSSONI (**) LUCA GASPERINI (*), ANDREA ARTONI (**)

Key words: *subduction complex, Ionian Sea, active faults*

INTRODUCTION

The Calabrian Arc (CA) evolved during Cenozoic time in response to Eurasia-Africa convergence as part of the Apennine subduction system (Fig. 1). Its evolution is controlled by the south-eastward retreat of the subduction zone that caused rifting and lithospheric thinning culminating in the opening of the Tyrrhenian Sea (MALINVERNO AND RYAN, 1986; DOGLIONI et alii, 1999; FACCENNA et alii, 2001)

The thick sedimentary section of the African plate, at the toe of the CA, has been scraped off from the descending plate, and piled up along thrust faults resulting in the emplacement of a thick (up to 10 km) and about 200-300 km wide accretionary complex.

We analysed the structure and evolution of the CA subduction complex through an integrated geophysical approach involving multi-channel and single-channel seismic data at different scales (POLONIA et alii, 2011).

Pre-stack depth migrated crustal-scale seismic profiles (Fig. 2) have been used to reconstruct the overall geometry of the subduction complex (i.e., depth of the basal detachment, geometry and structural style of different tectonic domains) and location and geometry of major faults. High-resolution multi-channel seismic (MCS) and sub-bottom CHIRP profiles, as well as multibeam data, integrate deep data and constrain the fine structure of the accretionary wedge as well as the activity of individual fault strands.

THE CALABRIAN ARC SUBDUCITON COMPLEX

We identified four main morpho-structural domains in the subduction complex: 1) the post-Messinian salt-bearing accretionary wedge; 2) a slope terrace; 3) the pre-Messinian accretionary wedge and 4) the inner plateau. Variation of structural style and seafloor morphology in these domains are related to different tectonic processes, such as frontal accretion, out-of-sequence thrusting, underplating and complex faulting. The CA subduction complex is segmented longitudinally into two different lobes characterised by different structural style, deformation rates and basal detachment depths. They are delimited by a NW/SE deformation zone that accommodates differential movements of the CA and represent a recent phase of plate re-organization in the central Mediterranean.

The CA has been struck repeatedly by destructive historical earthquakes. We analysed the structure of major tectonic features likely to have been sources of past earthquakes (POLONIA et alii, 2012) that include: i) the Malta Slab Transfer Edge Propagator (STEP) fault system; ii) a system of out-of-sequence thrusts (splay faults) at the rear of the salt-bearing outer accretionary wedge; and iii) the wide transfer zone separating the different lobes of the accretionary wedge.

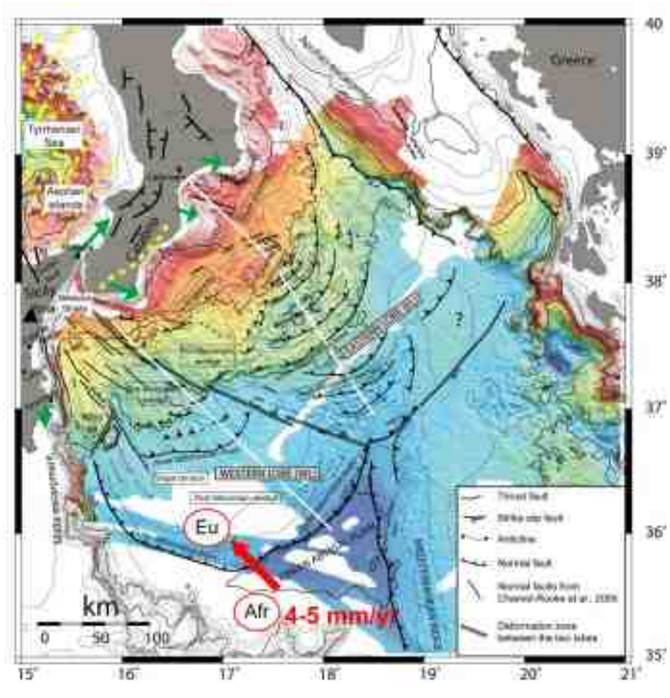

Fig. 1 – Structural map of the CA region derived from integrated interpretation of available seismic data and multibeam bathymetry (modified from POLONIA et alii, 2011). Major structural boundaries, active faults and the extent of the structural domains (i.e. pre and post-Messinian wedges and inner plateau) are indicated.

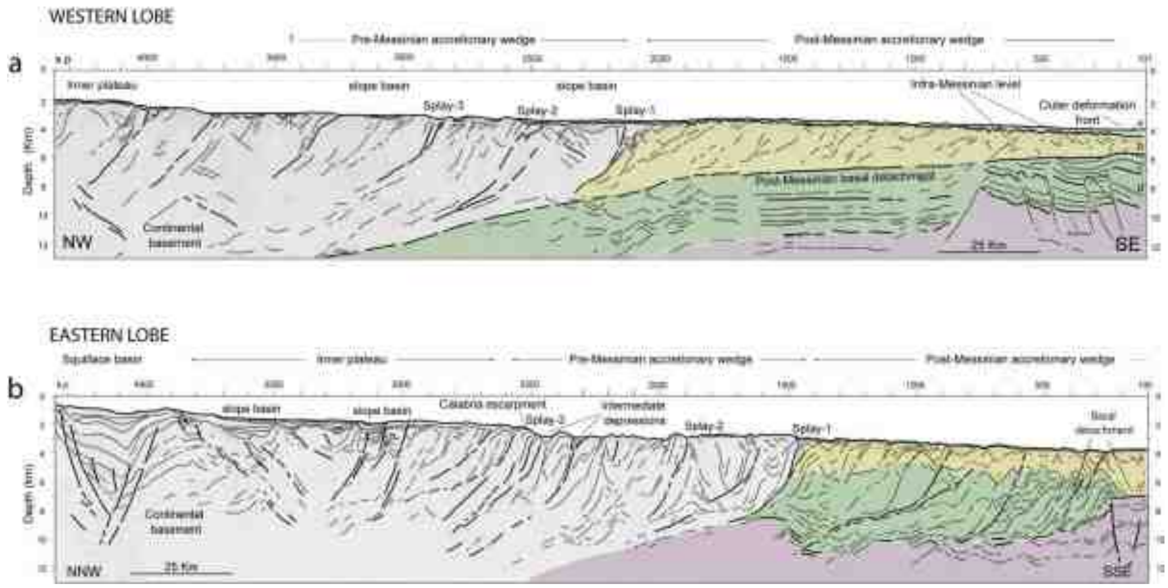

Fig. 2 - a: PSDM (Pre Stack Depth Migrated) MCS line CROP M-2B with superimposed the line drawing. b: PSDM 36 fold MCS line CROP M-4 and line-drawing. Location of seismic profiles is shown in Figure 1. Yellow domain: Messinian and Plio-Quaternary sediments; green domain: Tertiary and Mesozoic sediments; dark pink colour: African plate basement. Modified from POLONIA et alii (2012).

These tectonic features are first order structural elements directly ascribed to regional Africa/Eurasia plate convergence, slab break-off, tearing and recent plate-boundary re-organization. Fault inception and kinematics is related to the succession of major tectonic phases of the Ionian subduction system such as a mid-late Pliocene shortening acceleration and the longitudinal expansion of the system resumed during Early Pleistocene that may account for transtensional deformation in the inner portions of the subduction complex described both along the Malta STEP fault and Messina Straits fault systems.

Integrated analysis of location, geometry and kinematics of the active tectonic features, as well as correlation with the catalogue of historical earthquakes has been carried out in order to define causal relationships between the proposed seismogenic features and specific seismic events in the area. We propose that the 1908 earthquake may have been triggered by the Messina Straits fault system while, the 1693 and 1169 may be related to the Malta STEP fault and/or the splay fault systems (POLONIA et alii, 2012; POLONIA et alii, submitted).

These findings have implications for seismic and tsunami hazard, because the described active faults are likely to be source regions for future large magnitude earthquakes as they are long, deep and bound sectors of the margin characterized by different deformation and coupling rates on the plate interface. The geological setting of the CA, which shows very high uplift and erosion rates of the mountain range behind the sedimentary basins, increases the possibility of mass failures (POLONIA et al., submitted) and this makes the CA more prone to tsunamigenic risk, because of the intense sediment discharge into the slopes and the occurrence of medium to large earthquakes.

The tectonic structure of the Tyrrhenian Basin, a complex interaction among faulting and magmatism

C. R. RANERO (1), V. SALLARÉS (2), N. ZITELLINI (3), I. GREVEMEYER (4), M. GUZMAN (2), M. PRADA (2), S. MOELLER (3), R. DE FRANCO (5) & THE MEDOC CRUISE PARTY

Key words: *Tyrrhenian rifting, tectonic structure, crustal structure*.

INTRODUCTION

The Tyrrhenian basin has formed in a subduction setting context, by extension of the overriding continental lithosphere in a process fundamentally driven by the retreat of a Ionian slab across the mantle. The lack of important normal-fault seismicity across the northern half of the basin seems to indicate that extension fully stopped there. The preserved basin structure provides information of the time evolution of the processes involved in rifting. The basin rifting rates and amount of extension changes from north to south, with rifting stopping after progressively larger stretching factor towards the south. The northern region stopped opening after a relatively low extension factor. Towards the south extension increased up to full crustal separation that produced mantle exhumation and locally collocated large-scale volcanism. The final structure displays two conjugate margins with asymmetric structures. Thus, the basin provides a natural laboratory to investigate a full rift system, that displays variable amounts of extension.

THE MEDOC EXPERIMENT

We present observations from a two-ship seismic experiment that took place in spring 2010. The cruise took place on two legs. In the first leg, the Spanish R/V Sarmiento de Gamboa and the Italian R/V Urania collected five E-W trending wide-angle seismic (WAS) profiles across the entire basin using 17 Ocean Bottom Seismometers and 25 Ocean Bottom Hydrophones and a 4800 c.i. G-II gun array. The profiles were extended with land stations that recorded the marine shots. During a second leg the R/V Sarmiento de Gamboa collected 16 Multichannel Seismic Reflection (MCS) profiles using a 3.75 km-long streamer and a 3000 c.i. G-II gun array. MCS profiles were acquired coincident with the WAS profiles, and a number of additional lines concentrated in the central region of the basin where mantle exhumation took place. The seismic profiles were located to cover regions of the basin that displays different amount of extension, and the coincident wide-angle and MCS transects cross the entire basin to image the two conjugate margins.

We compare observations from the different transects mapping the structures produced at different extension factors and possibly a different extension rates. Each transect provides the tectonic structure, the geometry of sedimentary deposits, and P-wave seismic velocity distribution. This information allows to interpret the mechanisms of deformation, infer the significance and potential role of magmatism in the rifting process, and estimate the region of mantle exhumation, currently inferred from only one drill site. The analysis of the data provides insight in the process of formation of the asymmetric structure of conjugated margins.

The structure of the Tyrrhenian from integration of multichannel seismic images, wide-angle seismic data, and gravity modeling

V. SALLARÉS (1), C. R. RANERO (2), N. ZITELLINI (3), I. GREVEMEYER (3), M. GUZMAN (1), M. PRADA (1), S. MOELLER (3), ROBERTO DE FRANCO (5) & THE MEDOC CRUISE PARTY

Key words: *Tyrrhenian rifting, tectonic structure, crustal structure*

INTRODUCTION

Most of the Tyrrhenian basin has formed by extension of the upper-plate continental lithosphere in a subduction-zone geodynamic setting, in a process fundamentally driven by the migration of a Ionian oceanic slab across the mantle. The amount of extension abruptly changes from north to south. In the north east of Corsica rifting stopped after low extension factor. Towards the south extension increased up to full crustal separation that was followed by mantle exhumation, and locally collocated large-scale volcanism. We use 5 transects across the basin with coincident wide-angle seismic data and multichannel seismic images to analyze the changes in the tectonic and crustal structure with increasing amount of extension. Thus, the basin is a unique location to investigate a full rift system with one survey.

THE MEDOC SEISMIC DATA

We The P-wave velocity models are obtained by joint refraction and reflection travel-time tomography that constrain the seismic structure of the entire crust and uppermost few km of mantle, and the geometry of the Moho boundary, when observed as a wide-angle reflection. The arrival times used in the inversion are phases refracted through crust and upper mantle (*Pg* and *Pn*), and reflected at the Moho (*PmP*). A statistical uncertainty analysis has been performed to evaluate the accuracy of the seismic velocity and the geometry of the Moho.

The seismic structure of the models reveals a significant lateral variation of the velocity structure and vertical velocity gradient from north of the basin to the south and from the basin margins to the center region. The models show a progressive transition between >20 km-thick continental crust at the basin flanks to thinned crust in the center. The type of crust from the margins to the center changes as indicated by velocities and in some cases it may have been magmatically intruded. In the central part f the Tyrrhenian there is a region that lacks *PmP* reflections and the velocity model indicates that most basement is made mantle rocks with overlying crystalline crust. Here the ODP Leg 107 drilled peridotites under the sediment cover.

The comparison of wide angle velocity models with multichannel seismic reflection images indicate a correspondence between the seismic reflection images and the velocity models. The seismic images display well the tectonic structure and also regions where the crust shows well developed reflectivity and/or Moho reflections.

Deformed Pleistocene marine terraces along the Ionian sea margin of southern Italy: Unveiling blind fault-related folds contribution to coastal uplift.

ENRICO SANTORO (*°), LUIGI FERRANTI (*), PIERFRANCESCO BURRATO (**), MARIA ENRICA MAZZELLA (*), CARMELO MONACO (***)

Key words: *marine terraces, regional uplift, fault propagation folds, fault modeling.*

Morphotectonic analysis and fault numeric modeling of uplifted marine terraces along the southern half of the Taranto Gulf , between the Sibari and San Nicola plains (Fig. 1), allow us to place quantitative constraints on Middle Pleistocene-Holocene deformation in the Southern Apennines.

At the end of the Early Pleistocene, a tectonic change occurred in southern Italy (HIPPOLYTE *et alii*, 1994). At this time, NW-SE striking transpressional faults in the frontal part of the Apennines (Fig. 1a) were activated, related to involvement of the foreland continental lithosphere in the collision (CATALANO *et alii*, 1993). Based on seismic reflection profiles and borehole data, DEL BEN *et alii* (2007) and FERRANTI *et alii* (2009) demonstrated that the strike-slip fault zones continue in the offshore and deform up to the Middle-Upper Pleistocene sequences (Fig. 1a). FERRANTI *et alii* (2009), through morphometric, structural and seismic data (Fig. 1a), proposed that a compression phase, under a ~NE to ENE-trending shortening axis, was active since Early Middle-Pleistocene and, probably, is still ongoing. Previous works proposed the existence of paleo-shorelines deformations induced by local thrust and transpressional faults (FERRANTI *et alii*, 2009; CAPUTO *et alii*, 2010).

The observations discussed here build on, and refine, the works published by FERRANTI *et alii* (2009) and SANTORO *et alii* (2009), by slightly adjusting their marine terrace positions and by extending their terrace map to the southern sector of the San Nicola Plain (Fig. 1a). Terraced surfaces have been identified through aereophotography analysis (1:17.000 scale) and morphological and sedimentological field surveys (1:10.000 and 1:5.000 scale topo maps and orthophotos, respectively).

Ten terrace orders uplifted up to +660 m were mapped along ~80 km of the Taranto Gulf coastline (Fig. 1a). Terrace chronology (Fig. 1a) was established through a critical review of all the available dating in the Taranto Gulf [Brükner, 1980; DAI PRA & HEARTY, 1988; AMATO *et alii*, 1997; CUCCI, 2004; ZANDER et alii, 2006; SANTORO *et alii*, 2009; CAPUTO *et alii*, 2010]. The lack of an agreement among authors dealing with this problem hampers a correct estimate of the local and regional uplift rates. We are confident that the application of Optical Stimulated Luminescence and Cosmogenic Radionuclides exposure ages methods will pose further constraints about terrace chronology (RISTUCCIA *et alii*, this volume).

The shorelines, projected along section A-B (Fig. 1a) document both a regional and a local, fault-induced contribution to uplift (Fig. 1c). Two major undulations, hereafter named Valsinni and Pollino anticlines (labeled as 1 and 2 in Figs. 1a and 2c, respectively) were found along the Pollino coast. The undulations spatially coincide with the trace of NW-SE striking transpressional faults that affected the coastal mountain range during the Early Pleistocene, but display scarce evidence of more recent activity. To test whether fault activity continued to the present, we modeled the differential uplift of marine terraces as progressive elastic displacement above blind oblique-thrust ramps seated beneath the coast.

A first step toward determining the fault-induced signal and derive fault parameters from the paleo-shorelines record requires splitting the total uplift of individual terraces in its regional and local tectonic component. The two components, local and regional, are characterized by different wavelength, which varies from the few 10s to the several 10s to 100 km, respectively, and their understanding requires assessment of different spatial distribution of markers. The large wavelength geomorphological signature of the regional uplift was reconstructed by using the elevation of the MIS 5.5 terrace along a ~300 km long coastal sector of the Taranto Gulf (Fig. 2). Specifically, we used MIS 5.5 elevation data from sectors where the terrace chronology is well constrained and the paleo-shorelines are not appreciably deformed by local sources, namely from the northernmost Taranto Gulf [Ferranti et al., 2006], the Sila Massif [Santoro et al., 2009] and the San Nicola Plain (this work) (Fig. 2a).

The linear regression (R^2=0.979) through the MIS 5.5 elevation data highlights a northeastward tilt of the coast with a mean regional gradient of 0.4 m km^{-1} and a tilt rate (gradient of the coastline divided by the MIS 5.5 age) of $3*10^{-3}$ m km^{-1} ka^{-1} (Fig. 2a). The accuracy of our regional uplift trend was verified by plotting it against the observed

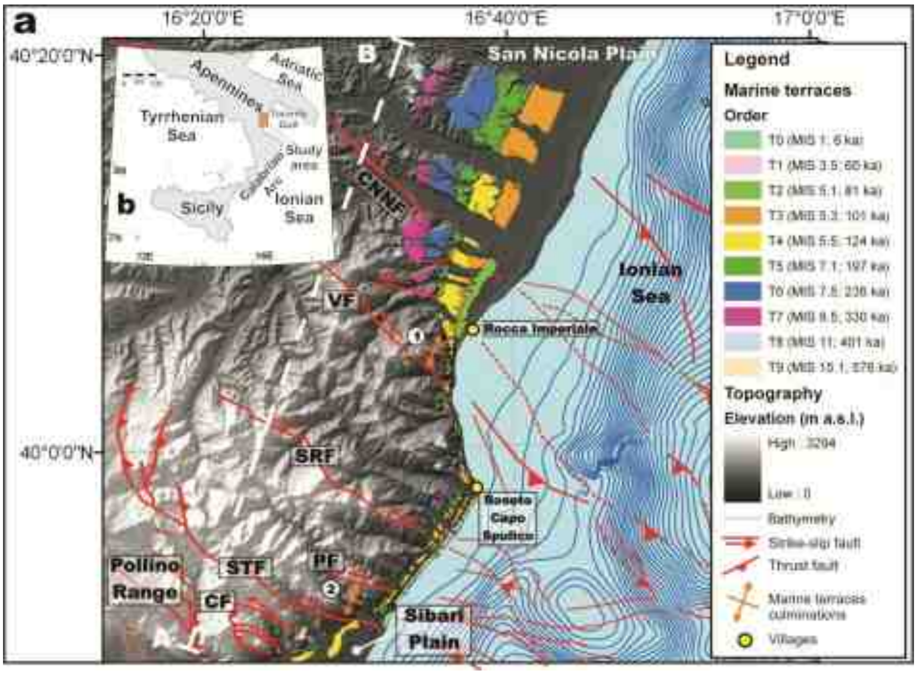

Fig. 1 – a) Morpho-structural map of the southern Apennines between the Sibari and San Nicola plains (location in Figure 1b). Bathymetric and structural data for the offshore area modified after FERRANTI *et alii* (2009). The trace of section A-B against which the terraces paleo-shorelines are projected is reported. Major terraces positive undulations (labeled as in Figure 2c) are localized along the southern Pollino flank (2) and the Valsinni Ridge (1). Faults: CNNF, Canna Fault; CF, Civita Fault; PF, Pagliara Fault; SRF, Saraceno Fault; STF, Satanasso Fault; VF, Valsinni Fault.; b) location of the study area.

T4 (MIS 5.5) paleo-shoreline elevation (Fig. 2c). Indeed, if we force the regional curve to pass close to the tilted (but not folded) terraces of San Nicola Plain, it apparently runs very close by the inflection points between uplift and subsidence for the Pollino and Valsinni anticlines (Fig. 2c). The inflection point position for the two anticlines was derived using the elastic deformation models of OKADA (1985) that predict, for a blind thrust with a geometry similar to that of the northern Calabria faults, a co-seismic surface deformation partitioned on the average between an ~84% uplift and ~16% subsidence. It is evident from Fig. 2c that the model condition is closely matched by the combined terrace observation data and computed regional trend. Finally, relying on the simplistic assumption that the regional uplift is steady and uniform, we derived regional and local uplift signals for lower and higher terraces (Fig. 2b).

Through an iterative and mathematically based

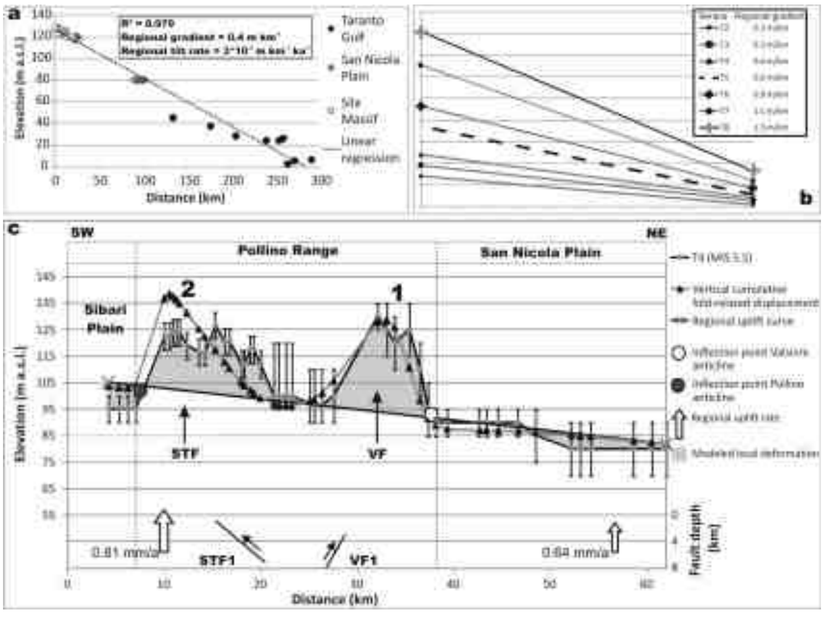

Fig. 2 – a) Elevation-distance plot of the MIS 5.5 terrace along the Ionian coast (from north to south: northern Taranto Gulf, southern San Nicola Plain and northern Sila slope); b) regional gradient of terraces T2-T8 used for fault modeling; c) fault modeling results compared with the MIS 5.5 paleo-shoreline elevation trend. The vertical cumulative fold-related displacement curve is the sum of regional uplift and local fault-induced displacement. The position and depth extent (scale on the right of diagram) of the modeled faults and the regional uplift curve and rates (large arrows) are also reported. Valsinni (1) and Pollino (2) anticlines labeled as in Fig. 1a.

procedure we defined the best geometric and kinematic fault parameters as well as the number and position of fault segments. Only the local vertical displacement (elevation difference between paleo-shoreline and regional uplift curve) was modeled (Fig. 2c).

Kinematics parameters (rake) of the modeled transpressive faults rely on structural analysis carried out in Early-Middle Pleistocene sequences and on strain tensor data derived from available focal mechanisms (FERRANTI *et alii*, 2009). In light of the small scatter in both the finite and incremental shortening trend estimates, we determined the preferred orientation (N30°E) carrying out a set of fault models with different shortening axis trend changing from NNE-SSW to E-W, tested against the MIS 5.5 terrace.

Regarding to the geometric parameters, we started from strike, dip direction, minimum depth and dip derived from geological maps, geological cross sections and geophysical data. Because the fold wavelength is controlled by dip and width of the fault plane, we used our deformed paleo-shorelines (geographic position and distance between anticline and syncline axis) to calibrate the width, maximum depth and dip of the fault surfaces by moving in the value ranges derived from seismic sections, with steps of 1 km and 1°, respectively. The width we obtained following this procedure can be assumed as the subsurface rupture width of WELLS & COPPERSMITH (1994). Once this parameter was fixed, we were able to evaluate the moment magnitude and, hence, the length (subsurface rupture length) trough the empirical relationships of WELLS & COPPERSMITH (1994).

We found that only the Satanasso and Valsinni faults (STF and VF, respectively; Fig. 1a) are involved in warping of the marine terraces. Indeed, the surface deformational areas predicted by the numeric models for CF, PF, SRF and CNNF (Fig. 1a) are not geographically coincident with paleo-shorelines dislocation. Therefore, we regard these latter faults as inactive and discard them from further modeling.

Fault numerical models predict two fault-propagation folds cored by blind thrusts (STF1 and VF1 in Fig. 2c) with slip rates ranging from 0.5 to 0.7 mm/a and capable of generating an earthquake with a maximum moment magnitude of 5.9-6.3. The modeled slip on the thrust faults reproduces with fair accuracy not only the MIS 5.5 paleo-shoreline shape, through which the model itself was tested, but also the elevation trend of terraces from T2 to T8.

In the time period investigated, local, fault-induced, vertical deformation was not constant but occurred as an alternation of more rapid (up to ~1.9 mm/a) and slower or null periods of vertical displacement rates. Remarkably, we found that not only the fault segments activity was not constant at the 400-ka scale, but also that deformation shifted during time between the two modeled fault segments.

It is not clear if the active deformation is seismogenic or dominated by aseismic creep; however, the modeled faults are embedded in an offshore transpressional belt that may have sourced historical earthquakes. Thus, acknowledging that the elastic fault model can overestimate the maximum expected magnitudes, we propose that the modeled fault zones can be responsible of moderate-high intensity earthquakes, probably not registered in the historical record due to recurrence time interval exceeding the record length.

Active and recent transpressive strike-slip tectonics along at the NE border of the Calabrian Arc (Southern Italy)

C. TANSI (*), G. MARTINI (*), M. FÒLINO GALLO (°) & G. IOVINE (*)

Key words: *strike-slip tectonics, transpressional thrust, Calabrian Arc, recent and active tectonics, structural analysis, radon concentration*.

INTRODUCTION

A main reverse/left-lateral strike-slip active fault system, NW-SE trending - located along the northernmost portion of the regional Middle Miocene-Middle Pleistocene shear zone defined by Van Dijk *et al*. (2000 - cf. study area in fig. 1) - profoundly conditioned the post-Tortonian evolution of NE Calabria during the final stages of post-collisional processes which involved the Calabrian Arc (TANSI *et alii*., 2007).

This system– in addition to dismembering and contributing to the uplift of an Oligocene-Early Miocene orogene made of Alpine nappes overthrusted over the Apennine Chain - locally inverted the primary geometric relationships between the units of the orogene itself .

The study area (fig. 2) is marked by crustal oblique transpressional fault zones, mainly dipping toward NE and characterized by left-reverse movements, along which the extrusion of the deep-seated units of the Calabria Arc occurred.

Superficial effects - in terms of morphology (cf. fig. 3), geometry and kinematics - related to the regional strike-slip fault system, were mapped in detail through interpretations of aerial photographs and field assessments. Structural data include orientations of more than 500 fault planes with slickensides, collected from 54 measure stations sited near the main faults, within the cataclastic belts. Such information allowed to determine of the related stress field (ANGELIER, 1979, method), and permitted the "in situ" validation of the regional deformational model.

As atmospheric and near-surface gas concentrations are considered as background values, while concentrations conducted by faults and fractures are considered as anomalous, analyses of gas emanations is a suitable way of identifying active and recent faults and of detecting possible earthquake predictor (KLUSMAN, 1993; KING *et al*., 1996; TORGERSEN & O'DONNELL, 1991). Radon gas, the isotope of which (222Rn) is considered in this work, is especially useful as inert. The movement distance of radon through the subsurface depends on diffusion rate, permeability, and the half-life of 222 Rn (3.824 days).

The established structural arrangement were compared with macroseismic fields of the main earthquakes, instrumental seismicity and focal mechanisms, and soil gas radon concentrations (TALLARICO, 2005), to investigate evidence on activity of the faults.

Morphological, structural and seismological data suggest an activity of the regional strike-slip system up to Present.

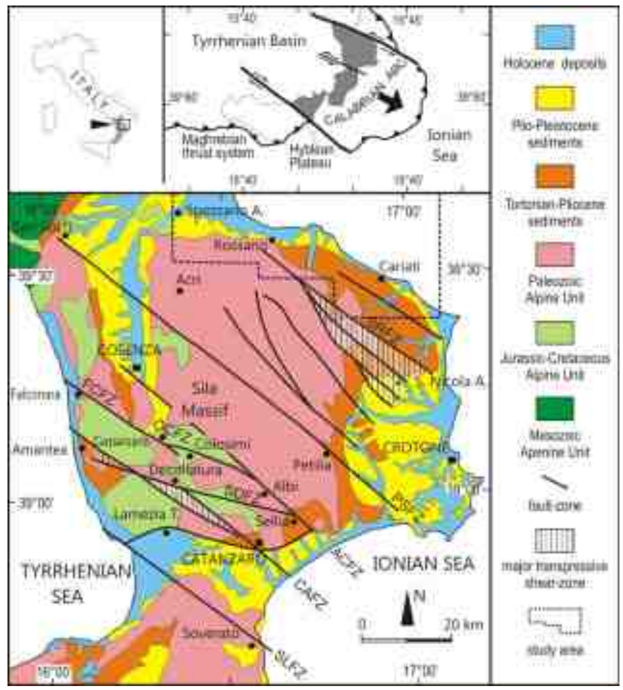

Fig 1 - Schematic tectonic map showing the main Middle Miocene-Middle Pleistocene left-lateral strike-slip lineaments of central-northern Calabria (after Van Dijk et al., 2000). Key: (SLFZ) Soverato-Lamezia Fault Zone; (CAFZ) Catanzaro-Amantea Fault Zone; (ACFZ) Albi-Cosenza Fault Zone; (SDFZ) Sellia-Decollatura Fault Zone; (OCFZ) Ospedale-Colosimi Fault Zone; (FCFZ) Falconara-Carpanzano Fault Zone; (PSFZ) Petilia-S. Sosti Fault Zone; (SRFZ) S. Nicola-Rossano Fault Zone. Dotted polygon indicates the study area.

(°) ARPACal Dipartimento di Catanzaro, Italia

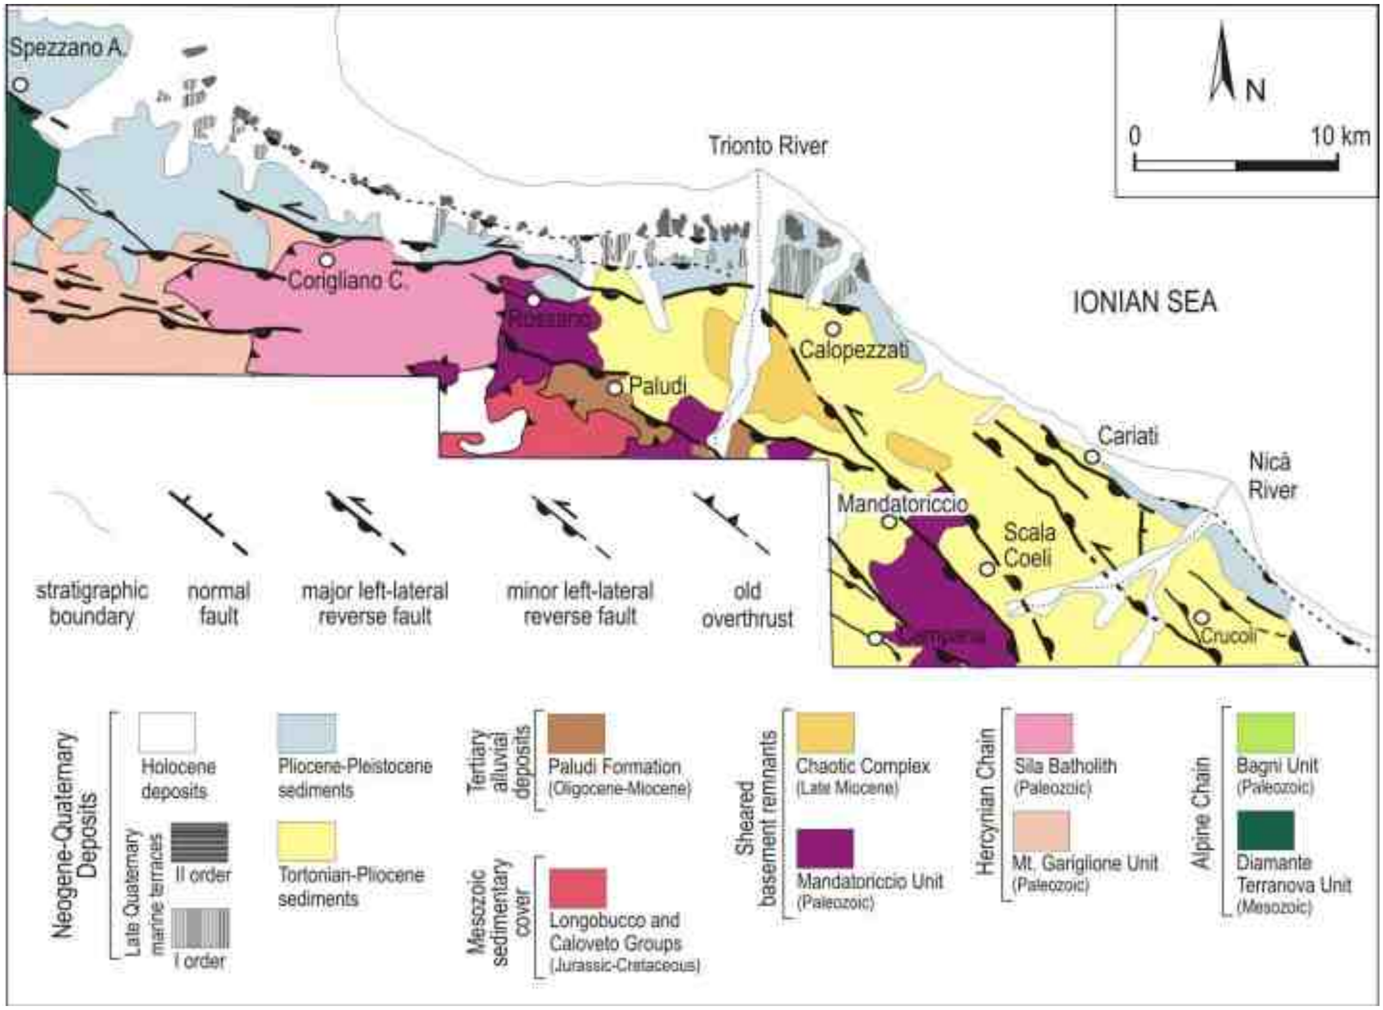

Fig. 2 - Structural map of the study area.

Fig. 3 – Triangular facets along the southernmost portion of the regional strike-slip system.

Moreover, by taking into consideration the regional extent and the hierarchical order of the system, together with its kinematic characteristics, it can be stated that, in NE sector area of the Calabria, sectors exposed to the highest seismic risk are those affected by the NW-SE shear zone.

Royal Roads Military Architectural Elements in the Peloritani Mts. (NE Sicily, Italy): Conservation and Valorization Projects

VINCENZO CARUSO (*), ELISA MACAIONE (*), ANTONIA MESSINA (*)

Key words: *Army Engineers, Geo-cultural Itineraries, Milestones, Military Architecture, Military Roads, Peloritani Mts., Royal Roads.*

INTRODUCTION

This study focuses on the value and conservation of the very important Natural and Historical-Cultural Heritage of the Peloritani Mts. (North-East Sicily) insisting along and around the road network built by Italian Army Engineers in the late 18th century. These Royal Military roads were projected to link together all the Messina Straits fortifications erected on the hills of both Sicilian and Calabria sides to defend the Territory from possible enemy attack by sea.

Due to their characteristic features, these roads have been preserved over 130 years and, despite the several natural and anthropic events realized in the NE Sicily in this interval of time, they are still “legible”.

This research reconstructs the history of the Royal Roads in the Peloritani Mts. with the aim to promote environmental routes in an area rich in geological and morphological features and scenic landscapes.

MORPHOLOGICAL AND GEOLOGICAL OUTLINES

The Peloritani Mts. extend from Peloro Cape in the NE Sicily to the Mazzarà-Novara-Paratore Torrent at W, delimited by the Tyrrhenian and Ionian Seas in the N and E, respectively, and by the Alcantara Valley, in the S, which separates them from the Etna Mt..

The morphology of the territory involves the Ionian and Tyrrhenian coasts and an inland made up of hills and mountains. The Ridge, with an average altitude of 1.000 m, develops in a NE-SW direction, from Dinnammare (1.127 m) to Montagna Grande (1.374 m) and Rocca di Novara (1.340 m), defining the watershed, and continues with an E-W trend, up to the joint with the Nebrodi Mts.. The landscape is characterized by steep reliefs, very deep valleys, acute peaks and a hierarchical hydrography with torrent-like water courses. Marine and alluvial terraces are widespread at different sea levels.

From a geological point of view, the Peloritani Mts. belong to the Southern Sector of the Calabria-Peloritani Arc. They consist of a series of south-vergent crystalline units which overthrust the underlying Apenninic-Maghrebian sedimentary units along the transpressive Longi-Taormina Line (MESSINA *et alii*, 2004).

According to new studies on the Peloritani Mts. (CARBONE *et alii*, 2008, 2011; SERVIZIO GEOLOGICO D’ITALIA - F° 601 Messina-Reggio di Calabria, 2008; F° 587-600 Milazzo-Barcellona P.G., 2011), the thrust belt is made up of nine units consisting of Pan-African and/or Variscan crystalline basements and of localized Meso-Cenozoic sedimentary covers. Basements and covers are locally affected by an Alpine overprint. Going to bottom, the Alpine Units are *Aspromonte, Mela, Piraino, Mandanici, Alì, Fondachelli, San Marco d'Alunzio, Longi-Taormina* and *Capo Sant'Andrea*.

Upper Oligocene-Lower Miocene siliciclastic turbidites of the Capo d’Orlando Flysch unconformably cover and seal the Alpine units. Burdigalian to Modern deposits unconformably cover the units, and together with them, are deformed by meter- to kilometer Burdigalian folds and thrusts, and by different Plio-Quaternary fault systems.

THE ROYAL ROADS HISTORY AND USED STONES

At the end of the 18th century, Army Engineers was asked to choose suitable sites to build forts and which today dominate the heights of the Messina and Reggio Calabria coasts in the Straits of Messina.

After these dominant sites had been decided with the aim of keeping the forts out of the range of naval cannon fire, it was, in fact, deemed necessary to construct an impressive road network to allow the transfer of necessary goods and materials along these rises for the construction of batteries and in addition, for the need to move heavy cannons safely (CARUSO, 2006). Today some of these roads have been asphalted and made practical for the transit of ordinary vehicles of public use. Many others, which are the object of this study, can be followed on foot and horseback and by mountain bike.

With regard to these roads, there is notable interest, in the extension and the area which crosses, the Royal Road par excellence, commonly defined as the “Carriage Road” of the Peloritani Mts. (Fig. 1). It develops between 800 and 1200 metres

(*) Dipartimento di Fisica e Scienze della Terra, Università di Messina - Messina (Italy).

above sea level for approximately 70 km near the Peloritani ridge and allowed troops and artillery to move from north to south, protecting them at the same time from the naval cannons that were situated along the coast.

The road network was initially conceived to reach the town of Castrogiovanni (now called Enna) from the peak of Mt. Dinnamare and to allow the transfer of troops from the centre of Sicily in case of enemy attack on the southern and eastern coasts of the island (ISCAG). Due to the consultation of military maps preserved in the archives of the XI Infrastructure Department of the Army Engineers in Palermo, it has recently been possible to identify an old road which crosses through different communities in the province of Messina and reaches Portella Mandrazzi (Novara di Sicilia in the Central Peloritani Mts.) and from which the Ionic and Tyrrhenian sides can be seen both at the same time or alternately.

The construction of these roads was somewhat complex and as construction machinery such as excavators and dump trucks did not then exist, it was necessary to open up the roads with mines and gunpowder. These explosions brought rocks and outcrops into the open and they are still visible today. After an accurate selection, the excavation of materials to build these forts was carried out by manpower and animals.

The construction of these roads were realized under strict laws and standards, in relation to the paving, restrictions, slope and width of the bends which had to wide enough to allow wagons and artillery to be manoeuvred; particular attention was paid to the canalization of rainwater through drainage channels, decantation drains and underpasses for the downflow of water (Fig. 2) all of which were achieved to an excellent standard of work (MINOLA).

Fig. 1 - "Carriage road" of the Peloritani Mts..

Milestones, which are still scattered about, were a characteristic feature of military roads. They not only showed kilometres and hectometres, but also delimited army land, appropriately numbered areas within their competence and army staff quarters and buildings within the fort (CARUSO, 2010).

Other conically trunk shaped stone posts with an angled finish served to protect the corners of walls from wagon wheels in transit on the road (Fig. 2).

Particular care was also given to the construction of scarp walls, the small retaining walls which had to support the road and the slopes to the side. These walls were always built with cut blocks of stone, often of notable size. Even today, the presence and the particular production of such features enable the military origin of the route to be recognised by even people with no particular knowledge of such matters.

In steep and rugged areas where rainwater naturally collected, the road was equipped with downflow drains for the decantation of detritus which were accessible for cleaning and maintenance.

Daily maintenance was assigned to groups of soldiers and each unit was responsible for approximately for 1 km. Main duties included keeping the road clear of rocks and stones, cleaning the drains to the side of the road and rain drains (BOGLIONE, 2003).

Large scale maintenance carried out on a daily basis by hundreds of soldiers in vast areas of army land throughout the whole national territory protected the terrain from landslides, rockslides and flooding.

PETROGRAPHY

Meso- and microstructural analyses on still preserved natural stone used in the various elements of military architecture indicate that most of them came from the Peloritani Mts. crystalline basements and sedimentary covers, quarried from outcrops sited along and nearby the working areas of the road network. Etna basaltic lavas and very localized and subordinate in amount Aeolian volcanics are also present.

In sites of the *North-Eastern Peloritani Mts.* occurs a predominant use of Variscan medium-high grade massive to less-foliate metamorphics of the Aspromonte Unit. Whitish coarse-grained augengneisses, equigranular to inequigranular grey paragneisses and green amphibolites are prevalent. Subordinate Late-Variscan plutonics, mainly pegmatites (Fig. 3) and aplites, are also present.

In the *Central Peloritani Mts*. Variscan medium-grade whitish medium-fine and strongly crenulated marbles and grey paragneisses of the Mela Unit are common. Upper Oligocene-Lower Miocene Capo d'Orlando arkosic sandstones and massive Upper Burdigalian-Langhian Floresta Fm. calcarenites also occur.

In the *Western Peloritani Mts.* and in the *Eastern Nebrodi Mts.* which belong to the Calabria-Peloritani Chain, San Marco d'Alunzio Unit and Longi-Taormina Unit polychrome massive, mainly micritic and fossil-bearing Mesozoic limestones and subordinate dolostones are the most used rock types.

FINAL REMARKS

The creation of geo-cultural itineraries aimed at the fruition of this road network forms part of a wider scale project for the exploitation of the whole Peloritani Territory and the recuperation of this peculiar Geo-Military Heritage.

INTRODUCTION

The studied area is located in the eastern-central sector of the Peloritani Mts..

The Peloritani Mountains correspond to the southernmost tract of the Calabria-Peloritani Arc orogen in the NE Sicily (Italy). They consists of a stack of nine continental crust tectonic units, involving Pan-African and Variscan crystalline basements, and remnants of Meso-Caenozoic sedimentary covers. Basements and covers are locally affected by an Alpine overprint. Geometrically to both the top and to the north, the Units are: *Aspromonte*, *Mela*, *Piraino*, *Mandanici*, *Alì*, *Fondachelli*, *San Marco d'Alunzio*, *Longi-Taormina*, *Capo Sant'Andrea*. The Pan-African basement (Aspromonte Unit) derives from a Proterozoic plutonic and metamorphic low crust, the Variscan basements (other units) from Paleozoic sedimentary-volcanic sequences (MESSINA *et alii.*, 2004; CARBONE *et alii*, 2008; 2011)

MATERIALS AND METHODS

A total amount of 122 topsoil samples were collected over an area of 300 km^2. The concentration of 53 elements, including potentially toxic metals, were determined in the soil samples by means of ICP-MS after an *aqua regia* acidification. Data were georeferenced and geochemical maps were produced by means of a GIS aided spatial interpolation process.

GEOLOGICAL OUTLINES

Sulphide and sulphosalt mineralizations are widespread in the Peloritani Mts.. The current research aims to geochemically characterize the eastern-central sector of Peloritani Mts., from the Alì Village on the Ionian cost to the Bafia Village on the Central Peloritani Mts.. In the studied area going to the top, Mandanici, Piraino and Mela Units extensively crop out. In the area, t*he Mandanici Unit basement* prevalently consists of a monotone alternance of Variscan white mica + chlorite ± chloritoid ± biotite ± garnet ± albite phyllites and metarenites, and by paragonite to muscovite marbles Upper Triassic-Lower Liassic limestones and gypsum-rich cargneules are locally also present. The *Piraino Unit basement* is mainly made up of Variscan graphite ± white mica ± chlorite ± chloritoid ± biotite ± garnet ± albite/ oligoclase ± staurolite phyllites and metarenites. The Mela Unit basement outcrop in the studied area with garnet-relict + two mica ± garnet ± staurolite ± kyanite ± sillimanite ± cordierite ± andalusite paragneisses and micaschists. At the top of the unit very thick muscovite ± biotite ± garnet marble levels including relict-garnet amphibolites after Eo-Variscan eclogites are also present (Servizio Geologico d'Italia - F° 601 Messina-Reggio di Calabria, 2008; F° 587 Milazzo - F° 600 Barcellona Pozzo di Gotto, 2011).

RESULTS AND DISCUSSION

In accordance with a regional study carried out by DE VIVO *et alii* (1999) on 1198 stream sediments, collected across the Peloritani Mts area, results obtained by the present study show that higher values of Pb, As, Zn, Cu, Cd and Sb are mostly concentrated in a spatially limited area between the Fiumendinisi and Ali Villages.

In these latter areas concentration of Pb, As and Cd often overcome the trigger and action limits established by the Italian environmental law (D. Lgs. 152/06) for both residential and industrial/commercial land use.

To discriminate between an anthropic or a geogenic origin of toxic metals in soils, ratios of Pb isotopes were determined. Lead isotopic composition of leach and residue soil samples indicated that contamination of soils collected in the area between the villages of Fiumendinisi and Alì are geogenic and mostly related to the presence of sulphide and sulphosalt minerals.

A factor score analysis was also ran on the dataset and results obtained show that the Ag, As, Sb, Pb, Cd, Zn, Hg, Ni association clearly marks the areas where old mines were present: San Carlo (Triscari and Saccà, 1982), Vacco, Magliuso (inside the Fiumedinisi territory) and Tripì (inside the Alì territory) (SACCÀ & SACCÀ, 2007) .

Specifically the aim of this study was to carry out a soil follow-up survey investigating more in detail geochemical anomalies already individuated (mostly for As and Au, related to the known occurrence of sulphide deposits in the area) with the stream sediments surveys (DE VIVO *et alii*, 1993; 1998A AND B) and to discriminate geogenic from anthropogenic source of

([3])Dipartimento di Fisica e Scienze della Terra, Università di Messina - Messina (Italy).

metals using isotope Pb ratios (AYUSO *et alii*, 2003; 2005). This also because the territory is polluted by the illegal waste disposal of all sort of materials, such as old cars, tires and batteries and others along the investigated "fiumare" (Vallone Pardu and Fiumara Alì). In addition to the local contamination there is a potential pollution from aerosols from the relevant industrial settlements of Messina, Catania and Milazzo, located, respectively 20 km to the East, 60 km to the South-West and 15 km to the North from the studied area (Fig. 1). This discrimination is important because for 15 toxic metals, the Italian environmental legislation (D. Lgs 152/2006) fixes the threshold limits permitted for residential and commercial/industrial land use, but a tolerance thresholds is permitted for higher concentration levels in consideration of the background values determined in the territory.

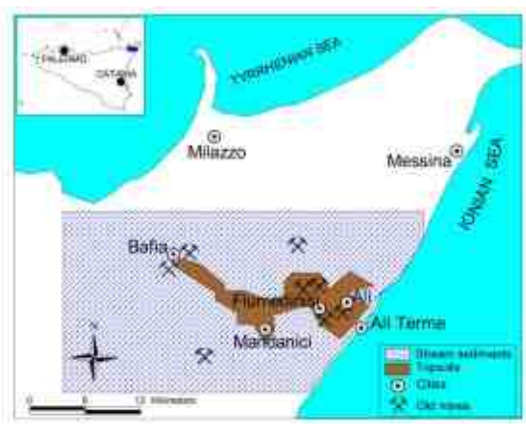

Fig. 1 - The investigated area for soils, following stream sediments surveys (DE VIVO ET ALII. 1998a; 1998b)

As a matter of the fact, among others, Pb shows anomalous concentration values in correspondence of some mineralized areas (at Postlioni-Mandanici area with values >1600 mg/kg and S-W of Ali with values >400 mg/kg); As presents values of concentrations higher than 700 mg/kg between Fiumedinisi area and Ali villages (Fig. 2); Cd shows values of 11 mg/kg in correspondence with the Fiumara of Fiumedinisi. Concentrations of Pb, As and Cd often exceed the trigger and action limits established by the Italian environmental law (D. Lgs. 152/06) for both residential and industrial/commercial land use.

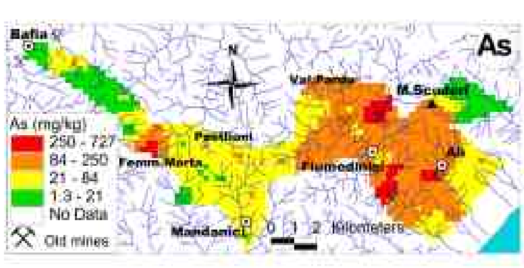

Fig. 2 - The content of arsenic in the topsoils.

ISOTOPIC STUDIES ON SOILS

To discriminate between anthropogenic and geogenic origin of harmful elements (mostly metals), the ratios of $^{206}Pb/^{207}Pb$ versus $^{208}Pb/^{207}Pb$ isotopes, determined both in local galena and soil samples, have been used. Results show that the leached fraction of soil samples, with more 1600 mg/kg of Pb (Postlioni), has ratios $^{206}Pb/^{207}Pb$ = 1.169539 and $^{208}Pb/^{207}Pb$ = 2.460557, indicating that contamination of soils collected in the area between the Mandanici area and Ali Village are geogenic and mostly related to the presence of sulphide and sulphosalt minerals in the area.

CONCLUSIONS

The presence of anomalous content of heavy metals as lead, arsenic, zinc represents an interesting area for investigation, although some elements exceed the limits imposed by law 152/06, but isotopic studies confirm that all topsoils come from a geogenic source.

Towards understanding the origin and evolution of the parent magmas of the Grey Porri Tuffs, Monte dei Porri, Island of Salina, Aeolian Islands

DOHERTY, A. L. [1], BODNAR, R. J. [2] & DE VIVO, B. [3], MESSINA, A. [1]

Key words: *Salina, Aeolian Islands, magma plumbing system, volatiles, magmatic evolution*

INTRODUCTION

The Aeolian Islands are an arcuate chain of islands and submarine seamounts lying just north of Sicily in the south Tyrrhenian Sea. The second largest of the islands, Salina, exhibits a wide range in the composition of its erupted products ranging from basaltic lava to rhyolitic pumice. While the more active Aeolian Islands have been the subject of much research, work on Salina has focussed mainly on Fossa delle Felci and the rhyolitic explosion crater in the northwest, Pollara. This study examines the origin and evolution of the magma(s) that produced the Grey Porri Tuffs (GPT) and lava units of Monte dei Porri.

GEOLOGICAL SETTING

The Aeolian Arc developed atop a block of continental crust, along the northern and western regions of the Calabro-Peloritani continental margin. This region consists of both Tethyan oceanic and Proterozoic/Paleozoic continental crust covered by Meso-Cenozoic units, recently interpreted as originating from the delamination of the Jurassic-Cretaceous Meso-mediterranean Microplate (CARBONE *et al., 2*004, 2008; PERRONE *et al.*, 2008). Volcanic activity in the region began as early as 1.3 Ma ago at the Sisifo seamount and continues to this day on the island of Stromboli.

Salina grew from at least 5 volcanic edifices in two distinct cycles of activity. The first cycle, which occurred between 420-127 ka, produced the basalt to basaltic-andesite units of Pizzo di Corvo, Serro del Cappo, Monte Rivi, and Fossa delle Felci. After approximately 60 ka of repose, the second cycle of volcanism began on the island with the building of the basaltic-andesite to dacite cone of Monte dei Porri (67-30 ka) and ended with the rhyolitic explosions of Pollara (30-13 ka).

The units of Monte dei Porri consist of basaltic-andesite to dacite lava flows interlayered with weakly consolidated tephras consisting of juvenile scoria fragments, entrained lithics and pumice. The second cycle of volcanism began with the eruption of the GPT units. These eruptions were described by Keller (1980) as perhaps the most violent eruptions in the history of the Aeolian Islands. Outcrops of the GPT are found throughout the Aeolian Islands and as far away as the Milazzo Peninsula on the island of Sicily, approximately 30 km distant.

PETROLOGY AND GEOCHEMISTRY

The GPT are a series of scoria- and pumice-supported beds interlayered and intercalated with indurated ash-lapilli tuffs. Flow units dominate exposures in close proximity to the vent and exposures become increasingly air-fall dominated with distance from the source. All beds contain entrained lithic material of varying sizes and apparent origins.

The typical mineral assemblage for the GPT is calcic plagioclase, clinopyroxene (augite), olivine ($Fo_{72\text{-}84}$) and orthopyroxene (enstatite) ± amphibole and Ti-Fe oxides. The Monte dei Porri lava units have a similar mineral assemblage but the olivines have a lower Fo content ($Fo_{57\text{-}78}$).

Both the GPT and Monte dei Porri lava units contain silicate melt inclusions (MI) that vary in size, shape and degree of crystallisation, depending on the host unit and phase (Fig. 1).

Bulk-rock analyses identify the GPT host units as andesitic pumice (average SiO_2 = 60 wt%) and high-silica basaltic scoria

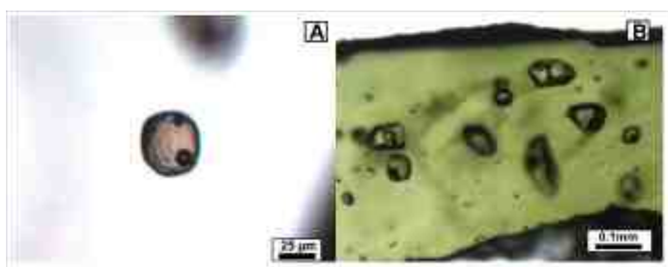

Fig. 1 – Examples of MI in the GPT. A. Glassy MI in olvine host of GPT pumice unit. These and similar inclusions were chosen for study. B. MI in pyroxene host containing crystal inclusions. These types of inclusions were not included in the initial study.

(average SiO_2 = 51.5 wt%). Electron Microprobe Analysis of 38 naturally quenched (glassy) MI in olvine from the GPT pumice unit have basaltic compositions (average SiO_2 = 50 wt%) and MI hosted in the scoria unit show basaltic andesite (average SiO_2 = 56 wt%), after correction for the effects of post-entrapment crystallization (Fig. 2). The Monte dei Porri lava units have bulk rock SiO_2 contents of 53.1-56 wt% and total alkali contents of 4.3-4.9 wt%.

Secondary Ion Mass Spectrometric (SIMS) analysis of 23 olivine-hosted MI reveals a similar bimodal distribution in the

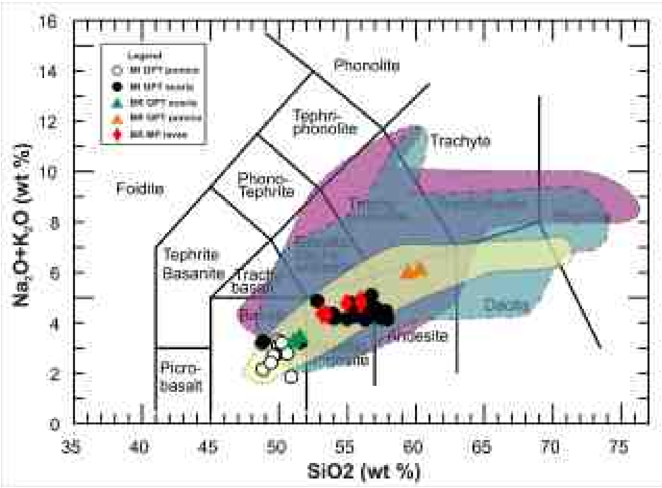

Fig. 2 – TAS diagram showing bulk rock composition of the Grey Porri Tuffs (GPT) and Monte dei Porri lava units and compositions of olivine-hosted MI in the GPT (Doherty et al., 2012).

volatile contents of the GPT pumice- and scoria-hosted MI. MI from the GPT pumice unit have higher average H_2O and S contents (4.5 wt% and 3,790 ppm, respectively) compared to MI from GPT scoria unit (2.7 wt% and 1,772 ppm, respectively) but slightly lower F contents (659 ppm in pumice-hosted MI and 875 ppm in scoria-hosted MI). Cl contents are fairly uniform, averaging 3,339 ppm in scoria-hosted MI and 3,559 ppm in pumice-hosted MI.

Analysis of several spots within the same large olivine-hosted MI shows CO_2 abundances of approximately 187-492 ppm in the GPT pumice unit and 233-576 ppm in the scoria unit. If the melt was saturated in CO_2 at the time of MI entrapment, CO_2/H_2O ratios indicate that the olivine in the pumice units crystallized at approximately 6.5 km, whereas those in the scoria units formed at 4.8-6.2 km, based on the model of Papale et al., (2006).

DISCUSSION

The lava units contain numerous mono- and multi-mineralic glomerocrysts, some of which contain quartz, K-Feldspar and mica, sometimes associated with olivine. These features represent micro-scale xenoliths from the walls of the chamber that were incorporated into the magma during ascent. This is consistent with earlier studies that suggested that crustal assimilation played an important role in the evolution of the Monte dei Porri magma (ZANON AND NIKOGOSIAN, 2004).

EMPA and SIMS analysis of the MI and their hosts reveal a complex evolutionary history. Scoria-hosted MI have more evolved compositions than the bulk rock composition of their host unit, while pumice-hosted MI have more primitive compositions than their bulk rock composition of their host (Fig. 2). This suggests that the more mafic, olivine-hosted MI in the GPT pumice unit more closely represent the parental magma composition of the GPT scoria unit. In addition, most MI trapped in the GPT scoria unit have a composition that is similar to the bulk rock composition of the Monte dei Porri lava units. This may further indicate that the MI in the GPT scoria unit represent the parental magma composition of the Monte dei Porri lava units.

It appears that the parental magma composition of the andesitic GPT pumice unit is not represented by the MI sampled thus far. This may be due to fact that the studied MI are hosted in olivine, and the GPT pumice parental magma may have been trapped in more evolved phases (i.e. pyroxene and feldspar) or because the parental magma of the GPT pumice unit intruded an existing magma body and triggered the eruption of the GPT (analogous to the Pollara eruptions which followed the Monte dei Porri eruption cycle) and therefore, its composition was not preserved in MI.

The higher H_2O content of MI from the pumice-hosted MI compared to scoria-hosted MI is consistent with the more explosive nature of eruptions that produced the pumices, compared to the less-explosive scoria eruptions. The difference in depth of entrapment recorded in the relative H_2O/CO_2 abundances of the scoria- and pumice-hosted MI support other geochemical evidence that indicates that at least the olivine phases of the scoria and pumice units of the GPT crystallised at different locations within the magma plumbing system under Monte dei Porri. Whether this is a result of mixing of a stratified magma chamber that had developed as a result of fractional crystallisation, or represents the introduction and mixing with another magma, is not yet clearly understood.

Future work will focus on MI from the more evolved phases and modelling potential paths of fractional crystallisation and equilibration. These results are expected to provide a more complete understanding of the origin and evolution of the magmas involved in the Monte dei Porri eruptions and the plumbing system that delivered these magmas to the surface.

The CARG-PROJECT in Sicily: a contribution to the knowledge of the Geology of the Southern Calabria-Peloritani Orogen

LENTINI F. (1), CARBONE S. (1), MACAIONE E. (2), MESSINA A. (2)

Key words: *Calabria-Peloritani Chain, CARG-PROJECT, Sicily, Tectono-stratigraphic Units.*

INTRODUCTION

In the orogenic belt running from southern Apennines to Sicily (Italy) some structural domains can be distinguished: the foreland domains are represented by two continental blocks, the Apulian Block to the north and the Pelagian Block to the south, respectively belonging to the Adria and Africa plates. They are separated since Permo-Triassic times by the oceanic crust of the Ionian Sea (LENTINI *et alii*, 2006). The Apenninic-Maghrebian Orogenic Belt is located between two oceanic crusts: the old Ionian crust, at present time subducting beneath the Calabria-Peloritani Arc, and the new crust of the opening Tyrrhenian Sea.

The orogenic belt, represented by a multilayer allochthonous edifice, is composed of the Calabria-Peloritani Chain (CPC) tectonically overlying the Apenninic-Maghrebian Chain (AMC), which in turn overthrust the Upper Miocene and Pliocene top-levels of a deep seated thrust system, originating by the deformation of the innermost carbonates of the Foreland Domains (External Thrust System).

The AMC tectonic units derive from the orogenic transport during Oligo-Miocene times of sedimentary sequences deposited in palaeogeographical domains located between the Europe and the Afro-Adriatic plates. The Meso-Cenozoic basinal units, that compose the AMC, belong to two main groups of sequences, originally located on oceanic crusts separated by the Panormide Block.

The CPC is composed of basement nappes, some of them include remains of the original Meso-Cenozoic cover. It consists of a stack of continental and oceanic crust tectonic units. This chain represents the highest structural edifice and the innermost allochthonous orogenic domain of Sicily.

THE CARG-PROJECT IN NORTH-EASTERN SICILY

Eight 1:50.000 scale geological maps have been realized in Sicily; two of them concern the southern extremity of the CPA in NE Sicily (CARBONE *et alii*, 2008; 2011; APAT, 2008 - F° 601 Messina-Reggio di Calabria; ISPRA, 2011 - F° 587 Milazzo - F° 600 Barcellona Pozzo di Gotto).

They have been obtained thanks to some years of field works, enriched with chronostratigraphical, petrological, sedimentological, structural and geomorphological analyses. The mapping has been integrated with very intensive sampling and this was fundamental to distinguish the several basament nappes and understand the complicate geodynamic evolution of this edifice since the pre-Palaeozoic times.

The geological mapping delineates a Peloritani Chain structural setting made up by nine Africa-verging tectonic units, named from top to bottom: *Aspromonte, Mela, Piraino, Mandanici, Ali, Fondachelli, San Marco d'Alunzio, Longi-Taormina, Capo Sant'Andrea* (Fig. 1). It confirms the presence of the new recognized Mela and Piraino Units (MESSINA *et alii*, 2004 and references therein) and the geometrically lower San Marco d'Alunzio, Longi-Taormina and Capo Sant'Andrea Units (LENTINI, 2000), detailing their geological and petrographic characters and tectono-metamorphic evolution.

The Peloritani Chain Units involve Pan-African and Variscan crystalline basements, as well as remnants of Meso-Cenozoic sedimentary covers.

The Pan-African basement, recognized in the Aspromonte Unit, corresponds to a Proterozoic crystalline lower crust, whereas the Variscan basements, reconstructed in the remained units, derived from Palaeozoic sedimentary-volcanic sequences.

In this tectonic pile the uppermost structural units are those composed of high grade metamorphic rocks; while the lowermost ones consist of low grade metamorphic rocks. The latter are characterized by more or less condensed Meso-Cenozoic sequences.

Since Late Oligocene the Balearic tectonic phase (LENTINI *et alii*, 2006) gave rise to the stacking of the units, implying cataclastic effects to localized, metamorphic re-equilibrations, recorded both in the Aspromonte Unit basement and in the Alì Unit basement and cover. Late Oligocene-Early Miocene siliciclastic turbidites of the Capo d'Orlando flysch unconformably covered and sealed Peloritani crystalline units.

Since Early Miocene tectonic activity affected the Peloritani edifice, during the orogenic transport onto the AMC, and since Middle Miocene, as consequence of the Tyrrhenian back-arc basin development. The whole edifice is a result of a

(1) Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Università di Catania – Catania (Italy);

(2) Dipartimento di Fisica e Scienze della Terra, Università di Messina - Messina (Italy).

polyphasic tectonics, in which the thrust system has been affected by decoupling of the sedimentary cover, and by breaching of the nappes sequence.

Middle Miocene to Recent deposits unconformably cover both crystalline and terrigenous units, further affected by Plio-Pleistocene and Recent fault systems (LENTINI, 2000).

The biostratigraphical, petrological and structural constraints, accurately applied, are sufficient to define the architecture of the orogen.

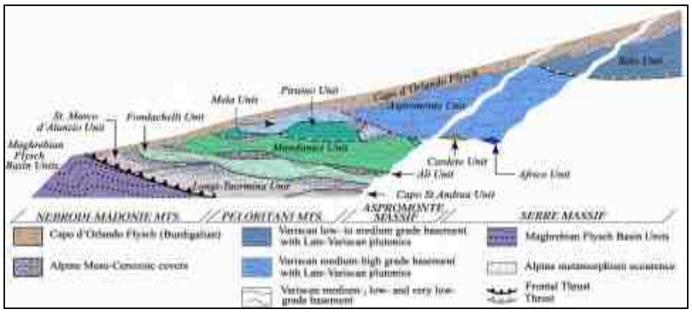

Fig. 1. Tectonic sketch of the Southern Sector of the Calabria-Peloritani Chain (MESSINA *et alii*, 2004, *modified*).

Geological and petrological features of the nine Peloritani Alpine tectonic units are here synthesized.

The ***Aspromonte Unit*** (AsU - BONARDI *et alii*, 1976) represents in Sicily the highest tectonic element with a thickness of about 1200 m and overlies all the other units, except the Longi-Taormina and Capo Sant'Andrea Units.

The AsU consists of a reversed Variscan mid-lower metamorphic and plutonic crustal segment showing records of a Proterozoic to Cambrian evolution and a localized Alpine metamorphic overprint.

The *metamorphic segment* is composed of Pan-African ultramafic (Palaeo-Proterozoic magmatism) and acidic granulites and Late Pan-African intermediate to acidic plutonics, both affected by a Variscan polyphasic (Dv_1-Dv_2) Bosost-type L-T granulite to L-T amphibolite facies metamorphic retrograde zoning, and by a localized Alpine polyphasic (Da_1-Da_4) Barrovian-type greenschist to amphibolite facies overprint (Palaeo-Proterozoic-Cambrian).

Rocks are kilometer in extension gneisses, locally migmatitic, passing to schists, including amphibolite (s.l.) and metaperidotite lenses and meter-thick marble and quartzite levels. The metatonalite to metaleucogranite series, where augengneisses prevailing, in large body and dykes, forms the 40% of the AsU outcrops (Neo-Proterozoic-Cambrian). Rocks show a crenulated Sv_1 main foliation. Along Alpine shear zones, a different intensity of the polyphasic greenschist to amphibolite facies overprint is also present. Rocks exhibit a crenulated Sa_2 main foliation.

The *plutonic segment* consists of Late Variscan intermediate to acidic peraluminous intrusives, in small stocks and dykes, interested by a localized Alpine polyphasic greenschist to amphibolite facies metamorphism (Upper Carboniferous-Permian).

The ***Mela Unit*** (MeU - MESSINA *et alii*, 1997) crops out from Giampilieri Marina to Capo d'Orlando in an area previously ascribed to the AsU. It is interposed between the AsU and the Piraino Unit or, rarely, Mandanici Unit. Its thickness is of about 700 m.

The MeU consists of a Variscan mid-crustal segment originated from a Palaeozoic pelitic-arenaceous-carbonatic and volcanic (mafic series and acidic-intermediate series) sequence affected by an Eo-Variscan eclogite facies metamorphism and a polyphasic (Dv_1-Dv_4) Variscan Barrovian-type retrograde L-T amphibolite- to H-T greenschist facies re-equilibration.

The MeU basement is made up of a monotone alternation of kilometer in extension *grey-silver medium-fine grained garnet-relict paragneisses and micaschists*, marked by a large static blastesis of *kyanite, staurolite (sillimanite), garnet, cordierite and andalusite*, with hectometer to meter intercalation of *andesine- or orthoclase-relict orthogneisses*. At the top of the unit thick layers of *whitish medium-fine grained muscovite±biotite±garnet marbles* including meter-thick lenses of *green amphibolites* and *garnet-relict amphibolitized eclogites* and metric bodies of *quartzites* also crop out. Rocks show a crenulate Sv_3 main foliation.

The ***Piraino Unit*** (PU - MESSINA *et alii*, 1998) extends from F.ra d'Agrò to F.ra Sant'Angelo with a thickness of about 400 m. It is interposed between the MeU or, rarely, the AsU and the Mandanici or Fondachelli Units, in an area previously ascribed to the Mandanici Unit.

The PU consists of a Variscan mid-upper crustal segment originated from a Palaeozoic sequence interested by a Variscan polyphasic (Dv_1-Dv_4) greenschist to amphibolite facies metamorphic prograde zoning. The unit preserves slices of an Upper Triassic?-Aelenian sedimentary cover.

The PU basement consists of hectometer in extension layers of *dark graphite+garnet+chloritoid+staurolite phyllites* passing to *metarenites* with intercalation of meter-thick lenses of rare *amphibolite schists* and metric bodies of *quartzites*. Rocks exhibit a Sv_2 main foliation cut by a thin and spaced Sv_3 foliation.

The ***Mandanici Unit*** (MaU - OGNIBEN 1960) extends from F.ra d'Agrò to F.ra Naso, reaching a thickness of about 600 m. It is tectonically interposed between the PU and, locally, MeU or AsU and the Fondachelli or San Marco d'Alunzio Units.

The MaU consists of a Variscan upper crustal segment, originated from a Palaeozoic sequence affected by a Variscan polyphasic (Dv_1-Dv_3) L-T to H-T greenschist facies metamorphic prograde zoning, preserving slices of an Upper Triassic - Lower Liassic sedimentary cover.

The MaU basement is made up of kilometer in extension layers of *green, silver* and *leaden ±chlorite+biotite+garnet+ chloritoid phyllites* passing to *metarenites*, with hectometer intercalation of fine-grained and banded *marbles*, meter-thick lenses of *amphibolite schists*, plurimetric bodies of *porphyroids* and *quartzites*. Rocks show a crenulate Sv_2 main foliation.

The ***Alì Unit*** (AU - BONARDI *et alii*, 1976) crops out in the areas of Alì village and of Montagnareale. In the former area, the AsU and the MeU tectonically rest upon the AU (Modderino *klippe*) and the substratum is not exposed. Here the unit reaches the thickness of about 500 m.

The AU is a thin upper crustal segment originated from a Devonian-Early Carboniferous pelitic-arenaceous sequence affected by a Variscan subgreenschist facies metamorphism, preserving a Middle Uppe Triassic?–Cretaceous cover and showing an Alpine polyphasic (Da_1-Da_4) ML-P subgreenschist facies metamorphism.

The basement is composed of metric layers of Alpine *dark grey graphite metasiltites* and *metarenites*, intercalated by *metalutites*, with *Lepidodendron*, *Sigillaria* and *Bothrodendron* frustules and imprints. Rocks exhibit a Sa_2 main foliation.

The ***Fondachelli Unit*** (FU - BONARDI *et alii* 1976) extends from Mt. Galfa to Rocca di Caprileone, with a thickness of about 600 m. The unit is geometrically interposed between the MaU and the San Marco d'Alunzio or Longi-Taormina Units.

The FU represents an upper Variscan crustal segment, originated from a Palaeozoic (Early Carboniferous?) pelitic-arenaceous and volcanic sequence affected by a Variscan polyphasic (Dv_1-Dv_4) chlorite-zone of greenschist facies metamorphism, also characterized by an Upper Jurassic (Tithonian)-Oligocene? sedimentary cover.

The FU basement is composed of *dark graphite phyllites* passing to *metarenites*, *quartzites*, with intercalation of *metadiabases* and very rare *metalimestones*. Rocks show a crenulated Sv_2 main foliation.

The cover consists of the Rocca di Novara succession cropping out along the Forza d'Agrò to Raccuia alignment with a thickness of 170 m, often overturned.

The ***San Marco d'Alunzio, Longi-Taormina*** and ***Capo Sant'Andrea Units*** (LENTINI, 2000) represent parts of a single upper Variscan crustal segment. It was originated from a Cambrian to Early Carboniferous pelitic-arenaceous-carbonatic and volcanic (two basic series and one intermediate to acidic Ordovician series) sequence, affected by a Variscan polyphasic subgreenschist to chlorite-zone of greenschist facies metamorphism, and preserves a Meso-Cenozoic cover.

The ***San Marco d'Alunzio Unit*** (SMU - LENTINI, 2000) crops out north of Savoca, to San Fratello Mt., interposed between the overlying FU, locally MaU or PU or AsU and the underlying Longi-Taormina Unit. It reaches a thickness of about 500 m.

The SMU Palaeozoic sequence was affected by a Variscan polyphasic (Dv_1-Dv_4) chlorite zone of greenschist facies metamorphism. The Meso-Cenozoic cover consists of an Upper Triassic–Eocene condensed carbonate pelagic platform succession.

The SMU basement is composed of layers of *pinkish porphyroids, grey-violet slates* alternated to *metarenites*, *grey-pinkish quartzites*, *metalimestones* and *grey-bluish metabasites*. Rocks show a crenulated Sv_2 main foliation cut by a thin and spaced Sv_3 foliation.

The ***Longi Taormina Unit*** (LTU) extends from Taormina to Sant'Agata di Militello, interposed between the overlying SMU, or FU and the underlying Capo Sant'Andrea Unit. In the western Peloritani Mts., it constitutes the innermost structural element of the CPC Southern Sector, directly resting onto the Sicilide Units.

The LTU Palaeozoic sequence was affected by a Variscan polyphasic (Dv_1-Dv_4) subgreenschist to chlorite-zone of greenschist facies metamorphism. The Meso-Cenozoic cover consists of a thick Hettangian up to Lower Oligocene succession.

The basement, going to the top, consists of layers of *metapelites* and *metasiltites* with alternation of *metarenites*, *metabreccias*, *quartzites*, *porphyroids*, *metalimestones* and *metamarls*, *violet metabasalts*, *metadiabases*, *metaconglomerates* and *dark metabasalts.* Rocks show a crenulated Sv_2 main foliation.

The ***Capo Sant'Andrea Unit*** (CSU) exclusively crops out in the Ionian side, between Capo Sant'Andrea and Gallodoro village and represents the lowermost tectonic unit of the CPC.

The CSU Palaeozoic sequence was interested by a Variscan polyphasic (Dv_1-Dv_4) subgreenschist facies metamorphism. The Meso-Cenozoic cover consists of an Upper Triassic–Lower Eocene very condensed succession.

The thin basement shows similar feeatures of that characterizing the LTU very-low-grade rocks.

Aspromonte Unit Variscan Migmatites (Southern Calabria-Peloritani Arc): Petrology and U-Th-Pb Zircon and Monazite

MACAIONE E. (1), MESSINA A. (1), RENNA M.R. (1), BELKIN H.E. (2), DOHERTY A. L. (1), LANGONE A. (3)

Key words: *Aspromonte Unit Variscan mid-lower continental crustal segment (Southern Calabria-Peloritani Arc), Migmatitic Process, Petrological study, Proterozoic basement, U-Th-Pb Zircon and Monazite Geochronology.*

INTRODUCTION

Migmatitic rocks typify the Scilla (SW Calabria) - Capo d'Orlando (NW Peloritani Mts.) belt in the Aspromonte Unit basement (AUb) of the Southern Calabria-Peloritani Arc.

Works have already been undertaken in the most important remobilized sites (FERLA & NEGRETTI, 1969; D'AMICO *et alii*, 1972; ATZORI et *alii*, 1975; MESSINA & IOPPOLO, 1982).

The current research focuses on Punta del Tono-Punta Riali migmatites of the Milazzo Peninsula (Central-Northern Peloritani Mts.) and provides the initial petrological and geochronological results of what will become a larger integrated study.

GEOLOGICAL SETTING

The AUb, which extends from the homonymous massif in Calabria to the Peloritani Mts. in Sicily, is interpreted as a reversed Variscan mid-lower continental crustal segment, made up of metamorphic and intrusive rocks, preserving evidence of a Proterozoic evolution (including granulite metaultramafics) and the effects of a localized Alpine low to medium-grade metamorphic overprint.

The Variscan evolution of the basement was responsible for a retrograde Bosost-type L-T granulite to L-T amphibolite facies metamorphic zoning (MESSINA *et alii*, 1996, 2004; BONARDI *et alii*, 2008; CARBONE *et alii*, 2008, 2011).

There is evidence of partial melting in rocks of the second retrograde zone, defining, with localized L-T granulite outcrops (first zone), the upper regions of the thick (2.000 m of apparent thickness) AUb.

Kilometers of mobilized gneissic bodies outcrop in the studied area, including amphibolite (s.l.) lenses which can be up to several meters thick. These bodies show *phlebitic to phlebitic-stromatitic* structures (Fig. 1), which are typical of metatectic processes, developing along the Sv_{1m} main foliation (or Sv_n=last pervasive foliation) and are locally crenulated.

Migmatites are cut by centimeter- to meter-thick Alpine shear planes and by Plio-Pleistocene fault systems (typically NNE-SSW in orientation), which are both responsible for cataclastic effects (the former also for retrogressive processes). Micrite and sparite calcite systems, some of them also including Pliocene fossils, fill the multiple fractures.

PETROGRAPHY

Meso- and microstructures indicate that preserved massive metahornblendites, and less oriented equigranular medium-fine grained biotite gneisses, are ***mesosomes*** of all mobilized lithotypes described below.

In the gneissic rocks, the difference in intensity of the mobilization is indicated by layers of quartz+plagioclase±K-feldspar leucosomes, sub-millimeter to many tens of centimeters in thickness, extending parallel to foliation, rimmed by biotite melanosomes.

The varyingly and irregularly mobilized rocks vary in grain-size, structure and composition and range from ***less-oriented*** *grano-xenoblastic biotite* ***gneisses***, ***less-banded*** *granoblastic/lepidoblastic biotite±garnet* ***gneisses*** and ***banded*** *granoblastic/lepido-diablastic biotite±garnet±muscovite* ***gneisses***, up to *trondhjemitic and leucogranodioritic granoblastic*/*polygonal* plagioclase±Kfeldspar±muscovite ***leucosomes*** and *diablastic biotite* ***melanosomes*** (Fig. 2).

The same evolution is shown by the metamafics (s.l.), from ***massive metahornblendites,*** to ***less-banded*** *biotite±garnet* ***amphibolites***, to ***banded*** *biotite±garnet* ***gneissic amphibolites***.

Rare centimeter-thick garnet-biotite-sillimanite-plagioclase glomerocrysts are considered ***restites***.

MINERAL CHEMISTRY

Mineral chemistry data (Geological Survey of Reston VA Laboratory - USA) indicates that:

- in the *massive metahornblendites, less-banded biotite±garnet amphibolites* and *banded biotite±garnet gneissic amphibolites*, *amphibole* changes from tschermakitic-(X_{Mg}=0.51) and Mg-hornblende (X_{Mg}=0.50-0.58), to Fe-

(1) Dipartimento di Fisica e Scienze della Terra, Università di Messina - Messina (Italy);

(2) U.S. Geological Survey, 956 National Center, Reston, VA (USA);

(3) CNR - Istituto di Geoscienze e Georisorse U.O.S., Pavia (Italy).

tschermakitic- (X_{Mg}=0.41-0.42) and Fe-hornblende (X_{Mg}=0.43-0.45), to Fe-pargasitic hornblende (X_{Mg}=0.41), respectively. *Plagioclase* exhibits An values from 81-54 mol%, 91-25 mol% and 62-37 mol%, respectively. *Garnet* in the less banded and banded gneisses, is Ca-rich almandine (XAlm=66-59, XGrs=27-18) and *biotite* in the same rocks has annitic (Fe/Fe+Mg ratio=0.46-0.49 and 0.49-0.52, respectively) compositions;

- in the three gneissic rock types (the *less oriented*, *less banded* and *banded gneisses*), *plagioclase* varies from An=33-29 mol%, to An=31-27 mol%, to An=28-26 mol%, respectively; *biotite* shows annitic compositions (Fe/Fe+Mg ratio=0.53-0.50, 0.49-0.48 and 0.49-0.43, respectively); *garnet* is Mn-rich almandine (XAlm=64-57, XSps=31-22) in the less banded and banded gneisses and *muscovite*, where is present, has contents of Si=3.00-3.09 (a.p.f.u.);

- in the leucosomes, *plagioclase* has values of An=32-6 mol%, *K-feldspar* is orthoclase (Ab=5-7 mol%, Or=93-95 mol%) and *muscovite* has contents of Si=2.98-3.08 (a.p.f.u.);

- in the melanosomes, *biotite* also shows annitic (Fe/Fe+Mg ratio=0.53-0.46) compositions.

GEOCHEMISTRY

Analyses of major, trace and rare earth elements from representative *gneissic and anphibolitic mesosomes*, *mobilized rocks*, *leucosomes* and *melanosomes*, are in progress (Geological Survey of Reston VA Laboratory - USA).

This work is intended to define both the relationships between the geochemical modification and the increase of mobilization, and the magmatic affinity of the metahornblendites.

In the Calabrian AUb migmatites the hornblende-rich amphibolites show MORB character (MESSINA & IOPPOLO, 1982).

GEOCHRONOLOGY

The following recent reconstructed composite AUb evolution, was developed on the basis of geological and petrological studies (MESSINA *et alii.*, 2004, 2010; MACAIONE *et alii*, 2010; CARBONE *et alii*, 2008, 2011) and is also supported by geochronological data:

- a *Paleo-Meso-Proterozoic plutonic process*, documented by pre-Variscan relics of metaperidotites, metapyroxenites and metahornblendites, is dated at 1771-1562 Ma in metahornblendites (U/Pb titanite age, DE GREGORIO *et alii*, 2003);

- *a Neo-Proterozoic granulite metamorphic process*, attributed to the Pan-African event, is supported by the same rocks, and dated at 860-653 Ma in the same metahornblendites ($^{39}Ar/^{40}Ar$ amphibole age, DE GREGORIO *et alii*, 2003);

- *a Neo-Proterozoic-Cambrian orogenic peraluminous intermediate to acidic plutonic process*, attributed at a Late Pan-African event, is dated at 572-537 Ma in the Variscan augengneisses (U/Pb zircon age, MICHELETTI *et alii*, 2007);

- *an Upper Carboniferous metamorphic process, ascribed to the Variscan event*, is dated at 314-308 Ma in schists (Rb/Sr mica age, BONARDI *et alii*, 2008);

- *an Upper Carboniferous–Permian plutonic process*, correlated to the Late-Variscan event, is dated at 290 Ma (Rb/Sr mica age, ROTTURA *et alii*, 1990);

- *a Late Oligocene*, ascribed to the Alpine event, was responsible for cataclastic to mylonitic shear zones accompanied by retrogressive processes to a polystage metamorphic re-equilibration (MESSINA *et alii*, 1990, 1992, 1996), from the Barrovian-type MH-P and H-T greenschist facies in the first stage, to the ML-P amphibolite facies in the second stage, that is dated at 28.9-25.1 Ma (Rb/Sr mica age, BONARDI *et alii*, 2008).

The AUb migmatite phenomena are not dated.

U/Pb monazite and zircon dating of the migmatites are in progress to define the age of this peculiar zone of the Aspromonte Unit Variscan mid-lower crustal segment, marked by mesosome and nesosome features, and also to confirm or modify the complex evolution reconstructed by the same authors.

PRELIMINARY CONSIDERATIONS

The defined geological, structural and compositional data, included in the context of the AUb metamorphic history, indicate that the studied rocks were affected by up to four Variscan progressive and continuous stages:

- the first, which occurred during the start of the Variscan Dv_1 (or Dv_n) deformation, was responsible for a retrograde re-equilibration of ***Neo-Proterozoic ultramafic and acidic granulite palaeosome*** into ***Variscan metahornblenditic*** (probably partly re-equilibrated) and ***gneissic amphibolite facies mesosome***;

- the second stage developed contemporaneously with Dv_1 (or Dv_n), creating the leucosomatic and melanosomatic veins, parallel to the main foliation (Sv_1). The time-span of anatexis corresponds to the thermal peak of metamorphism identified in this layer of the Variscan AUb;

- the third stage, correlated to the post-Dv_1 deformation phase, was responsible for the start of cooling and exhumation of the AUb, recorded in the rocks by the crystallization of a late muscovite and low An content plagioclase, reaching albitic compositions in the leucosomes;

- the fourth stage, resulting from the Dv_2 (or Dv_{n+1}) compression, was the origin of the crenulation and boudinage of veins.

Cooling and exhumation of the Aspromonte Unit migmatites (post Dv_1 to Dv_2) can be obtained by the cooling age of monazite, whereas the zircon, recording multiple events, can be used to characterize the crystallization age of the gneissic and metaultramafic protoliths, and a previous, pre-Variscan (Pan-African) metamorphism. An attempt to resolve the P-T-(path) of this process will be also undertaken as part of this study.

The peculiar metamorphic history of the Mela Unit within the frame of the Variscan basement of the Calabria-Peloritani Arc, Southern Italy

MACAIONE E. (1), RENNA M.R (1), MESSINA A. (1), COMPAGNONI R. (2), BORGHI A. (2), LANGONE A. (3)

Key words: *Eclogite relics, Mela Unit, Metamorphic history, Peloritani Mts., Southern Calabria-Peloritani Arc.*

INTRODUCTION

An early eclogite event has been recognized in the polyphase metamorphic evolution of the Mela Unit in the Variscan basement of the Peloritani Mts. (Southern Sector of the Calabria-Peloritani Arc).

In late 1990's, the rocks of Mela Unit, previously ascribed to the medium-high grade Aspromonte Unit, have been recognized in a large area of the Peloritani Mts. (MESSINA *et alii*, 1997; MESSINA, 1998; COMPAGNONI *et alii*, 1998). The areal extension, thickness, lithology and mineralogy of the Mela Unit have been only recently detailed within the frame of a regional mapping project (CARBONE *et alii*, 2008, 2011; SERVIZIO GEOLOGICO D'ITALIA - F° 601 Messina-Reggio di Calabria, 2008; F° 587 Milazzo- 600 Barcellona Pozzo di Gotto, 2011).

The current research, which is focused on the relict amphibolitized eclogites and hosting paraschists of the Mela Unit, provides new petrological data useful for a better understanding of the tectonometamorphic evolution of this portion of the Peloritani Mts.

GEOLOGICAL SETTING

The Mela Unit extensively crops out in the Peloritani Chain, from Giampilieri Marina on the Ionian coast to Capo d'Orlando on the Tyrrhenian side. It is sandwiched between the overlying medium-high grade Aspromonte Unit and the underlying low-medium grade either Piraino Unit or, rarely, Mandanici Unit. The maximum apparent thickness of the Mela Unit has been estimated to be about 700 m (CARBONE *et alii*, 2008, 2011).

Unlike other tectonic units of the Peloritani Mts., the Mela Unit lacks a Meso-Cenozoic cover. It is only made of a Paleozoic basement, that mainly consists of alternating *paragneisses* grading to *micaschists*, both characterized by the occurrence of *relict garnet porphyroclasts.*

Paragneisses and micaschists include:

- foliated *andesine amphibolites*, occurring as lenses up to one hundred m long, with relics of garnet in the innermost most massive portions;

- *orthogneisses* with relict *K-feldspar;*

The unit is capped by *impure marbles*, several tens of m thick, which also include bodies of amphibolites, similar to those present in the paragneisses, m-thick layers of *quartzite* and *polymetallic mineralizations*.

The Mela Unit is cut by localized zones of cataclastic to mylonitic deformation, accompanied by low-*T* recrystallizations, which are referred to the Late Oligocene "Balearic" tectonic phase responsible for the nappe stacking of the Peloritani Mts..

It is locally unconformably covered by the Late Oligocene - Early Miocene Capo d'Orlando Flysch formation and by Middle Miocene to Recent deposits and affected by Plio-Pleistocene to Recent fault systems (CARBONE *et alii*, 2008, 2011 and references therein).

PETROGRAPHY

The *graphitic two-micas paragneisses and micaschists* are muscovite-rich and contain relict garnet porphyroclasts (Grt_r), wrapped around by the crenulated main foliation (Sv_{3m}). Garnets consist of a core crowded with opaques and a rim mostly retrogressed to a plagioclase±quartz±biotite symplectite (Fig. 1). Four main deformation phases have been recognized, the most important being D_{V3} responsible for the regional transposition foliation Sv_{3m}, mainly defined by preferred orientation of white mica flakes.

An important post-Sv_3 static event is marked initially by porphyroblastic staurolite (Fig. 1), rare kyanite (Fig. 2) and local fibrolitic sillimanite (Fig. 3), and later by plagioclase, cordierite (Fig. 3) and large poikiloblastic andalusite.

The *amphibolite* consists of an andesine-hornblende association that includes relics of garnet and diopside-plagioclase symplectite after former omphacite (Fig. 4). The omphacite-garnet mineral assemblage, indicating eclogite-facies conditions, has developed after a previous amphibolite-facies metamorphism. The presence of titanite instead of rutile and the apparent stable occurrence of hornblende suggest that the lower limit of the eclogite facies has been hardly overstepped.

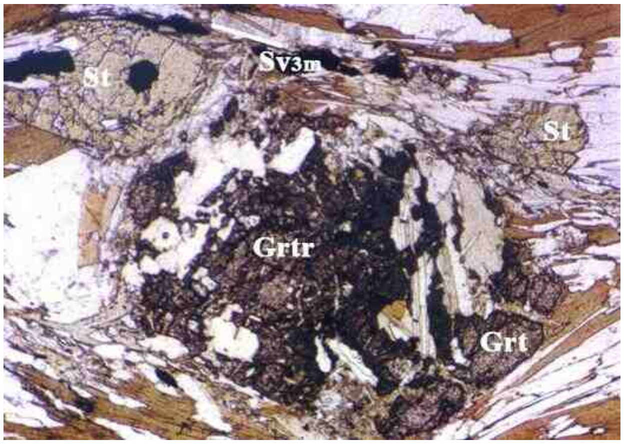

Fig. 1 – Micaschist of the Mela Unit.
Relict garnet (Grtr), rimmed by a re-equilibration quartz+biotite+oligoclase rim, is wrapped by the main foliation Sv_{3m} defined by micas. Post-kinematic Variscan staurolite (St) and second garnet generation (Grt) are evident.
Loc.: Pizzo Croce, Central-Northern Peloritani Mts.. Sample B2218bis, PPL, 60x.

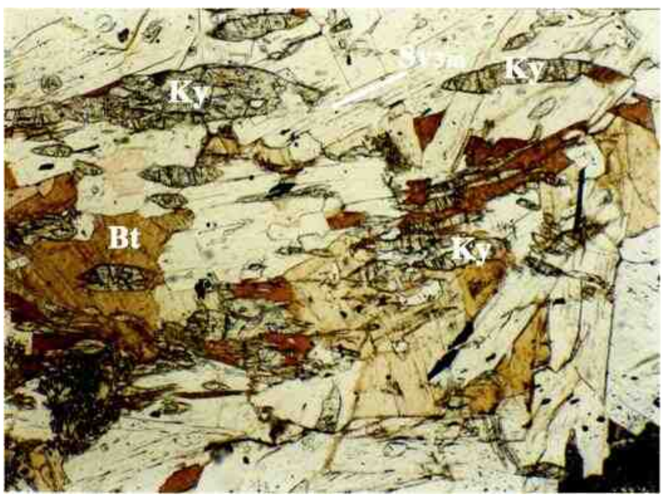

Fig. 2 – Photomicrograph of a micaschist of the Mela Unit.
Kyanite (Ky) and biotite (Bt) are overgrowing the main Variscan foliation Sv_{3m}, defined by micas.
Loc.: Pizzo Croce, Central-Northern Peloritani Mts.. Sample B2219bis, PPL, 60x.

CHEMISTRY

In the **micaschists**, *plagioclase* is *oligoclase* (An_{19-28}) with local *albite* rim (An_{3-9}).

Biotite has annitic compositions (Fe/(Fe+Mg) = 0.54-0.64) with a decrease of Al^{IV} and increase of Mg from core of syn-Sv_3 to post-Sv_3 flakes.

Garnet is almandine with composition slightly changing from core [X_{Alm}=60-79, X_{Grs}=4-30, X_{Sps}=0-14] to rim [X_{Alm}=80-87,

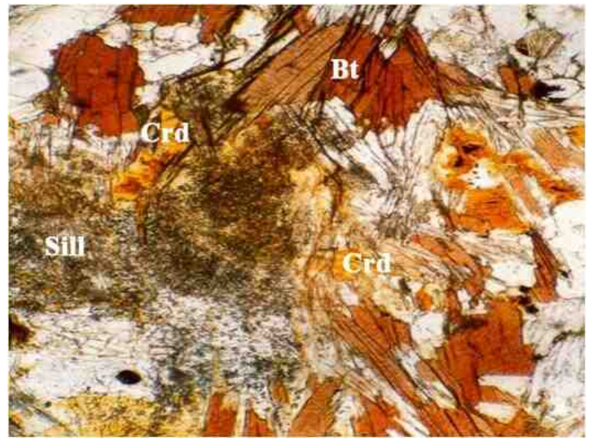

Fig. 3 - Micaschist of the Mela Unit.
Late cordierite (Crd) growing after fibrolite (Sill) and biotite (Bt) are evident.
Loc.: Piraino, North-Western Peloritani Mts.. Sample MG36, PPL, 45x.

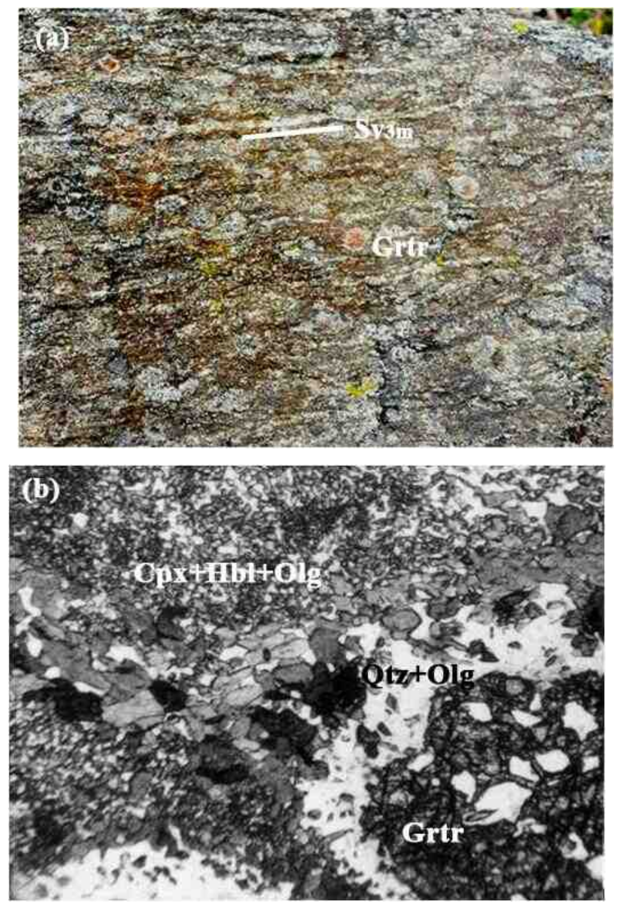

Fig. 4 – a) Close up of a Mela Unit amphibolite preserving relict garnet (Grtr) replaced at the rim by a plagioclase corona and amphibole+clinopyroxene pseudomorphs after former omphacite.
b) Photomicrograph of the above amphibolite, in which relict garnet (Grtr) surrounded by a plagioclase corona and plagioclase + diopside ± hornblende symplectite after former omphacite are evident.
Loc.: NW Pizzo Croce, Central-Northern Peloritani Mts. Sample Mm8, PPL, 60x.

X_{Grs}=0-9, X_{Sps}=3.0-6.0].

Muscovite is very close to the pure end member with Si=3.05-3.12 (a.p.f.u.) in the core and Si = 3.00 in the rim.

In the **relict garnet-amphibolites,** *amphibole* shows a Mg-hastingsite composition with Mg#=0.69-0.70, Ti=0.03-0.06, Al=2.14-2.24, Ca=1.88-1.92 and Na=0.39-0.53 (a.p.f.u.).

Relict garnet is slightly zoned with X_{Alm}= 51, X_{Grs}=30, X_{Sps}=11 in the core and X_{Alm}=42; X_{Grs} = 51, X_{Sps} = 4 in the intermediate zone.

Plagioclase shows a large compositional range from An_{78} of the relict *bytownite* to An_{39} for the newly formed *andesine*.

Preliminary Major, Trace, and Rare Earth Element whole-rock geochemistry of *relict garnet-amphibolites* show within-plate alkali basalt affinity.

GEOCHRONOLOGY

Previous geochronological data support the complex polyphase tectono-metamorphic evolution of the Mela Unit:

- an early stage, dated at 349 Ma ($^{40}Ar/^{39}Ar$ amphibole, DE GREGORIO *et alii*, 2003) has been ascribed to an Eo-Variscan, most likely eclogite facies event;

- a later stage, dated at 315 Ma ($^{40}Ar/^{39}Ar$ amphibole, DE GREGORIO *et alii*, 2003) has been referred to the amphibolite facies Variscan Event.

In order to better understand the tectono-metamorphic evolution of the Mela Unit, and especially to unravel if the eclogite facies metamorphism is pre-Variscan or Eo-Variscan in age, an *in situ* U-Th-Pb dating of zircon and/or monazite by LA-ICP-MS is in progress on selected samples.

CONCLUSIONS

The new detailed field and laboratory data obtained from the CARG Project (CARBONE et alii, 2008, 2011) together with the previous (DE GREGORIO *et alii*, 2003) and in progress geochronological data will give important constraints to the complex tectono-metamorphic history of the Mela Unit and consequently to the whole Calabria-Peloritani Arc.

It is expected that these new data will be useful to a better insertion of the Calabria-Peloritani Arc within the frame of the southern European Variscan basement.

Archaeological and Archaeometric Study of Musive and Tecnological Materials of the Patti Marina Roman Villa (Southern Sicily, Italy)

MASSACCI G.A.M. (*), MESSINA A. (*), MOTTANA A. (**), PERRONE V. (***), MATTIAS PP. (°), SPIGO U. (°°) & COPPOLINO P. (°°)

Key words: *Archaeological and Archaeometric study*, *Opus Tessellatum*, *Opus Spicatum*, *Opus Tectorium*, *Patti Roman Villa of Imperial Age (Northern Sicily, Italy).*

INTRODUCTION

This investigation focuses on the mortar and mosaic tesserae (*opus tessellatum*, *opus spicatum*, *opus tectorium*) of the Patti Roman Suburban or Maritime Villa, with the aim of realizing an archaeological and archaeometric study.

The monumental complex extends over 20,000 m^2 and consists of a central rectangular peristyle (33.5 m x 25.0 m wide), surrounded by a portico supported by pillars with a height of 3.40 m. The most important room, which opens to the portico, is large, and is characterized by three apses; it is located in the southern side of the portico and linked to the apses by a wide arc.

Fig. 1- The three apses room with its mosaics

(°) Dipartimento di Scienze della Terra dell'Università di Camerino

(°°) Parco Archeologico delle Isole Eolie e delle Aree Archeologiche di Milazzo, Patti e dei Comuni limitrofi.

To NE of the peristyle, a thermal complex is located, with basins, floors with *suspensurae* (floor on vault) and *praefurnium.* (*Tepidarim*).

Fig. 2- The peristyle thermal complex

All rooms show dichromatic and/or polychromatic floor mosaics, the most interesting of which is located in a large, apsed room. The central part of this mosaic is characterized by the "*cerchi e mandorle*" ("circles and almonds") inlay scheme, which is intersected and rimmed by geometrical elements defining octagons, with domestic and wild animals figured inside.

The historical value of the Patti Marina Villa and its floor mosaics is of primary importance to understand the late Roman society in Sicily and in the Roman Empire.

This floor mosaic series is one of the largest and most complete preserved in late Roman Villas. The depicted subjects provide added information about contemporary human activities, such as capture and transport of large animals; in their depicted themes and conventions these mosaics offer important analogies with mosaics found in Northern Africa.

The Sicilian Roman Villas of Patti, in the central-northern part of Sicily, of Tellaro, south of Syracuse, and of Piazza Armerina, in central Sicily, have all similar dimensions and equally fine floor mosaic (VOZA 1976-77, 1980-8 1).

The Tellaro Villa was probably built in the second half of the 4th century, while the Patti Marina Villa is dated to the first half of the 4th century. It was built over a site dating to the 2nd- 3rd century. There is some evidence of a pre-existing structure also for the Tellaro Villa (WILSON 1990).

SAMPLING AND METODOLOGIES

The sampling of mosaic tesserae and technologic materials is a very important element conditioning both typologies and results of archaeometric analyses.

Following "Normativa UNI 11176/2006", this study was also finalized to identify weathered areas affected by delamination and swelling of the cards and the bedding mortar by cracks, structural failures and detachments of mosaic surfaces.

The colors of tesserae are: whitish, white-pink, reddish, pink-grey, grey-black, yellow-ochre, green and dark green.

Some red tesserae are made up of clay materials.

Among all types of tesserae, the most altered ones are the white, white-pink, yellow and red tesserae.

The grey-black-colored tesserae appear to be plastic and very friable. They show cracks and rounded margins; consequently, their original morphology is modified and altered.

The detachment of the tesserae was accelerated by the disruptive action originated by shallow roots sited between the tesserae and the bedding layer.

For the petro-archaeometric study 41 samples from mosaics of seven rooms have been collected: 4 samples of bedding mortar and background of the laying mortar; 2 of plaster; 1 of brick from the *opus spicatum* floor; 36 of mosaic tesserae.

In the 7 sampled rooms, the bending tessellated mortar consists of three strata which are, from bottom to top : I) calcarenite clasts on lime (10-15 cm in thickness); II) lime, sand, gravel, calcarenite and fictile materials shards (8-10 cm in thickness); III) mortar: the base for posing tesserae, consisting of lime and marble powder (1.5-2 cm thickness).

Micro- and mesostructural studies, and chemical analyses of mosaic tesserae and technological materials allowed to recognize the used rocks, which all result of local provenance.

Lithotypes come from the Peloritani Chain (CARBONE *et alii*, 2008; 2011 and references therein; Servizio Geologico d'Italia - F° 601 Messina-Reggio di Calabria, 2008; F° 587 Milazzo - F° 600 Barcellona Pozzo di Gotto, 2011). The most commonly used rocks are yellow-reddish arkosic sandstones, characteristic of the Capo d'Orlando Flysch (Burdigalian Stilo-Capo d'Orlando Flysch Fm of Bonardi et al., 2002), followed by Pliensbachian pink-greyish and reddish micritic limestones (wackestone, *sensu* Dunham) of the Meso-Cenozoic sedimentary cover of the San Marco d'Alunzio Unit; white fossil-rich (not datable) limestones of the same unit; whitish fine-grained and foliated marbles and green garnet-amphibolites, both coming from the Paleozoic basement of the Mela Unit; dark-grey graphite phyllites of the Paleozoic basement of the Fondachelli Unit; dark-green less oriented horneblende metaultramafics. According to the magmatic affinity, this last type (geochemical analysis is *in itinere*) is to be ascribed to the Paleozoic basement of the Mela Unit or to the Proterozoic basement of the Aspromonte Unit.

The red fictile tesserae are made up of brick.

STATE OF THE ART AND RESTORATION PROGECT

Mosaics of the Patti Marina Roman Villa have been subjected to atmospheric and biological weathering, being these the consequences of daily and seasonal climatic changes; to mechanisms triggered by anthropogenic degradation; to the utilization of inappropriate materials for restoration together with a generalized lack of protection.

The interventions include tile detachment, which can be solved with acrylic resin injections within the interstices. When tile detachment is present, direct intervention on the mortar is needed. Cement puffs over interstices and stains on the tiles caused by previous maintenance can be removed by vibro-engravers, while gentle cleaning of the entire mosaic surface will proceed in two steps: 1) dry soft brush removal and dust extraction, and 2) cleaning with a modified AB 57 solution using nylon brushes.

Small gaps in the original portions of the mosaic will be filled with the technique of carved mortar infilling and watercolor painted. This operation will be fully recognizable and reversible.

A microcrystalline wax coating will be spread over the mosaic surface for its protection and to obtain a color-balance of blurry portions.

To improve the status of the pavement, the hue of the mortar within large gaps will be changed with the exclusive aid of colors.

CONCLUSIONS

Mosaics of the Patti Marina Roman Villa found August 1973 are stylistically related to North-African traditions, which diffused into Proconsular Sicily in times between the III and IV century AD.

Consequently, during the IV century AD, the Sicily was not only the granary of Rome, but it represented a Roman aristocratic Province with luxurious suburban villas.

From the historical and architectonic point of view, the Patti Roman Ville can be consider a prototype for the late-Roman empire society.

Archaeology vs Geology: the Native-Greek Apollonia Acropolis on San Fratello Mt., in the Nebrodi Natural Park (Central-Northern Sicily, Italy)

MAZZITELLI M. ([1]), MACAIONE E. ([1]), NATOLI R. ([2])

Key words: *Calabria-Peloritani Chain, Native-Greek Archaeological Site, Nebrodi Natural Park, Petro-architectonical Heritage, San Fratello Mt., San Marco d'Alunzio Unit Meso-Cenozoic cover*.

INTRODUCTION

The richness and heterogeneity of the Geocultural Heritage of the Territory laying in the Nebrodi Natural Park (Central-Northern Sicily – Italy) do not let that its related scientific and historical themes can be exhaustively discussed and illustrated.

The current research focuses on the geo-cultural uniqueness of the San Fratello–Acquedolci area, representative of the high value of this Sicilian Reserve. It provides the reconstruction of the geological and archaeological relationships characterizing the Native-Greek Apollonia Acropolis, sited on the famous and scenic San Fratello Mt., contributing to the knowledge, valorization, preservation and fruition of this petro-architectonical Heritage.

This study is a part of a project promoted by Ente Regionale Parco dei Nebrodi finalized to the realization of the San Fratello – Acquedolci Geo-Itinerary Guide-Book, which defines the evolution of the selected Territory, starting from the oldest geological natural processes up to the recent anthropic historical events, as innovative and important element aimed at a correct and modern *Territorial Management* and *Cultural and Emotional Tourism.*

GEOMORPHOLOGICAL FEATURES

The San Fratello-Acquedolci Geo-Itinerary develops through *Geological, Morphological, Biological, Paleontological, Archaeological* and *Architectural* sites, including 20 STOPS, in a geographical context responsible for scenic landscapes.

For its strategic position, the Territory was place of important Paleolithic settlements and Greek, Roman, Byzantine, Arab, Lombard, Norman, Angevin, Aragon and Bourbon bulwark and fortress, for the supremacy of the Tyrrhenian colonies and commercial routes in the Mediterranean basin.

In 1993 for its high naturalistic value, the Territory became part of the *Nebrodi Regional Park* that, with its surface of 86.000 ha, is the largest natural protected area in Sicily.

The Geo-Itinerary develops in the area between T. Inganno and T. Furiano, limited by the Acquedolci Tyrrhenian coast in the N, and by the E-W alignment of Pizzo Ramosa (570 m) - Pizzo di Marzullo (577 m) - Pizzo Costanzo (844 m) in the S.

The area consists of a N-S thin hill chain, which extends about 15 km in length, starting from the coast and reaching, through steep tracts and marine terraces, the San Fratello Mt. (or Vecchio Mt.) at 718 m (a.s.l.).

These reliefs are placed on the tectonic boundary between Calabrian-Peloritani and Apenninic-Maghrebian Domains.

The San Fratello Mt., characterized by a carbonatic composition, appears as a sub-triangular upland, with the summit extended for about 85 ha, defined by a wide marine terrace, known for the diffused presence of the remains of the Native-Greek Apollonia Acropolis (IV century B.C.-I century A.D.). The mount slopes down to NNW, limited by a big scarp in fault line, high about 200 m, at E. Going to the N, other three wide scarps reduce all the structure until to Pizzo Castellaro (280 m a.s.l.), where the most important karst cave of this area: the San Teodoro Cave, located at S of Acquedolci village, preserves a precious palaeo-archaeological site, with remains of Pleistocene mammalian fauna and of Paleolithic humans.

At SSE of the San Fratello Mt. summit the homonymous village extends, with its historical centre, where a few walls of the ancient Norman castle (XI–XII century) are still preserved. Today the village extends to S and SW, affected by old and recent landslides, which made uninhabitable the two ridge sides, corresponding to the right hydrographic slope of the T. Furiano and the left slope of the T. Inganno. In particular this last area, which was characterized by new buildings, is now a ghost urban nucleus.

The morphological features of the Territory originate seasonal and torrential streams, which from specific mountain drainage basins converge into the two main watercourses: T. Inganno in the E and T. Furiano in the W. The T. Inganno, 24 km in length, receives Filici, Gavarino, Murba, Paraspolo, Rizzotto and Rocca tributaries from S to N. The T. Furiano, 19 km in length, with a basin of about 146 sq km, is initially named T. San Fratello, but it becomes T. Furiano when Sanbarbaro tributary flows into it.

The various and thick vegetation is typical of the NE Perityrrhenian Sicily, distributed according to the altitude and the rainfall, sometimes abundant.

GEOLOGICAL SETTING

In the Nebrodi Park Palaeozoic to Tertiary terrains outcrop. They derive from the deformation both of crystalline basements of the Calabria-Peloritani Chain (CPC), and of sedimentary covers mainly belonging to the Apenninic-Maghrebian Chain

([1]) Dipartimento di Fisica e Scienze della Terra, Università di Messina - Messina (Italy).

([2]) Ente Parco Regionale dei Nebrodi – Messina (Italy).

(AMC) and subordinately to the Calabria-Peloritani Chain (CARBONE *et alii*, 1998; LENTINI *et alii*, 2000a, b). The two orgenic domains override the Pelagian-Sicilian thrust system. They consist of a pile of southern-verging tectonic units, of which the innermost and the geometrically most elevated are the CPC units.

The CPC is made up of Pre-Palaeozoic and Palaeozoic basement units, some of them preserving slices of the original Meso-Cenozoic cover. The tectonic stack occurred during Early Oligocene and was sealed by the *Capo d'Orlando Flysch*. This deposit is tectonically overlain by the chaotic formation of the *Variegated clays Antisicilide Units*, which passes to the Upper Burdigalian–Langhian *Floresta Calcarenites*, proceeding towards the top. The CPC units, cropping out in the NE area of the Nebrodi Park, overthrust the AMC along the Taormina-Sant'Agata di Militello tectonic line.

The *AMC* consists of Meso-Cenozoic sedimentary sequences, derived from deformation of basinal and platform areas, originally laid between European and African margins. These sequences are made up of carbonatic deposits which pass to huge terrigenous sediments in the upper part, often attributed to flysch type formations. The innermost basinal sequences are chaotic and ascribed to the Alpine-Tethydes Units (Sicilide Units), because originally deposited in the Alpine Tethys' realm along the European margin.

The *Panormide Carbonate Platform* rests upon the (Imerese, Sicanian and Mt. Judica) basinal successions of the Ionian palaeobasin, owing to a Middle Miocene deformative phase.

The Oligocene-Miocene clayey-arenaceous Numidian Flysch is commonly present in many Apenninic-Maghrebian tectonic units.

The *CPC* units crop out with small extensions in the north-eastern sector of the Nebrodi Park, with only the San Marco d'Alunzio and Longi-Taormina Units. The remaining part of the territory is occupied by the Sicilide succession and the AMC Numidian Flysch. The former, which extends in the central and southern areas of the Park going to the top, consists of the three main tectonic units of Mt. Soro, Nicosia and Troina. The Numidian Flysch extensively crops out in the central-western and northern sectors of the territory, with the Maragone and the Mt. Salici-Mt. Castelli Units, from the bottom to the top.

Consequently, from the geological point of view the San Fratello-Acquedolci area is placed on the western limit of the CPC and includes part of the tectonic contact between Calabride and Maghrebian units.

For the current research a geological map at 1:10.000 scale with the illustration of the itinerary has been undertaken.

The studied territory occupies an area of 80 sq km and lies in two tablets at 1:25.000 scale of the IGM (Military Geographic Institute) Sheet 252 "Naso", and in detail 252 III SE "S. Agata di Militello" and 252 III SO "Pizzo Michele". The geological surveys (CARBONE *et alii*, 1998) and the revisions carried out for the present project have been performed at 1:10.000 scale, using the Technical Regional Maps (CTR Sections), edited by the Territory and Environment Department of the Sicily Region at the end of the 80's. These sections are: 598-120 S. Agata di Militello, 598-160 San Fratello, 598-110 Acquedolci, 598-150 Torre del Lauro. They all lie in the IGM Sheet 598 "S. Agata di Militello" at 1:50.000 scale.

The area involves part of the Nebrodi-Peloritani orographic limit and is entirely comprised in the Messina Province.

ARCHAEOLOGICAL FEATURES

The recent archaeological investigations (BONANNO & PERROTTA, 2008) confirm the existence of a large ancient urban centre on the top of San Fratello Mt. and along its NW and NE slopes. A Native-Greek Acropolis, surrounded by thick walls, was erected on the summit.

New archaeological researches indicate the *Greek-Hellenistic* (Late IV–Early III century B.C.), *Roman* (I century B.C. – I century A.D.) and *Norman-Swabian* (Middle-Late XII century) periods.

The ancient urban site, with the discussed name of *Agathirso or Alontiun or Apollonia,* is officially ascribed to the Apollonia Acropolis indicated by Cicerone (Late II B.C. century-second half of I B.C. century) and Diodoro Siculo (I B.C. century). This is also confirmed by the finding of a copper, dated at Late III–Early II century B.C. (Hellenistic age) (BERNABÒ BREA, 1975).

The boundary wall discontinuously surfaces for about 790 m in length. Two towers beside the main access, in the SW, and ruins of sighting towers along other possible accesses, in the S and SE, have been picked out. These structures were built with the Hellenistic technique *ad emplekton*, similar to the Roman *opus caementitium*. The old quarries of provenance of the stones used in the Apollonia site are still recognizable at SW of the Mount.

The Hellenistic urban plant shows orthogonal roads, which define rectangular blocks where edifices were laid.

In the SSW there is a flight of steps, by the main entrance near the door. The hole for the hinge of the door is recognizable in a block (Late I century B.C. - I century A.D.). The principal road, *plateia odòs* o *decumanus,* with E-W direction, divided the territory in northern and southern areas defined by roads parallel and perpendicular to the main one (Fig. 1). In the NE sector there are remains of a Hellenistic-Roman peristyle *domus*, with boardrooms plastered of red and floored with *opus signinum* (white mosaic tesserae with geometrical and curvilinear design), and a bathroom with a hipbath.

A large tank is made up of white calcareous blocks and plastered by hydraulic mortar (Fig. 2). In the western side a big rectangular tank, dug into the rock with walls integrated by squared blocks and unsquared rocks, is coated with hydraulic mortar. It was probably reused during the Middle Age. Next to this thank, there is a holy complex, dug into the rocks.

In I century A.D. the Hellenistic-Roman urban centre was left becoming only a military outpost.

The site was reoccupied in the Middle Age (early XII century), reusing in part the preexistent structures, with different structural orientation, technique and typology of constructive elements. The one-roomed habitations, with a rectangular plant, had the entrance on the long side, floor in dirt floor, with the fireplace outside.

In 1090 the Norman Church of Tre Santi (Alfio, Cirino and Filadelfio) was built on the preexistent structures (Fig. 3).

Archaeological and numismatic finds coming from the archaeological site are exposed in the *Antiquarium* of San Fratello village.

Fig. 1 - San Fratello Mt. summit: old paved road of the Apollonia Acropolis, Nebrodi Park.

Fig. 2 - San Fratello Mt. summit: tank, made up of white brecciated algal limestones of the San Marco d'Alunzio Unit cover. Apollonia Acropolis, Nebrodi Park.

Fig. 3 - San Fratello Mt. summit: façade and lateral left view of the Church of Tre Santi. Nebrodi Park (ME).

THE MATERIALS USED IN THE ARCHAEOLOGICAL SITE

Field, mesoscopic and laboratory analyses of rocks used in the Apollonia archaeological site have allowed the recognition of the quarries in situ from which they come from, part of them still preserved. The used rocks are *white brecciated algal limestones*, which are the predominant rock types; *pale-pinkish encrinites*, *brachiopod and coral-bearing limestones*; *grey massive dolostones*; rare *nodular limestones of the Rosso Ammonitico facies*. They belong to the Jurassic levels of the Meso-Cenozoic cover of the San Marco d'Alunzio Unit, that widely outcrop in the Mt. San Fratello.

These rocks are recognized in the square blocks of the different walls and tanks (Fig. 2) and also in the remains of structural elements of buildings.

The same rocks are used in the Church of Tre Santi (Fig. 3).

Fragments of potsherd and striated tiles are also present.

CONCLUSIONS

The San Fratello-Acquedolci Geo-Itinerary develops in the Natural Nebrodi Park. The Territory is similar to a stage rich of changing scenery created by the flow of various landscapes, where the natural and anthropic elements are observed in a contextualized ensemble, finalized to admire the typical beauty of this place. The Apollonia Acropolis represents a valuable geo-cultural gem.

The ancient lands and remains, evidences of the past, become the "object" to know, valorize, preserve and enjoy.

Bedding-parallel veining and fluid overpressure at the base of the Lagonegro sequence, Southern Apennines, Italy

ROCCO NOVELLINO (*), FRANCESCO BUCCI (***), CECILIA VITI (*), PAOLA GUGLIELMI (**), GIACOMO PROSSER (**) & ENRICO TAVARNELLI (*)

RIASSUNTO

Formazione di vene parallele alla stratificazione e sovrappressione dei fluidi alla base della successione Lagonegrese, Appennino meridionale, Italia.

Vengono anticipati i risultati di uno studio strutturale, microstrutturale e mineralogico condotto su vene di calcite parallele alla stratificazione, ritrovate all'interno di Formazioni Triassiche Lagonegresi affioranti lungo il bordo occidentale dell' alta Val d'Agri fra i paesi di Marsicovetere e Marsico Nuovo in provincia di Potenza.

Le fratture di origine idraulica parallele alla stratificazione, sono comuni in successioni bacinali, sopratutto all'interno di argille nere.

L'origine e la formazione di queste vene sono molteplici, le principali cause sono da ritrovarsi nella compattazione meccanica, nella generazione di idrocarburi, oppure come conseguenza di stress compressivi orizzontali alla stratificazione stessa. Nel nostro caso, l'ipotesi più accreditata, risulta essere quella della sovrappressione dei fluidi contenuti nei sedimenti.

Studi futuri mirati alla caratterizzazione microstrutturale, inclusioni fluide e isotopi stabili, possono meglio vincolare le condizioni e il tempo della formazione di tali strutture, nonchè portare un contributo di carattere regionale.

Key words: Microtectonics, bedding-parallel fibrous veins, 'Beef', Lagonegro succession, Val d'Agri basin.

INTRODUCTION

Hydraulic fractures along bedding planes are common in compacted shale sequences of numerous sedimentary basins (MARSHALL, 1982; AL-AASM, *et alii*, 1992; PARNELL *et alii*, 2000; SUCHY *et alii*, 2002; COBBOLD *et alii*, 2007; RODRIGUEZ *et alii*, 2009).

Where mudrocks and shale predominate, bedding-parallel fibrous veins ('Beef') are found at the base of Lagonegro sequence in the Southern Apennine of Italy.

Structural and microscopical (SEM) analyses have been used to constrain the kinematic history of the bed-parallel fibrous calcite veins outcropping in a key sector of the high Agri Valley. They represent the earliest generation of vein found in the rocks. The veins range from 1 to 8 cm. in thickness. Although some veins separate beds of contrasting lithology, particularly limestone from superimposed shale, the majority are located in apparently homogeneous shale.

Veins mostly consist of calcite, in fibrous to columnar crystal oriented perpendicular to the vein walls, at optical microscope, the calcite fibrous also seem to be twinned in Type I (BURKHARD, 1993; FERRIL, *et alii*, 2004).

The commonest mineral in the fibres is calcite, other mineral present in the veins are quartz and minor pyrite, iron oxides/hydroxides.

Vein opening is interpreter to be the result of vertically oriented stressed generated by hydraulic overpressuring. The possible causes of overpressure are a matter of debate. The popular would be mechanical compaction, hydrocarbon generation and the onset of horizontal compressive stress.

However, vein-wall normal calcite columns and fibres provide a more convincing evidence for a pre-folding rather than an early-folding origin of bedding parallel veins of fibrous calcite in the study area.

We suggest that the bedding-parallel fibrous veins ('beef') formed during burial processing, in sediments that were compacted and lithified. They formed before the onset of Miocene folding and thrusting, marking an early stage of tectonic inversion of the Lagonegro Basin.

Future studies of fluid inclusions and stable isotopes may help to constrain better the time and depth of formation of the 'Beef'.

The role of the Geodiversity in the historical evolution of the Milazzo - Santa Lucia del Mela Territory (NE Sicily, Italy)

ROSARIO TORRE (*)

Keywords: *Geodiversity, Geo-cultural Heritage, Milazzo - Santa Lucia del Mela Territory (NE Sicily, Italy), Thematic Geo-Itineraries.*

INTRODUCTION

The Milazzo - Santa Lucia del Mela Territory is one of the most important and fascinating areas of the Southern Italy (Fig. 1). It is characterized by morphological, geological, petrological and mineralogical uniqueness and specificity, as well as very important historical and cultural peculiarities.

The purpose of this study is to reconstruct its extraordinary geodiversity and the most representative relationships between it and the Historical-Cultural Heritage.

GEOMORPHOLOGY

The Milazzo-Santa Lucia del Mela Territory shows a heterogeneous geomorphology related to its complex geologic setting.

The Territory is located in the North-Eastern Peloritani Mts. It is made up of three different zones:

- the mountainous zone, in the S, corresponding to the intermediate tract of the NE-SW Peloritani Ridge, from which three secondary ridges depart. They form the watershed lines of the Muto, Floripotema and Mela Torrents, going to the Tyrrhenian Sea;
- the flat zone, which includes the Milazzo-Barcellona Plain;
- the coastal zone, formed by the Milazzo Peninsula and the two, eastern and western, coasts that rim the Milazzo and Patti Gulfs, respectively.

Orography. From NE to SW, the crystalline reliefs of the main Peloritani Ridge are characterized by the highest peaks of Poverello Mt. (1.279 m), Acqua Menta Pk. (1.110 m), Croce Pk. (1.214 m), Acqua Bianca Pk. (1.210 m), Mualio Pk. (1.200 m), Batteddu Pk. (1.228 m).

The secondary ridges start with peaks of 1200 m of altitude, decreasing towards the Tyrrhenian Sea, cut by river terraces, and at about 4-6 km from the coast, they are formed by Miocene to Modern sedimentary covers.

The same sedimentary deposits surround the central part of the Milazzo-Barcellona Plain, which shows three main marine terraces (110-130 m; 70-90 m; 25-40 m, a.s.l.).

Hydrography. From E to W, the Territory is crossed by the three river basins of Muto (18.5 km, 39.54 sq km), Floripotema (22 km, 30.15 sq km) and Mela (24.6 km; 64.97 sq km) Torrents. They have a seasonal torrential course strictly dependent on the rainfalls.

The three river basins are dominated by scenic landscapes with hypogean karst phenomena (canyons and caves, Fig. 2), beautiful springs and waterfalls, small natural oasis with endemic and endangered flora and fauna.

Coastal Morphology. The Milazzo Peninsula, located about 30 km at W of Peloro Cape, extends on the Tyrrhenian Sea, with S-N trend, developing for about 7.5 km in length. The Peninsula, characterized by a valuable natural and historical Heritage, with its peculiar shape delimits two physiographic units: in the E, the Milazzo Cape-Peloro Cape unit, in the W, the Milazzo Cape-Calavà Cape unit.

The Milazzo Peninsula exhibits active and fossil sub-vertical cliffs, with narrow beaches (pocket beaches) at the base, produced by the collapse of the fractured walls, and terraced marine abrasions at the top. The extreme part, the Milazzo Cape, consists of a large marine terrace (with an average altitude of about 70 m a.s.l.) formed by a strip of Miocene limestones resting on crystalline basement.

Karst. Geological investigations in the Territory showed hypogean karst phenomena in the Mela Unit Variscan marbles (MESSINA *et alii*, 2010), with subhorizontal or subvertical tunnels and cavities, such as potholes, and epigean karst phenomena, with surf karren.

In the river basin of the Mela Torrent have been identified the "Luca Valley Cave", the "Caves of Santa Lucia", the "Sàutu i Lapa Cave", the "Caves of Portella dell'Orso"; in the river basin of the Floripotema Torrent the "Cave in Avarna District".

In the Milazzo Peninsula are present surf karren at "Gamba di Donna Point" and some hypogean structures set in the migmatites, such as the "Golden Cave" and "Point Grottazza Cave".

GEOLOGICAL SETTING

The Milazzo - Santa Lucia del Mela Territory has been recently studied within the frame of the CARG Project (CARBONE *et alii*, 2008, 2011; SERVIZIO GEOLOGICO D'ITALIA, F° 587 Milazzo-600 Barcellona Pozzo di Gotto, 2011).

The Territory is composed of metamorphic, plutonic and sedimentary rocks that tell a fascinating Proterozoic to Modern evolutional history.

It belongs to the Peloritani Chain, that is the southernmost tract of the Calabria-Peloritani Orogen.

In the studied area four of the nine of the Peloritani Alpine tectono-stratigraphic units are present, which, going to the bottom and from N to S, are: the Aspromonte, Mela, Piraino and Mandanici Units (MESSINA *et alii*, 2004; CARBONE *et alii*, 2011).

The *Aspromonte Unit*, which shows the most complex history of the Calabria-Peloritani Arc, outcrops near Santa Lucia del Mela village, and in the whole Milazzo Peninsula. It is made of a Palaeo-Proterozoic basement (1700 Ma) of deep crust, documenting three plutonic events (Palaeo-Proterozoic, Late Pan-African and Late Variscan) and three metamorphic (Pan-African, Variscan and Alpine). In the Milazzo Peninsula consists of gneisses and metahornbledites showing a metatectic processes responsible for *phlebitic to stromatitic* structures with leucosomes and melanosomes (Palaeo-Proterozoic). Near Santa Lucia del Mela village bodies of Variscan augengneisses with localized Alpine metamorphic overprint prevail (Neo-Proterozoic-Cambrian).

The *Mela Unit*, recently recognized in the homonymous area, consists of a Palaeozoic basement affected by an Eo-Variscan (Middle Carboniferous) eclogitic facies metamorphism, and a Variscan Barrovian-type amphibolite- to greenschist facies re-equilibration (Lower Carboniferous). The basement is made up of both garnet-relic paragneisses and micaschists including bodies of intermediate to acidic feldspar-relic orthogneisses. At the top of the unit thick marble levels, with wide karst phenomena (Fig. 2), including amphibolites after eclogites, are also present.

The *Piraino Unit* locally crops out in the high Mela Valley (Cerasiera Torrent), with small thicknesses. It is made up of a Palaeozoic basement affected by a Variscan metamorphic prograde zoning from the greenschist- to the amphibolite facies (Upper Carboniferous). Along the Cerasiera Torrent, dark gray chlorite-garnet-biotite phyllites passing to metarenites crop out.

The *Mandanici Unit* extends in the high-medium tract of the Mela Valley, with very small thicknesses. It consists of a Palaeozoic basement affected by a Variscan greenschist facies metamorphism (Upper Carboniferous). In the Mela Valley silvery and greenish phyllites and metarenites are present.

Pb, Zn, Cu, Sn, Sb, As, W, Ag, Au mineralizations are widespread in the four units (Fig. 3). They are ascribed to Proterozoic and Palaeozoic plutonic deposits (Aspromonte Unit) and Palaeozoic syn-sedimentary and syn-volcanic deposits (Piraino and Mandanici Units). Variscan and Alpine remobilizations and Miocene to Modern hydrothermal deposits are also present. Several ancient mines mainly found in the middle and lower tract of Mela Torrent (Malonato District, Nevola Peak, Scifo Woods, Caporale Valley).

The units are locally cut by Late Oligocene shear zones responsible for cataclastic to mylonitic effects, accompanied by a bland overprint in the Aspromonte Unit and low-T recrystallizations in the other units. The Aspromonte Unit is also unconformably covered by the Late Oligocene-Early Miocene Capo d'Orlando Flysch, and all units are affected by Late Burdigalian thrust systems and a Middle Miocene tectonics. They are also unconformably covered by Middle Miocene to Recent deposits and further affected by Plio-Pleistocene and Recent fault systems (CARBONE *et alii*, 2008, 2011 and references therein).

Fig. 3 - Argentiferous galena and chalcopyrite mineralization: mineralized vein in a quartz gangue in the Variscan marbles of the Mela Unit (Cerasiera Torrent, right hydrographic slope of the Mela Torrent).

HISTORICAL FEATURES

The morphology of the Territory has strongly influenced the evolution of human settlements. The oldest find are located in the Milazzo Peninsula (Bronze Age Village of Cypress Avenue), in the Isthmus and Plain (several Greek-Roman necropolis and artifacts), along the watershed lines of the major rivers (archaeological find of the late Bronze Age - IV century BC

Lanzaria Mt. and Lando Pk.) and in the bed of the Mela Torrent (Cattera District Roman necropolis).

An engraving prehistoric rock has been identified in the E Rocca Timogna.

Historically, the most important settlements in the Territory are the Town of Milazzo and the village of Santa Lucia del Mela.

Milazzo was founded by Greek colonists of Zancle (Messina) in 716 BC (*Mylai*). Its current urban structure is characterized by four main areas: the "Walled City" (around the Castle from the thirteenth century), the "Hamlet" (late XIII century), the "Lower Town" (the "New Land", developed after the XVI century and in the XVIII century), the "hamlets" of the Plain (XIV century). Since 1530 the Spanish Walls incorporated part of the Village and the Aragonese Walled City, which was also included in the Norman-Swabian Castle (with Arabian elements).

The most important monuments are: the Castle, the Old Cathedral (1608), the Shrine of San Francesco di Paola (1482-1626), the Cave Shrine of Sant'Antonio da Padova (1221), the Church of Madonna del Rosario (XVI-XVII century), the Convent of the Dominicans (XVIII century), the Church of San Giacomo (XV century), the Church of Santa Maria Maggiore (XVII century), the Church of Carmine (XVII century), the Archaeological Antiquarian Museum.

The old centre of Santa Lucia del Mela shows Arabian, Norman, Swabian and Aragonese architectural styles.

The symbol of the site is the Castle which presents three towers, with triangular (remains of a Ravelin), cylindrical and quadrangle forms, respectively, rebuilt on a pre-existing *Palatium* by the Aragonese in 1322. According to historical reconstructions, the Arabs built the first structure on the top of the Makkarruna Hill (*Makrun* in Arabic, means "attached, protected"). In 1675, the Shrine of Madonna della Neve was erected on the quadrangle tower of the Castle. It is characterized by the valuable marble statue sculptured by A. Gagini (1529).

There are numerous churches and palaces in Santa Lucia del Mela and in the rural villages, including: the Cathedral (1094-XVII century), the Church of Santa Maria dell'Annunziata (XV century), also famous for its imposing bell tower of 32 m in height, the Church of San Nicola (XIII-XV century), the Church and the Crypt of the Capuchins (XVII century), the ruins of the Church of San Michele Arcangelo (XV century) the Bishop's Palace (1609-1613), the Basile-Vasari Palace (XVI century).

THEMATIC GEO-ITINERARIES

During this investigation, 9 Geo-cultural Itineraries have been reconstructed, discussed and illustrated, involving a total of 86 STOPS.

They include 74 known sites, 5 revisited sites, 7 sites characterized for the first time.

The Geo-Itinerary *"The First Tract of the Mela Torrent*" is here reported as the best example to summarize the abiotic, biotic and cultural territorial aspects.

It comprises the following localities and themes:

- STOP 1. *Melia Mt. (686 m)-Pietra del Chiodo Mt.* (647 m) *tract*, consisting of a very important site with geological (thick outcrops of the Variscan silicate marbles of the Mela Unit including Eo-Variscan eclogite relics), morphological (natural sculpture of a primate or a human face in the Mela Unit marbles, originated by rock falls and karst phenomena), biological (wonderful *Pinus pinea* woods) and anthropological (remains of an ancient limekiln named "*Calcara*") aspects and a spectacular landscape in the entire analyzed Territory; STOP 2. *Suriceddi District*, with a *Thòlos structure*; STOP 3. *Rosarello Peak* (1,025 m), with a *Thòlos*, a *Neviera* and a geo-archaeological hypogean structure; STOP 4. *Mammureri Peak* (817 m), showing a *Neviera*; STOP 5. *Boccaneddo Peak* (698 m), showing widespread hydrothermal phenomena; STOP 6. *Malonato District*, preserving pyrrotine and galena mines; STOP 7. *Mandrazza Valley*, with a very rare *Woodwardia radicans* biosite; STOP 8. *Ferrà Valley*, with the "Ferrà Falls" bio-geomorphosite; STOP 9. *Avvelenato Valley*, with the "Schicciu a Saìtta Falls" and a newly recognized *Woodwardia radicans* biosite.

FINAL REMARKS

This research project is aimed at the *Knowledge*, *Valorization*, *Conservation* and *Fruition* of the rich Heritage which characterizes the *Milazzo-Santa Lucia del Mela Territory*, in terms of *Geodiversity*, *Biosites*, *Historical and Cultural* sites, because part of them is poorly known or for the first time defined in the course of this study.

The results are directed at promoting a *Territorial Management Model* and a *Cultural*, *Emotional and Élite Italian Tourism*.

A preliminary study of heavy metal contamination in marine sediments of the western Calabria (Southern Italy)

SACCÀ CARMELO, SACCÀ DOMENICA (*), NUCERA PREZIOSA (**) & DE FAZIO ANNA (*)

Key words: *Calabria, Enrichment Factor, Geoaccumulation Index, heavy metals, Tyrrhenian Sea.*

ABSTRACT

In this study we examined 24 sediment samples collected along Calabria's Tyrrhenian coast, in the area comprised between Falerna and Bagnara Calabra. The sampling has been carried out at depths ranging from 50 m to about 400 m, from the shore to the open basin.

Analysis of grain-size fractions (sand, silt and clay) showed that silt is the principal component in all samples whereas the percentage of sand is inversely proportional to clay content. Clay fraction is high in the samples collected between Falerna and St. Ferdinando (6.41-42.13%) and lower in the stretch Gioia Tauro-Bagnara (5.38-18.72%). All the samples collected in this latter area show the presence of relatively high sand fraction (13.08-45.47%).

The concentrations of As, Cu, Cd, Cr, Hg, Ni, Pb and Zn were determined on size fraction below 2µm. Heavy metals unlike other pollutants are non biodegradable and accumulate in sediments over time. Metals in coastal marine environments can originate both from human activities and natural sources. In order to determine if the heavy metals found in the fine fraction sediments are the result of anthropogenic sources, the Enrichment Factor (EF) for each metal was calculated. The following equation was used for EF calculation

$$EF= (x/Al)_{sediment} /(x/Al)_{crust}$$

where $(x/Al)_{sediment}$ is the ratio of the heavy metal being tested (x) to the Al in the sediment sample and $(x/Al)_{crust}$ is the same ratio regarding crustal rocks (FENG *et alii*, 2004). The highest EF values were for As (15-51) in all stations, suggesting the high degree of As contamination (severe to very severe enrichment). Zinc and lead also shows high EF values varying from "moderately severe" to "very severe". The EF values for Cu suggest a "severe" enrichment only in some stations.

Another important evaluation criterion used in this study is the Geoaccumulation Index (I_{geo}), calculated to evaluate the degree of metal pollution in sediments in function of the grain size fraction analysed. For the I_{geo} calculation the following MÜLLER (1981) equation was used

$$I_{geo}=\log_2[C_n/1.5\ B_n]$$

where C_n is the measured level of the examined metal (n) in the sediment, B_n is the geochemical background content of the same metal (n), factor 1.5 is the background matrix correction factor relating to lithogenic effects (MEDIOLA *et alii*, 2008). Among metals studied, the I_{geo} of As ranges from "moderately to strongly" to "strongly polluted" (I_{geo}class=3-4). Most stations display moderate pollution in Zn and Pb (I_{geo}class=1-3). The I_{geo} of Cu is ranked from unpolluted to moderately polluted (I_{geo}class=0-1-2).

A positive correlation coefficient between some heavy metals contents indicated a common origin: Ni strongly correlates with Cr, As and Cu; Zn with Cu and Hg; As, Hg correlate with Pb and Cr. Heavy metals also showed a positive correlation with size fractions: Zn, Cu and Hg correlated strongly with sand whereas As with clay.

Finally heavy metal concentrations were compared with sediment quality guidelines (SQGs) and the values presented by the Italian Ministerial Decree 56/09 EQS. By comparison it was evinced that the limit value indicated for Zn, Cu, Pb, Ni and As concentrations were exceeded in all samples.

The iron content of sphalerites from the polymetallic ore deposits in the Peloritani Mountains (NE Sicily, Italy)

SACCÀ CARMELO, SACCÀ DOMENICA (*), NUCERA PREZIOSA (**) & DE FAZIO ANNA (*)

Key words: *Fe content, mineralizations polymetallic, Peloritani Mountains, sphalerite*.

ABSTRACT

The Peloritani Mountains extend in north-eastern Sicily and represent the southernmost part of the Calabria- Peloritani Arc. They consist of an Alpine pile of several Africa-verging tectono-stratigraphic Units, which geometrically, from bottom to top, and in order of increasing metamorphic grade (MESSINA, 2002; MESSINA *et alii*, 2004; MACAIONE *et alii*, 2010), are: Capo St. Andrea Unit, Longi-Taormina Unit, St. Marco d'Alunzio Unit, Fondachelli Unit, Alì Unit, Mandanici Unit, Piraino Unit, Mela Unit and Aspromonte Unit.

Sphalerite is a major constituent of the most mono- and polymetallic (Zn, Cu, Fe, Pb, Sn, Sb, As, W, Ag, Au, etc.) mineralizations present in all the units.

In this preliminary study we present compositional data on sphalerite belonging to different mineralizations in the Peloritani Mountains with the aim to show that there is a close correlation between iron content in the ore deposits and the thermobaric conditions of different tectono-metamorphic units (Mela, Mandanici, Fondachelli and Longi-Taormina Units)

Sphalerite is a rather common mineral and occurs in a wide range of hydrothermal environments (RAMDOHR, 1969).

It has a cubic crystal system and is composed of essentially zinc sulfide. The zinc and sulfur atoms are coordinated tetrahedrally in the crystal structure.

The chemical composition of mineral is characterized by S, Zn, Fe and other minor elements. Its coloration is function of the different elements, especially Fe content (RAGER *et alii*, 1996). Iron concentrations typically range between 5 and 10% or from trace levels up to more than 15% (BUBAN *et alii*, 1999; LEPETIT *et alii*, 2003).

The FeS content of sphalerite was recognized as an indicator of conditions of sulphide formation temperature (KULLERUD, 1953, 1959; HUTCHEON, 1978). This content in sphalerite also depends on its pressure of formation, in fact, has been widely used as a geological barometer (SCOTT & BARNES, 1971; LUSK *et alii*, 1993; MARTIN & GIL, 2005).

Mineral samples collected at 21 localities were analysed. The samples, after being included in resin and prepared as polished cross- sections, were studied in reflected light and observed by SEM for major element analysis in sphalerites.

Sphalerite results to be ubiquitous and shows different minerographic and chemical characteristics. Optical microscopy showed that sphalerites occur as masses with small inclusions of other minerals in the ore (pyrite, pyrrhotite, chalcopyrite), as filling in fractures (fluorite and arsenopyrite), as intergrowth with chalcopyrite. This study also showed evidence of other associated mineral phases (i.e., galena, chalcopyrite, pyrite, tetrahedrite, jamesonite, etc.).

Chalcopyrite is occasionally observable in iso-oriented lamellae inside sphalerite of *Lumbolo, Butigari, Vacco, St. Carlo* and *Fonderia* (SACCA' & CIMINO, 1988; SACCA' *et alii*, 1992; SACCA' & SACCÀ, 1996; SACCA' *et alii*, 2006).

The presence of both randomly dispersed and crystallographically oriented lamellae and granules of chalcopyrite within sphalerite is well known in the literature (BARTON & BETHKE, 1987; SUGAKI *et alii*, 1987). This texture, so-called "chalcopyrite disease" (CRAIG & VAUGHAN, 1981), is attributed to exsolution phenomena for temperatures above 500° C and to phenomena of replacement by copper-rich fluid for lower temperatures.

From chemical point of view, iron content in sphalerite reaches about 7% (*Cernicola*) in the high-grade metamorphic Mela Unit.

The mineralizations outcropping in the Mandanici Unit (*Bosci, Butigari, Carruggio Lummia, Colonne, Due Fiumare, Gialinello, Lumbolo, Migliuso, Pancardo, Rosario, Sciglio, St. Carlo mine, Tripi, Vacco* and *Viola* localities) are also characterized by a Fe-rich sphalerite (about 6%) whose content are within the variability margins concerning iron content in relation to P-T conditions typical of the unit.

Sphalerite with less iron content is typical of the low-grade metamorphic Units: Fondachelli (*St. Luigi mine*) and Longi-Taormina Units (*Acquafredda, Caudafredda* and *Fonderia* localities), where Fe content is 2.6% and 0.5% on average respectively.

(*) Dipartimento di Scienze della Terra – Università di Messina, Viale F. Stagno d'Alcontres 31, 98166 Sant' Agata di Messina (ME).

(**) Dipartimento di Biologia Animale ed Ecologia Marina – Università di Messina, Viale F. Stagno d'Alcontres 31, 98166 Sant' Agata di Messina (ME).

In conclusion, iron is always present in all examined samples, with values which range between 0.24% and 7.47%, in the low-grade (Longi-Taormina) and high-grade (Mela) metamorphic Units, respectively. This variability of iron content in sphalerite could be related in part to the thermobaric conditions of the different Units.

Mesozoic evolution of the Caloveto Group, NE Calabria

MASSIMO SANTANTONIO (*)

Key words: *Calabria, Jurassic, carbonates, paleotectonics, submarine escarpments.*

INTRODUCTION

The Caloveto Group in NE Calabria (Sila Greca) (SANTANTONIO & TEALE, 1987, and references therein) is a relatively thin stratigraphic succession documenting sedimentation on an offshore basement high that during the Jurassic was separated from mainland Calabria by the strongly subsiding Longobucco Basin. Although this latter basin behaved as an effective sink for continent-shed terrigenous sediment, the thin, dominantly carbonate Caloveto Group succession (Pliensbachian to Early Cretaceous) also received siliciclastic input sourced locally by the Paleozoic basement. This was initially exposed subaerially (islands) and subsequently along submarine escarpments, following tectonic extension and foundering. Both the Longobucco and the Caloveto groups were sedimented on the future margin of the European Plate, but they record contrasting histories of syndepositional faulting and subsidence, resulting in a complex pattern of unconformities and mixed carbonate/siliciclastic facies.

THE CALOVETO GROUP

The Caloveto Group is exposed in two main areas.

Caloveto area - The lowest unit, the Lower Caloveto Formation, is a white thick-bedded limestone, up to about 100m thick, with common basement-derived detritus. This detritus produces conglomerate facies near the contacts with the crystalline basement (a rugged nonconformity surface). The conglomerates are up to 46m thick, and are matrix (calcarenite)- to clast-supported, with elongate metamorphic and rounded polycrystalline quartz clasts, generally less than 10cm across and displaying only uncommon embrication. Obvious lenses and sedimentary structures are rare, as clusters of pebbles can form "clouds" within the calcarenite, having puzzling sharp, steep lateral contacts to the carbonate sand, as if they were filling invisible "buckets" within the limestone. This could be the result of sand liquefaction and "swallowing" of heavier clasts due to earthquakes. The Lower Caloveto Fm. is dominantly a strongly recrystallized grainstone, with crinoids, molluscs (gastropods, bivalves), benthic forams, *Tubiphytes*, possible *Cayeuxia*, and micrite-coated grains (micro-oncoids, often with a quartz crystal or metamorphic microclast at their nucleus). Coral colonies, up to 20cm across, are locally associated with coarse conglomerates (Mt. Brulline). Cross-lamination with dm-thick sigmoidal foresets is also observed. At Cozzo di Mastro Pasquale, the limestone is faulted and is penetrated by a dense network of oblique and bedding-parallel red neptunian dykes, as is the basement. The degree of fragmentation is such that the limestone locally takes the form of an *in situ* breccia. The limestone has steep lateral stratigraphic contacts to the phyllites, where varicolored bacterial microbialites could fill small caverns, so that modern erosion has often preferentially caused the detachment of bed stacks, forming chaotic piles of limestone clasts. Contacts with the younger units of the Group commonly occur through a rugged unconformity surface, due to faulting that accompanied drowning of the Lower Caloveto carbonate system, which is interpretable as a shallow peri-insular carbonate apron. One exception exists at Carito, ~0.5km east of Cozzo di Mastro Pasquale. Here the top ~6 metres of the Lower Caloveto Fm. display a spectacular pink-colored brachiopod (mainly rhynchonellids) coquina facies (~4m) in beds 20-70cm thick, also with rare ammonites (*Arieticeras* sp.; upper Domerian), followed by encrinites in 10-40cm-thick beds, with admixed metamorphic debris (~2m). These deposits are interpreted as a drowning succession. A Domerian *Protogrammoceras* sp. was identified by G. Pallini in the topmost levels at Cozzo di Mastro Pasquale. Besides these ammonite findings, the age of the greater part of the Lower Caloveto Fm. is poorly constrained, and the occurrence of the benthic foram *Agerina martana* FARINACCI only indicates a general Carixian and possibly Domerian age.

The Upper Caloveto Formation (<10m thick) is a red nodular marly mudstone (Rosso Ammonitico facies), with thin-shelled bivalves, benthic forams and crinoids. Along the dirt road descending the southern slopes of Cozzo di Mastro Pasquale, a narrow, flat topped terrace bordered by steep cliffs represents the Lower/Upper Caloveto Fm's contact that was downstepped along a synsedimentary normal fault (striking N-S to N30E), apparently reutilizing a sedimentary dyke. The contact is a drowning unconformity, in the form of an irregular Fe-encrusted rockground. The basal condensed levels of the Upper Caloveto Fm. bear *Hildaites serpentinus* BUCKMAN and

(*) Dipartimento di Scienze della Terra, Università "La Sapienza", Roma.

Polyplectus sp., as well as echinoids. These indicate the lower Toarcian Serpentinus Zone. Nodular marls a few dm's above give a younger Toarcian assemblage with *Hildoceras sublevisoni* FUCINI, *Catacoeloceras sp.* and *Mercaticeras sp.* (see also BOUILLIN *et alii*, 1988), while rarer *Phymatoceras* and *Hammatoceras* gr. *insigne* (SCHUEBLER) further upsection indicate the lower upper Toarcian.

Next come the red *Zoophycos* Marls, representing the base of the Sant'Onofrio Subgroup (initially defined as a formation, subdivided into members, and here meant to include formations up to the Maiolica). They are markedly micaceous, and form tabular beds, 10-40cm thick, intensely burrowed and with *Bositra* packstone levels. Mud clasts with black coatings probably resulted from bioturbation of incipient hardgrounds. The unit is about 16.2m thick at Cozzo di Mastro Pasquale, but could be twice as thick in the area. The lower levels locally bear remains of up to 15cm across Inoceramid bivalves. The dominant components of the macrofauna, however, are cephalopods, and this is a remarkable locality for belemnites, with species belonging to the genera *Holcobelus*, *Megateuthis*, *Brevibelus*, *Pachybelemnopsis* and *Hibolithes*. This assemblage provides a general Aalenian-Eearly Bajocian age, and is comparable with coeval assemblages in Romania, Bulgaria, France, southern Germany, Luxembourg, England and Caucasus (MARIOTTI *et alii*, 2010, and references therein). Ammonites bear evidence for an Aalenian age of the bulk of the unit (M. K. Howarth, G. Pallini and S. Cresta, pers. comm., 1984-1991). A level at about 7m from the base produced *Erycites fallifax* ARKELL, *Tmetoceras scissum* (BENECKE), *Ancolioceras opalinoides* (MAYER), indicating the Murchisonae Zone, Opalinoides Subzone (S. Cresta, pers. comm.). The topmost ~3 metres of the unit, however, capped by a red chert bed, produced *Docidoceras* c*f. perfectum* BUCKMAN and *Skirroceras sp*., two lower Bajocian (Discites Zone) forms. Also based on data from the Colognati area (see below), the age of the *Zoophychos* marls is (?)late Toarcian to early Bajocian. The marls can rest through an angular unconformity on the metamorphites (Cozzo Cerasello) and on the Lower and the Upper Caloveto fms.

The *Zoophycos* marls are followed by a few metres of red to dark brown radiolarian cherts. The radiolarites bear fine calcarenites, interpreted as distal turbidites sourced by a productive carbonate platform. The radiolarites rest conformably on the marls or, like the marls, onlap paleoescarpments made of Lower Caloveto Fm., in which case, and in analogy with observations in the Apennines, the limestone is silicified (GALLUZZO & SANTANTONIO, 2002).

The *Aptychus* limestone is ill documented at Caloveto, and the Maiolica is only found in small outcrops where BOUILLIN *et alii* (1988) recovered a Berriasian calpionellid assemblage.

Colognati Valley – The Jurassic and Lower Cretaceous rocks along the Colognati Valley form two larger outcrops, which served initially as the type area for the Sant'Onofrio Group (now Subgroup): one in the surroundings of the remote church of Sant'Onofrio, and the other – further up the valley - at a locality called Il Torno (SANTANTONIO & TEALE, 1987; SANTANTONIO, 1993). At Il Torno, a late Toarcian to earliest Cretaceous succession thins out and onlaps the crystalline basement, with the Aalenian red marls (and locally the highest beds of the Upper Caloveto Fm.) abutting an irregular spur-and-groove surface carved in the Carboniferous granite. A narrow (<10m) fringe of Lower Caloveto limestone, with rounded pebbles to boulders of granite, is locally interposed, passing laterally to the *in situ* granite (hosting red neptunian dykes). The top of the Upper Caloveto Fm. (with *Hammatoceras* sp.) bears a megabreccia with boulders (up to several metres across) made of granite and of the fringing Lower Caloveto limestone mentioned above, plus a matrix of red limestone with posidoniids, locally with convolute lamination (SANTANTONIO & TEALE, 1987; SANTANTONIO, 1993). The bumpy upper surface of the breccia has the inter-block lows hosting abundant, often large-diameter (>20cm) ammonites and rare nautiloids which, as much as the upper surfaces of the boulders, are encrusted by iron oxides. The ammonites have a pseudotest and include *Catulloceras* sp., *Dumortieria* cf. *evolutissima* PRINZ, *D.* cf. *meneghinii* ZITTEL, *Tmetoceras* sp., *Erycites* cf. *ovatus* GECZY, besides Phylloceratids (up to 50cm across) and Lytoceratids. This is a mixed assemblage of the late Toarcian Meneghini Zone (including the Aalensis subzone) and the early Aalenian Opalinum Zone. The breccia is onlapped by red marls, with *Chondrites* and *Zoophycos*, bearing internal molds (no pseudotest) of *Tmetoceras scissum* (BENECKE), *Erycites fallifax* ARKELL, *Erycites* spp. and *Abbasitoides* sp., indicating an early Aalenian (possible Comptum Subzone/Murchisonae Zone transition) age (G. Pallini, pers. comm. 1985-1991). These relationships, coupled with recent field-mapping data, suggest: 1. A submarine rockfall/slide, involving both lithified material and the ambient pelagic mud, occurred in the late Toarcian, carving a ~250m across scar in the granite and producing a tongue-shaped breccia, up to several metres thick and having its tip ~550m away from the detachment zone, where the white fringing limestone was completely removed; 2. The perched upper surface of the breccia hosted condensed sediment as ammonite shells were trapped in the hollows while pelagic mud was sieved through the breccia; 3. Exposure at the sea bottom, marked by iron crusts, and spotty condensed sedimentation lasted until the topography was levelled by onlapping marls in the early Aalenian. Given the stratigraphic relationships at Il Torno, and the fact that no ammonites of the late Toarcian Meneghini Zone were ever recovered from the Upper Caloveto Fm., it is inferred that the base of the marls can be late Toarcian, coeval with the first deposition of condensed epi-breccia sediment.

Following the marls, up to ~15m thick and bearing thin pebbly mudstones, graded sandstones, and a thin conglomerate near the top, with peloids and ooids in the calcarenite matrix, a pink to whitish mudstone represents the *Aptychus* Limestone (SANTANTONIO, 1993). The radiolarian cherts are missing at Il Torno but for a thin cherty level at the top of the marls, and the contact with the *Aptychus* Limestone is a subtle angular unconformity. Besides common aptychi (*Lamellaptychus*), belemnites, rhyncholites and rare ammonites also occur. This unit bears rare thin ooid-rich turbidites. Ammonites include Perisphinctids and *Simoceras volanense* (OPPEL), a marker of the late early Tithonian Volanense Zone. As this form occurs near the formation top, a general Kimmeridgian-early Tithonian age, typical for Tethyan successions, can be inferred for the *Aptychus* Limestone of Sila Greca, so the missing radiolarites would produce a stratigraphic gap between the marl (lower Bajocian, if we correlate the base of the lowest cherty bed found here and at Caloveto) and the limestone (?Kimmeridgian), linked with pinch-out of the whole succession towards the granite paleoescarpment. The base of the Maiolica is a belemnite-rich (*Hibolithes*, *Duvalia*) conglomerate/breccia, (few decimetres), with clasts of granite, red marl and *Aptychus* Lmst. The Maiolica, however, is very thin, as the Mesozoic succession is truncated by unconformable Oligocene-Miocene marls and arenites of the Paludi Fm.

At Sant'Onofrio, where the succession is partly overturned, the two lower stratigraphic units are as yet un-named. The lowest is a white crinoid-rich hybrid arenite/conglomerate with granite and phyllite clasts, with very thin intercalated red posidoniid-rich marls. This should be partly lateral to the Upper Caloveto Fm. and/or the *Zoophychos* marls. Next comes a dark grey fine calcarenite (unidentified components) with black chert. This is followed by dominantly dark brown radiolarian cherts, bearing thin arenites and thick carbonate turbidites and debrites - ultimately capping the unit - with clasts of granite, phyllite as well as of pink *Aptychus* limestone and white mudstone bearing late Tithonian calpionellids. The carbonate turbidites are a few tens of meters thick and bear abundant shallow water material, with benthic forams, algae, gastropods and ooids with a siliciclastic nucleus (SANTANTONIO, 1993). The *Aptychus* limestone is missing, and is apparently replaced by cherts. These are followed by the Maiolica. The lowest levels are a thin-bedded mudstone with calpionellids of the Alpina and Remaniella Subzones (late Tithonian *p.p.* – Berriasian), followed by a thick package of hybrid arenites (carbonate content made of shallow-water material), with thick beds having crystalline and rip-up clasts up to boulder size. The upper Maiolica is dominantly a grey bioturbated (*Chondrites*) limestone, with greenish marl interbeds, with intercalated gravity flow deposits. This succession, and its granite substrate, are capped unconformably by the Paludi Formation.

CONCLUSIONS

The Caloveto Group documents a delayed transgression with respect to Longobucco, as the earliest marine deposits are Pliensbachian, and no continental redbeds are interposed. Until then the area stood proud as one shoulder of the Longobucco rift. Deposition of >1km thick turbidites around the Domerian-Toarcian boundary at Longobucco largely corresponds to a hiatus at Caloveto. By analogy with Southern Alps and Northern Apennines, the (Hettangian) rift axis then jumped in the (post-earliest) Toarcian to an area that had previously experienced very little subsidence (Caloveto Group), which became severely faulted, producing multiple unconformities (SANTANTONIO & CARMINATI, 2011). Neither the Longobucco nor the Caloveto Groups document any survived shallow water carbonate environment after the Pliensbachian, so inferring a source area for the resedimented calcarenites through the Sant'Onofrio Subgroup is speculative. The strongest candidates are the Middle Jurassic (*p.p.*)/Early Cretaceous carbonate shelves exposed in the Southern Calabrian Stilo Unit and in E Sardinia. Besides facies, a common tract across these regions is that they did not experience any significant subsidence in the Triassic and earliest Jurassic (with the partial exception of Longobucco), representing a vast high of the Hercynian basement at the time.

Ophiolites: their first steps

VALERIO BORTOLOTTI

Key words: *ophiolites, history.*

Geologists talk about ophiolites with familiarity, but how many know or took an interest in the birth of the concept?

The story begins in year 1813, when ALEXANDRE BROGNIART coined the term "ophiolite" studying the rocks also in the "Tertiary" sediments of the Northern Apennines. He refined the meaning in 1821 and 1827.

As defined by BROGNIART the 'ophiolites' were a triad of often associated rock types including "serpentinites", "gabbros" and "diabases". The so called 'Steinmann Trinity' should be rightly called "BROGNIART trinity".

As far as their interpretation is concerned, we can subdivide the ophiolitic history into four phases:

1- The ophiolites were initially considered as normal intrusive or extrusive rocks, usually associated, found in a definite succession. LOTTI (1910), for example interpreted them as thick Eocene lava flows intercalated within an autochthonous Tuscan succession. Steinmann (1927), on the contrary, considered them as allochthonous thick lopolites or laccolites intruded in the cherts. Successively BRUNN (1940) introduced the hypothesis of a very thick submarine flow, in which gravity caused the differentiation.

2- The ophiolites conquered a particular relevance in orogenic chains. According to BRUNN (1952) the ophiolitic flows were extruded during an extensional tectonic phase, along big flexures in deep basins (geosynclines) and subsequently were involved in the orogenic compressive tectonics. AUBOUIN (1959, 1965) improved these ideas, considering the ophiolites as rocks of a peculiar geodynamic environment, the 'eugeosyncline'.

3- The ophiolites were interpreted in a plate tectonic context, as portions of the oceanic lithosphere thrust onto the continents during the first phases of the orogenesis. They represented the only relics for studying and knowing the lost oceans, which existed all along the Earth history.

4- This simple scheme became then more and more complex: the new concepts of marginal seas (MIYASHIRO, 1973), supra-subduction zone, arc, back-arc, fore-deep, are currently used to interpret the specific genetic environment of the different ophiolites around the world..

But this non longer pertains to the topic of this talk.

Tectonometamorphic and structural evolution of the ophiolitic sequences from the central sector of the Catena Costiera (Northern Calabria)

FRANCESCO FILICE (*), FRANCESCA LIBERI (***), DANIELE CIRILLO (***), LUCA PANDOLFI (**)
MICHELE MARRONI (**) & EUGENIO PILUSO (*)

Key words: *Accretionary wedge, Calabria, Catena Costiera, deformation phases, HP/LT conditions, ophiolitic sequences.*

INTRODUCTION

Mesozoic ophiolitic units cropping out in the northern sector of Calabria. These are mainly composed of serpentinites, metabasalts and heterogeneous sedimentary covers, characterized by metapelites, metarenites, marbles and calcschists alternances (AMODIO MORELLI *et alii*, 1976; LIBERI *et alii*, 2006). The metabasalts show porphyritic and aphyric texture, and are characterized by both isotropic and foliated structures (DE ROEVER, 1972; AMODIO Morelli *et alii*, 1976; LIBERI *et alii*, 2006; LIBERI & PILUSO, 2009), with T-MORB tholeitic affinity (BECCALUVA *et alii*, 1982; LIBERI *et alii*, 2006; LIBERI & PILUSO, 2009).

In the metasedimentary cover, a remarkable increase in the carbonatic supply is noticed moving northtoward (LIBERI & PILUSO, 2009). In fact, the sedimentary sequences cropping out in the southern sector (Gimigliano-Monte Reventino Unit), consist of polychrome schist, marbles and alternating metapelites, metarenites and metacarbonate; the ophiolitic sedimentary covers cropping out in the northern sector (Diamante and Malvito Units) consist of thin levels of radiolarites and calcschists (LIBERI & PILUSO, 2009).

The present work focuses on the central Catena Costiera, considered as a transition zone between the siliciclastic-rich and the carbonate-rich sedimentary covers. On the base of a detailed geological survey and stuctural analysis two ophiolitic sequences has been identified: the Cozzo Cervello sequence, in the southern sector, and the Mongrassano sequence, in the

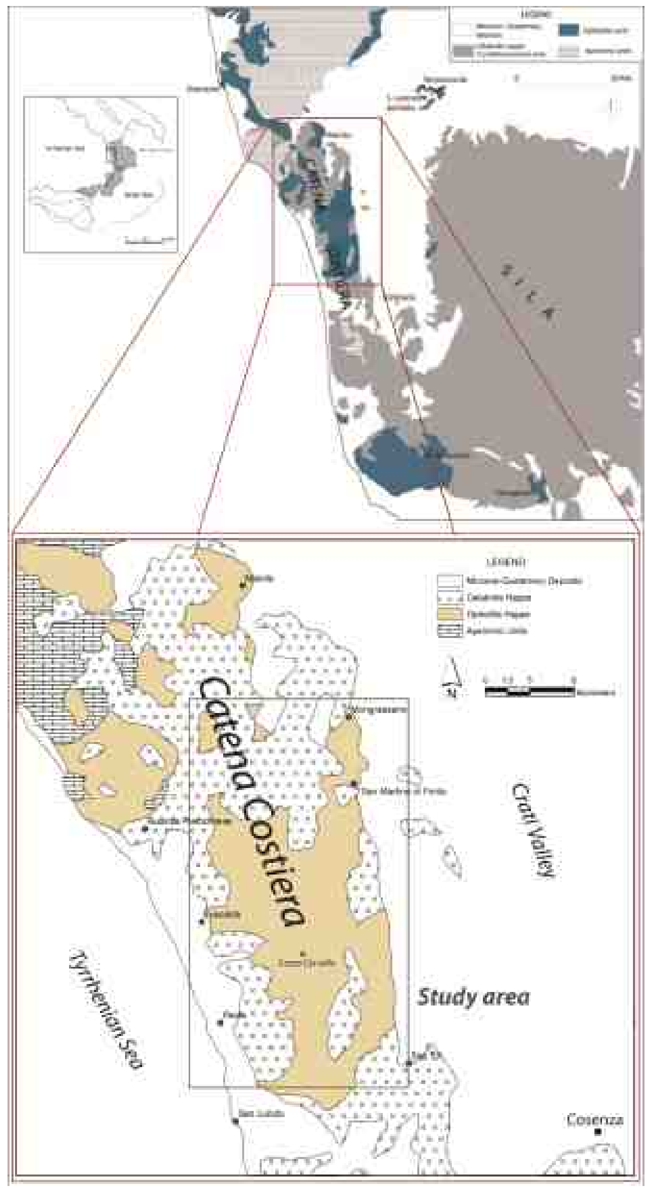

Fig. 1 – Tectonic sketch map of northern sector of Calabria and central sector of the Catena Costiera, with location of the study area (modified after Liberi & Piluso, 2009).

northern sector (Fig. 1).

The Cozzo Cervello sequence is characterized by metabasalts, rare metacarbonates, thin levels of meta-volcanoclastic sediments and alternating metapelites and metarenites; moving northward, the an increase in carbonate content can be observed in the metapelites. The Mongrassano sequence is characterized by metabasalts, meta-volcanoclastic sediments and calcschists. A thin level of cherty metapelites can be observed at the transition between the metabasalts and the calcschists, SW of Mongrassano area.

The tectonic contact between the two sequences can be observed along the left side of the Finita River. It is characterized by a cataclastic-mylonitic zone, about 15 meters in thickness, gently dipping to the NW (Fig. 2).

Fig. 2 – Tectonic contact between the Cozzo Cervello and Mongrassano ophiolitic sequences near the village of San Martino di Finita.

STRUCTURAL ANALYSIS

The studied rocks underwent a polyphase deformation history and the meso- and microstructural analyses allowed to distinguishing four main (D1-D4) deformation phases.

D1, this phase is characterized by a S1 foliation locally preserved in microlithons inside the S2 main foliation, testified by white mica and chlorite crystals;

D2, a N-S trending isoclinal folding event (F2; Fig. 3a-b-e) is responsible for the formation of the S2 foliation, which represents the main surface recognizable in the field. The blastesis of minerals indices of HP/LT conditions is associated to this S2 development: Na-amphibole + Lawsonite + Phengite in the metabasalts of Cozzo Cervello sequence; Lawsonite + Phengite in the metabasalts of Mongrassano sequence; Phengite + Stilpnomelane + Na-amphibole in the metapelites and metarenites; Phengite in the calcschist. Together with these minerals along the S2 grow: Albite + Chlorite + Epidote ± Quartz ± Calcite ± Magnetite ± Hematite in the metabasalts; Epidote + Chlorite + Albite + Quartz + Magnetite ± Pumpellyite ± Hematite in the metapelites and metarenites and Calcite + Chlorite + Albite + Quartz + Magnetite ± Epidote in calcschist.

The surfaces of the foliation S2 dip to ENE-WNW (Fig. 3c). The mineralogical lineation L2 associated with the D2 event is given by isoriented phenocrystals of albite and quartz, oriented mainly ENE-WSW (Fig. 4d).

D3, this phase is characterized by asymmetric folds (F3) developed at different scales and showing a NE-SW trending

axes with a NW vergence (Fig. 4a-b-e). An incipient NW-SE trending S3 foliation is locally developed in the phyllosilicate-rich levels (Fig. 4c). In particular, the blastesis of white mica and actinolite can be observed along the S3 in the metabasalts of Cozzo Cervello sequence and white mica and chlorite in the metapelites.

The mineralogical lineation L3 is oriented about NW-SE (Fig. 4d).

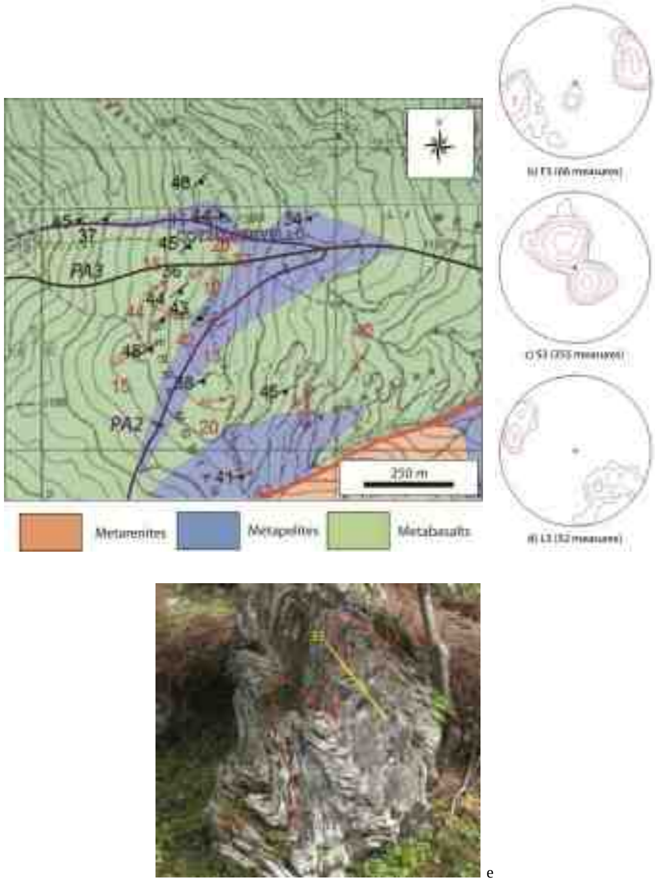

Fig. 4 – a) Asymmetric folding F3 at the map scale in the ophiolitic sequences. Stereographic projection (Schmidt net) of: b) Folds axes F3; c) poles to S3 foliation; d) stretching lineation L3. e) Folds F3 in the metabasalts of Cozzo Cervello area with development of foliation S3.

D4, this phase is characterized by close to open folds (F4) developed at different scales, with WNW-ESE trending axes. This folding does not develop a new foliation.

CONCLUSIONS

The field study and the tectonometamorphic evolution reconstructed for the ophiolitic sequences cropping out in the central sector of the Catena Costiera of Calabria show that a subduction and exhumation history inside an accretionary wedge can be proposed.

In particular, the characterization and the definition of the complex relationships existing within the ophiolitic sequences and metasedimentary cover allow us to propose:

- ✓ the metabasalts are involded, togheter with the metasediments, in the development of kilometric isoclinal structures of phase D2;
- ✓ since the D2 phase the metamorphic and structural evolution is perfectly comparable in the Cozzo Cervello and Mongrassano sequences;
- ✓ in the studied rocks the S2 foliation, which is the main structural surface, is characterized by the blastesis of minerals indicative of HP/LT physical conditions;
- ✓ the D3 deformation phase marks the path of exhumation of studied sequences;
- ✓ the contact between the Cozzo Cervello and Mongrassano sequences is tectonic, characterized by a cataclastic-mylonitic zone of about 15 meters in thickness.
- ✓ the actinolite has not been found in the Mongrassano sequence;
- ✓ the Mongrassano sequence, based on stratigraphic and petrographic features, can be regarded, as a working hypothesis, to a sub-unit of the Malvito Unit (*sensu* Amodio-Morelli *et alii*, 1976), which crops out in the northernmost sector of the Catena Costiera;
- ✓ the studied metasediments, previously included in a different tectonometamorphic unit (Bagni Unit: Dietrich and Scandone, 1972; Amodio-Morelli *et alii*, 1976), could be interpreted as the original sedimentary cover of the metabasalts.

Basic magmatism in the Triassic sequences from the Alpujarride Complex (Betic Cordillera, SE Spain) and the Lungro-Verbicaro Unit (Southern Apennines, Italy)

GILDA MATRANGOLO (*), FRANCESCA LIBERI (**), IVAN MARTIN-ROJAS (***) & EUGENIO PILUSO (*)

Key words: *Alpujarride Complex, Lungro-Verbicaro Unit, Triassic basic magmatism*

The basic rock intrude the mesozoic metacarbonate and metapelitic sequences belonging to the Alpujàrride Complex (Betic Cordillera, SE Spain) and Lungro-Verbicaro Unit (Southern Apennines, Italy).

These domains were involved in the geodynamic processes active in the Mediterranean region from the Mesozoic onwards and, in particular, in the opening of the Jurassic Tethys. In literature, both the HP/LT Alpujàrride Complex and the Verbicaro Unit are interpreted as passive margin successions deposited during the Triassic rifting. Triassic magmatic rocks in the Mediterranean area are distributed along the orogenic Apennines-Alpine-Dinaric-Hellenic-Rif-Betic belts.

In the Northern Calabria basic rocks are represented by pillow-lavas and dykes cutting through Triassic and Jurassic formations (Iannace et al., 2007). In the Betic Cordillera gabbros intrude metasedimentary successions until Middle Trias (Vera J.A.,ed. 2004 and references therein).

Within the Alpujarride Complex, the basic rocks are represented by: tabular bodies cutting through the Triassic phyllites-quarzites successions, in the SE sector where they are distributed on large areas, and by basic dikes intruding Triassic fractured carbonate in the SW sector.

In Northern Calabria, small intrusive complex intrudes in the Anisian phyllites and in the Ladinian-Carnian carbonate formation of Lungro-Verbicaro Unit. The stratigraphic succession of Lungro-Verbicaro Unit is affected by HP-LT (Iannace et al., 2007). Other basic rocks occurrences are represented by ortocumulites (limburgites Auct.), associated to gabbros intruding early-middle Jurassic calcarenites and basic dikes cutting through the Jurassic carbonate.

The field observations showing that the basic rocks of Alpujarride Complex and Acquaformosa area intruding Triassic carbonate successions, while the basic rocks of Verbicaro area differ both for the cutting age of Formation (get to Jurassic) both for HP-LT documented for Na-Amph.

Petrographic analysis carried on gabbros and basalts from the Alpujarride Complex, all intruding Triassic sedimentary sequences, allowed to distinguish:

i) variously retrogressed, medium-coarse grained gabbros with an ophitic structure and mineralogical assemblage made of Pl+Cpx+Hbl+Act+Ep+Bt+K-mica+Chl+Mag+Qz.;

ii) deformed gabbros showing the development of a milonitic pervasive foliation, the mineralogical assemblage is made of Pl+Cpx+Amph+Ep+Chl+Qz+Carb+Mag;

iii) the basalts, showing porphyritic to glomeroporphiritic texture, with a mineralogical assemblage of: Pl+Cpx+Ilm phenocrysts, set up in a fine grained groundmass.

The gabbros intruding the Triassic sedimentary sequences are characterized by a mineralogical assemblage made of Pl+Cpx+Hbl+Act+Ep+Chl+Qz+Mag.

The ortocumulites mineralogical assemblage is made of Ol+poikilitic Cpx+Phl. The associated gabbros appear to be retrogressed and mineralogical assemblage is made of Pl+ Cpx+Qz+Mag.

The mineralogical assemblage of the basic dikes that intruding the Jurassic sedimentary sequences is made of Na-Cl-Amph+Stp+Chl+Pmp+Cal+Mag, thus showing evidences of HP–LT metamorphism.

Bulk rock compositions (XRF) suggest the presence of two suites: 1) the samples from Northern Calabria and seven from the Betic Cordillera show an alkaline to alkaline-transitional character and have a relatively low Y/Nb vs Zr/Nb ratio; for these samples, according to the La/10-Y/15-Nb/8 diagram, a continental to intracontinental rift context is supposed; 2) most of the samples from the Alpujarride Complex show a linear fractionation trend in the Ti/V diagram, according to the La/10-Y/15-Nb/8 diagram they plot in the basalt calc-alkaline fields.

Coupled ferritchromite and chromian-chlorite in mantle rocks: a comparison from circum-mediterranean ophiolites

A. MERLINI (*), P. TARTAROTTI (*), G. GRIECO (*), M.T.C. SANSONE (**), G. RIZZO (***), G. PROSSER (**)

Key words: *ferritchromite, chlorite, alteration, ophiolite, serpentinite, chromitite.*

Spinel is a common accessory mineral in peridotites, where it ranges in composition from spinel s.s. to chromite. The chemical composition variation depends on the petrogenesis and physical conditions of the hosting peridotite (e.g. DICK & BULLEN, 1984). Unaltered, primary igneous spinel can be thus considered as a petrogenetic indicator however, the discussion on spinel alteration due to metamorphic modification is still ongoing (e.g. EVANS & FROST, 1975; OZE *et alii*, 2004). In ophiolites, late metamorphic alteration of spinel leads to the growth of secondary phases such as ferritchromite and chromian-chlorite.

In this study we focused on cr-spinels and chromite detected in serpentinite and in chromitite of different ophiolites, in order to highlight chemical and textural differences due to metamorphic alteration processes in the two lithologies. We considered the following ophiolite complexes: Vourinos (Greece), Troodos (Cyprus), Hatay (Turkey), Liguride and Antrona (Italy).

The Vourinos complex, located in Western Makedonia (Greece), exhibits an almost complete ophiolitic sequence belonging to the Tethyan ophiolitic belt. The mantle sequence comprises harzburgite interlayered with dunite, dunite bodies containing chromitites and websteritic dykes.

In Vourinos, chromitite pods are concentrated within the metalliferous zone, an incipient ductile thrust within the mantle section (RASSIOS, 2004). Spinel of the studied samples shows a wide range of compositions covering the fields of chromite, Fe-chromite and magnetite. Original high temperature spinel is chromite and is found as unaltered or only partially altered grains in chromitite, dunite and harzburgite, while in serpentinite it is sometimes completely altered or forms relics at the core of altered chromite. Chromite from chromitites has the highest Cr_2O_3 content, ranging between 57 and 60 wt%. The values of Mg# and Cr# cover the field of known Vourinos chromites within chromitite ores. No differences in primary chromite between the sampled mines (Rizo, Potamia, Xerolivado, Aetoraches) have been detected except for a generally lower Cr# for the Rizo mine. In chromitites, in spite of the narrow range of the primary chromite composition, ferritchromite composition spans over a large range of Cr# and Mg#. Fe-chromites from serpentinites show anomalously high NiO and MnO contents with respect to chromite from chromitite. In one serpentinite sample, Fe-chromite rims locally show a NiO enrichment up to 0.30 wt%, when compared with a normal content below 0.10 wt%. MnO in Fe-chromite was detected in two samples and it is as high as ca 8 wt%.

Troodos complex is a Mid Cretaceous (91 million years old) ophiolite showing a typical sequence from basal tectonite harzburgite to pillow lavas. The cumulate sequence overlaying and surrounding the harzburgite grades from a thick basal dunite to wehrlite, pyroxenite and gabbros. Two late plutonic sequences have been also recognized. Troodos ophiolite is moderately rich in chromite which occurs as an accessory mineral in several ultramafic rock types of the mantle sequence. Chromites detected in chromitite are generally characterized by high Cr# in the range 0.72-0.85, and by Fe# in the range 0.30-0.60; Cr_2O_3 content is never below 50 wt% and it is usually between 56 and 60 wt%, and between 53.5 and 54 wt% in few grains of more disseminated textures. MgO and FeO contents are respectively between 10 and 12 wt% and between 14 and 16 wt %. Al_2O_3 is generally between 7.8 and 9.5 wt%. Extremely high Cr_2O_3 concentrations (close to 63 wt%) have been detected in altered ferritchromite rims. Such values are related to late serpentinization and post serpentinization alteration processes that led also to formation of chromian-chlorite.

The Hatay Ophiolite complex (Southern Turkey) includes both crustal and serpentinized mantle units. Contacts between the units are both primary and tectonic. Serpentinites host several small chromitite lenses that underwent limited exploitation in the last century. The chromitite lenses show an average thickness of 0.2 m and they supposedly extend for several tens of meters. The chromitite bodies show a massive to densely disseminated texture with 30 to 80% modal spinel in a serpentinite-chlorite matrix. Chromite grains show typical textures of ophiolitic environment and are fractured, with minimal to intense alteration affecting the margins of the grains.

Ferritchromite-chromian chlorite alteration occurs with peculiar characters, with a coronitic texture related to the alteration of primary spinel. Alteration perfectly preserves the original shape of millimetric spinel grains (isolated or in aggregates) and transformation occurs from rim to core. Primary spinel is preserved only as irregular, optically homogeneous core portions. The first anomaly of this sample starts with the composition of the primary spinel cores, which are anomalously

(*) Università degli Studi di Milano, Dipartimento di Scienze della Terra "A. Desio", via Botticelli, 23 - 20133, Milano

(**) Università degli Studi della Basilicata, Dipartimento di Scienze Geologiche, Viale dell'Ateneo Lucano, 10 – 85100 Potenza

(***) Università degli Studi della Basilicata, Dipartimento di Chimica, Viale dell'Ateneo Lucano, 10 – 85100 Potenza

Cr-poor and Al-rich. Such cores are surrounded by a first corona composed of very fine-grained chromite highly enriched in Cr and moderately enriched in both Fe^{2+} and in Fe^{3+}. A second, external alteration rim is coarser and is made up of highly Fe^{3+}-enriched Cr-rich spinel intergrown with a fine-grained chlorite.

Chlorite also overgrows the altered spinel both along the margins and within fractures. Close to the spinel rims chlorite shows detectable Cr_2O_3 contents (1-2 wt%) which are however low if compared to kammererite usually associated to ferritchromite. A halo of fibrous serpentine encloses the altered spinel+chlorite assemblage.

The observed textures allowed the distinction of three types of Cr-bearing spinel, the primary type (I), the internal rim type (II) and the external rim type (III).

Type I primary spinel cores are rather Cr-poor and show a remarkably constant composition, with Cr_2O_3 around 27 wt%, Al_2O_3 around 40 wt%, and MgO about 17 wt%. Minor variations are shown for Fe contents, with FeO ranging between 11.4 and 12.3 wt% and Fe_2O_3 ranging between 2.3 and 3.1 wt%.

Much stronger compositional variations are shown by the two other spinel types which also possess highly complex textures.

Type II rim spinel is much more enriched both in Cr and, to a lesser extent, Fe (bivalent and trivalent) than the primary core spinel. Cr_2O_3 content ranges between 37 and 41.4 wt%, FeO varies between 19.3 and 26.5 wt% and Fe_2O_3 between 7.6 and 13.5 wt%. Comparatively Al and Mg are depleted, as Al_2O_3 can range between 5 and 9.4 wt% and MgO varies between 5 and 9.4 wt%.

Type III spinel in the external rim is still remarkably Cr-rich although it is affected by a substantial increase in ferric iron. As a matter of fact, MgO, Al_2O_3 and FeO contents are basically similar to type II spinel contents, whereas Cr_2O_3 content varies between 29.8 and 36 wt%, and Fe_2O_3 ranges between 24.5 and 35.6 wt%.

The Antrona Ophiolite is interpreted as a remnant of the oceanic lithosphere of the Mesozoic western Tethys, now inserted as tectonic slices in the Penninic nappe pile of the western Central Alps. The ophiolite sequence includes serpentinized ultramafites, metagabbros and mafic rocks covered by calcschists. The tectonic and metamorphic evolution of the Antrona Ophiolite is mostly related to the Alpine history, nevertheless, relics of the original textures are still recognizable. Namely, olivine-clinopyroxene-spinel-bearing serpentinites still retain relict porphyroclastic texture, commonly attributed to mantle-derived peridotites. Mineral chemistry of relict olivine, clinopyroxene and spinel, as well as olivine fabric also contribute to support a mantle nature of the serpentinite protolith (TARTAROTTI *et alii*, 2011).

Spinel has been studied in selected samples of coarse-grained ol-cpx-spl (±amp, ±chl)-rich rocks (sample ANT120) and in dunite (sample ANT64). Crystals are sub-millimetric and their shape recalls the holly-leaf habit commonly described in mantle-derived peridotites. Spinel is always rimmed by a thick corona of chlorite.

As shown by BSE images, spinel crystals reveal a porous texture without any evident core-to-rim zoning. These crystals have a ferritchromite composition with Cr# ranging between 96 and 98. In peridotite ANT120, Cr_2O_3 ranges between 53 and 58 wt%; MgO between 1.7 and 1.9 wt%; Al_2O_3 between 0.7 and 0.8 wt%; FeO_t wt% ranges between 35 and 40. In dunite ANT64 Cr_2O_3 ranges between 55 and 58 wt%; MgO between 2.4 and 3.2 wt%; Al_2O_3 between 1 and 1.4 wt%; and FeO_t wt% ranges between 35 and 37.

Chlorite surrounds holly-leaf-shaped ferritchromite. BSE images show that chlorite occurs not only as acicular crystals in coronae surrounding spinel but also as crystals intimately associated with porous ferritchromite core. Chlorite occurring in spinel core has a chromian-chlorite composition (e.g., Merlini et al. 2009) being characterized by Cr_2O_3 contents of ~3 wt%. Chlorite rimming spinel porphyroblasts and in the groundmass has relatively low Cr_2O_3.

The Liguride Complex in Southern Apennines consists of tectonic units including sedimentary and metamorphic sequences of Upper Jurassic to Upper Oligocene age (MONACO & TORTORICI, 1994). These units englobe several bodies of oceanic as well as continental crust (VEZZANI, 1969). In the Liguride Complex, the Frido Units is exposed for about 10 km, from the Frido Valley to NW, to the Sarmento valley, to SE.

The serpentinites of the Frido Unit were collected at San Severino Lucano village and at Fosso Arcangelo, located at the Calabria-Lucanian border. The studied serpentinites are distinguished into cataclastic and massive (SANSONE *et alii*, 2012). Primary mantle minerals are represented by olivine, orthopyroxene, clinopyroxene and spinel. Pseudomorphic minerals are serpentine, magnetite and tremolite. Olivine is replaced by serpentine forming a mesh texture; orthopyroxene is mostly altered to bastite and in some cases shows exsolution lamellae of clinopyroxene and kinkbands. Clinopyroxene is armoured by a tremolite rim. Spinel shows a holly-leaf habit and is often armoured by a corona of Cr-chlorite. Spinel forms red-brown coloured xenomorphic, holly-leaf shaped porphyroclasts. Spinel porphyroclasts are always rimmed by fine-grained chlorite. In some samples spinel is replaced by pseudomorphic magnetite occurring in fine-grained crystal aggregates. The analyzed spinel porphyroclasts are characterized by a strong chemical zonation with Al-rich cores and Fe-Cr-rich rims.

The core of the analyzed spinel has a Cr-Al spinel composition corresponding to chromite (Al_2O_3 = 29-31 wt%; Cr_2O_3 = 28-37 wt%), whereas the rim has a ferritchromite composition (Al_2O_3= 1-2% wt; Cr_2O_3=28-30 wt%). The Cr-Al spinel/ferritchromite ratio may be various in different spinel porphyroclasts. The Mg content ranges between 4.862 and 5.140 a.p.f.u. at the core and between 1.203-2.251 a.p.f.u. at the rim. Manganese content is very low at the core (MnO = 0.06-0.11 wt%), whilst it is as high as 5.41 wt% at the rim.

CONCLUSIONS

As confirmed by textural and chemical evidences in serpentinite units of Antrona and Liguride complexes, ferritchromite and chromian-chlorite formation after chromite and serpentine is due to a prograde metamorphic reaction that commonly goes unnoticed because of the rarity of chromitites in mantle rocks and the proportions of reactant phases. In serpentinites, due to high serpentine to spinel ratios, this alteration forms only small chromian-chlorite aureolas around spinel grains, while most of serpentine remains unreacted. In chromitites, the effects of alteration are much more visible as these rocks have chromite to serpentine ratios that are much closer to the 34.16 % modal chromite content necessary for leading to a more complete reaction within the rock (Merlini et al., 2009). The resulting assemblage in chromitites is a completely chloritized matrix and a chromite that is from partially (in massive chromitites) to completely (in disseminated chromitites) altered into ferritchromite.

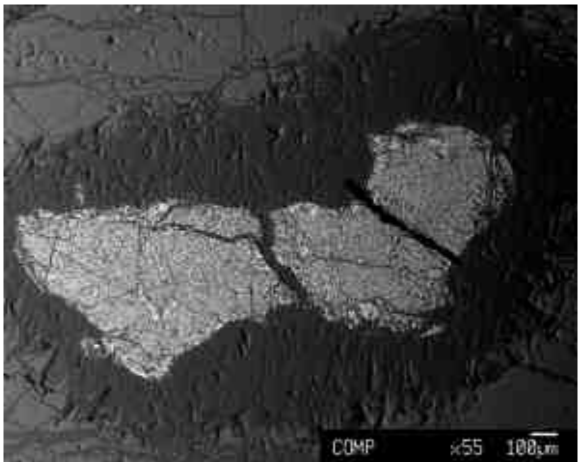

Fig. 1 – Completely ferritchromite altered grain surrounded by a chromian-chlorite aureola in serpentinites of Antrona ophiolite

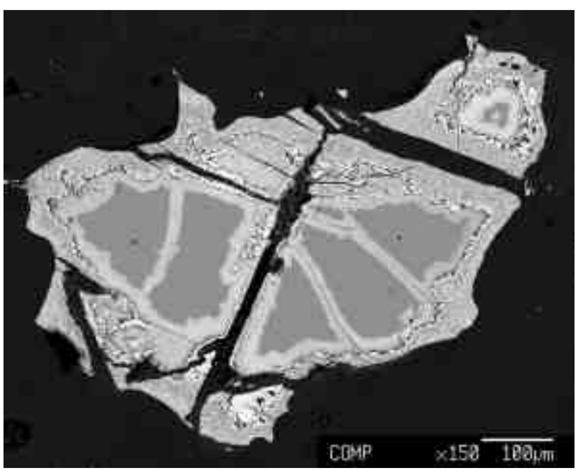

Fig. 1 – Chromite grain partially altered into ferritchromite and surrounded by chromian-chlorite with rare relics of serpentine in massive chromitite from Hatay ophiolite

The Voltri Massif: Hic sunt leones?

GIOVANNI B. PICCARDO (*)

PREFACE

We present and discuss new detailed field and petrologic investigations of the Voltri Massif (Ligurian Alps, Western Italy), and particularly on their ultramafic Units (Beigua serpentinites and Erro-Tobbio peridotites), and we furnish an innovative model for the formation of the Voltri Massif.

From the late seventies to present, the primary features of the unaltered Erro-Tobbio mantle peridotites were thoroughly investigated from structural, petrologic and geochemical points of view to unravel the evolution of the sub-continental mantle lithosphere during pre-oceanic continental extension and rifting of the Europe-Adria system Now-a-day the Erro-Tobbio peridotites represent one of the best, almost unaltered mantle peridotites of the whole Alpine-Apennine chain, which preserve mantle structural and compositional characteristics allowing to reconstruct their pre-Alpine (pre-oceanic) evolution.

Recently, it was sustained (CAPPONI, CRISPINI & SCAMBELLURI , 2009) that *"the eclogite-facies metamorphic imprint* (i.e., metamorphic recrystallization) *in the Erro–Tobbio is not a local feature, but is widespread and affects the entire volume of the Erro–Tobbio peridotites"*. These assertions imply that the entire volume of the Erro-Tobbio peridotites was affected by the eclogite-facies Ticlinohumite-bearing antigorite + olivine assemblages when subducted.

Recently it was sustained (e.g., SCAMBELLURI & TONARINI, 2011) that the Erro-Tobbio peridotites *"were early serpentinized by low-temperature metamorphic fluids likely arising from a subducting lower plate* (when residing in the Adria mante wedge), *were introduced in a subduction channel and underwent dehydration at eclogite-facies conditions"*.

I consider completely erroneous and unfounded these assertions.

A simply notation: the Erro-Tobbio peridotites are there, in the Voltri Massif, NW of Genova, andbasic knowledge of mantle petrology can help geologists and geochemists to study and understandthese rocks in the field, even these *"unknown and mysterious"* mantle peridotites.

Tom Thayer said to me at the 1972 Penrose Conference on Ophiolites:

"NATURE DOESN'T KNOW GEOLOGY"

(*) DISTAV.., University of Genova, Corso Europa 26, I-16132, Italy

INTRODUCTION

Because of the recently renewed interest on subduction and tectonic emplacement in the Voltri Massif, I will briefly summarize present knowledge on the Ligurian-Piedmont basin, and I willfocus mostly on petrology-constrained subduction and exhumation processes of the ultramafic Units of the Voltri Massif, to put firm petrologic and geodynamic constraints to the evolution of the basin.

The Ligurian Tethys basin was a slow-ultraslow spreading basin formed by continental extension in the Europe-Adria system, which formed extended rifted margins, and was mostly floored by mantle peridotites. The oceanic mantle consisted of extended and thinned lithospheric mantle which was percolated by MORB-type melts and underwent significant melt/peridotite interactions. On the contrary, the Europe and Adria rifted margins were characterized by the presence of exhumed subcontinental mantle of the Europe-Adria system.

The Voltri Massif was classically interpreted as a pile of tectonic units of mafic, ultramafic and sedimentary rocks deriving from the Late Jurassic Ligurian Tethys oceanic basin which, after subduction to, and exhumation from eclogite-facies conditions were emplaced westward onto the Brianconnaise (Europe) margin (CHIESA *et alii*, 1975). The Erro-Tobbio peridotites were considered sub-continental mantle of the Insubrian (Adria) plate that was tectonically emplaced above the HP units of the Voltri Massif. The presence of olivine + antigorite + Ti-clinohumite ± diopside assemblages in the Voltri Massif serpentinites and in the Erro-Tobbio peridotites were interpreted as records of HP metamorphism, comparable to the eclogitic recrystallization of the mafic rocks. Accordingly, both the Beigua serpentinites and the Erro-Tobbio peridotites underwent subduction to, and exhumation from HP conditions. At the level of the Voltri Massif E-W traverse of the basin, subduction was most probably intra-oceanic and located close to the Adria margin.

THE VOLTRI MASSIF

The protoliths of the Beigua serpentinites were the uppermost hydrated level of the Europe oceanic lithosphere which mostly consisted of lizardite + chrysotile serpentinite and was depleted of Ti, since the Ti repositories in mantle assemblages (clinopyroxene + spinel) were recrystallized to Ti poor/free diopside and magnetite. Moreover, the gabbroic intrusions into the Beigua protoliths frequently underwent rodingitization (Si-alkalies depletion, Mg-Ca enrichment). The protoliths of the Erro-Tobbio peridotites were the sub-continental lithospheric mantle of the Adria margin which mostly escaped sea-floor alteration and maintained the Ti contents in their mantle minerals. The eastward subduction of the oceanic slab of the Europe plate carried down the uppermost serpentinized level of the oceanic slab (the future Beigua antigorite serpentinites), which was the most significant carrier of water into the mantle. Oceanic serpentinites recrystallized to antigorite and then to olivine + antigorite at eclogite-facies conditions. Scarceness of Ti-clinohumite in the HP assemblages evidences that Ti was lost by the system during sea-floor alteration. HP assemblages in the Erro-Tobbio meta-peridotites are present in limited outcrops: they show significant contents of Ti-clinohumite. This suggests that these peridotites reached unaltered the HP conditions and underwent break-down of Ti-bearing mantle minerals (clinopyroxene recrystallized to Ti-poor/free diopside), in the presence of water. Accordingly, the unaltered sub-continental protoliths of the Erro-Tobbio peridotites were the carriers of Ti to HP conditions. HP assemblages in the Beigua serpentinites indicate partial antigorite dewatering and new olivine crystallization (***formation of olivine–bearing antigorite serpentinites*). In the Erro-Tobbio peridotites, mineral breakdown and Ti-clinohumite+olivine crystallization must were assisted by fluxing of external fluids (***formation of Ti-clinohumite+antigorite-bearing meta-peridotites***).

THE ECLOGITE-FACIES HYDRATION IN THE ERRO-TOBBIO PERIDOTITE

Limited outcrops of the Erro-Tobbio peridotite protoliths underwent a process of eclogite-facies hydration assisted by fluxing of water. HP hydration occurred also in unaltered Mg-Al gabbroic dykes cutting the Erro-Tobbio peridotite which recrystallized to HP omphacite + chloritoid + garnet + zoisite ± talc assemblages, in the presence of water. Eclogite-facies recrystallization in metagabbros occurred at pressure in the range 1.8-2.5 GPa and temperatures in the range 500 - 650°C These data are well consistent with P-T estimate for the eclogite-facies recrystallization in the Erro-Tobbio meta-peridotites. Partial antigorite dehydration of the Beigua serpentinites at eclogite-facies conditions, to form metamorphic olivine, released water which fluxed into the unaltered Erro-Tobbio peridotites, enhancing crystallization of hydrous phases (i.e., Ti-clinohumite and minor antigorite) in limited bodies. The relative abundance of Ti-clinohumite in the HP assemblages in meta-peridotite of the Erro-Tobbio peridotites indicates that Ti and Ti-bearing mantle minerals reached the eclogite-facies conditions . The presence of olivine + Ti-clinohumite veins suggests that Ti is mobile in fluid phases at eclogite facies conditions and that it was released at HP conditions. Accordingly, both hydrous antigorite serpentinites and anhydrous mantle peridotites must have reached together the HP eclogite-facies conditions.

SUBDUCTION AND EXHUMATION OF THE VOLTRI MASSIF ULTRAMAFIC ROCKS

Experimental data demonstrated the large stability field of antigorite to maximum depths of about 200 km. As for the Voltri Massif, convergence in the Ligurian Tethys basin caused eastward subduction of the oceanic lithosphere of the Europe plate, which mostly consisted of sea-floor exposed mantle peridotites. The uppermost level of hydrated oceanic peridotites provides reliable evidence for the presence of a weak serpentinite layer on top of the subducting slab, according to subduction-channel models and recent pertinent bibliography (see references in PICCARDO & PADOVANO, 2012), I suggest that slices of the unaltered sub-continental lithospheric mantle of the Adria plate (the future Erro-Tobbio peridotite) underwent ablative subduction, i.e, they were progressively eroded, dragged and buried within the serpentinite-subduction channel and carried to eclogite-facies conditions. The formation of a serpentinite-subduction channel, which acted as a low-viscosity carrier for high density subducted rocks, allowed exhumation of the Voltri Massif high-pressure mafic rocks (eclogites and HP meta-gabbros) and unaltered mantle rocks (Erro-Tobbio peridotites). The highly deformed serpentinite matrix of the subduction channel preserved most of the anhydrous Erro-Tobbio mantle peridotite from hydration and recrystallization during subduction and allowed its rapid exhumation. The almost unaltered peridotites from the Adria rifted margin reached HP conditions and preserved as a whole their primary mantle features, as they show now-a-day in mountain-wide outcrops. Our field investigations evidence that pluri-km-scale volumes of unaltered Erro-Tobbio peridotites are partially embedded within a carapace of Beigua serpentinites. Moreover, km-scale bodies of unaltered Erro-Tobbio peridotites are completely embedded within the Beigua serpentinites. The contacts between the two rock types are generally sharp, and the outer margins of the Erro-Tobbio peridotite bodies show meter/decameter-wide areas of HP Ti-clinohumite-bearing meta-peridotites. This indicates that partial hydration of anhydrous mantle peridotites occurred at eclogite-facies conditions. In most cases, the Beigua serpentinite schistosity envelopes the Erro-Tobbio peridotite bodies, which represent km-wide mega-boudins within the Beigua serpentinite-schists. These relationships represent a significant field evidence which constraints that the Erro-Tobbio peridotites were exhumed within a carapace of Beigua serpentinites or completely embedded within the Beigua serpentinites. Generally, these peridotite bodies show antigorite serpentinization for a few to several meters from the contacts, which partially obliterates the pre-existing HP metaperidotites. This serpentinization stage was, accordingly, related to exhumation and tectonic emplacement. Antigorite serpentinite shear zones (i.e. serpentine mylonites) are widespread in the Erro-Tobbio peridotites and their structural relationships with the Ti-clinohumite-bearing veins and meta-peridotites allow to recognize their role in subduction, exhumation and emplacement.

CONCLUDING REMARKS

Field, structural and petrologic studies of the mountain-wide outcrops of unaltered Erro-Tobbio peridotites confirm that they mostly escaped hydration, when residing at the Adria margin, and HP recrystallization, when subducted to eclogite-facies conditions. They mostly preserved their primary mantle structures and compositions, which allowed to reconstruct their pre-oceanic evolution.

The Levanto-Bracco ophiolitic units as a Core Complex of a Tethyan Jurassic slow spreading ridge

GIANFRANCO PRINCIPI (*), BENEDETTA TREVES (**) & FRANCESCO MENNA(*)

Key words: *Oceanic Core Complex, Apennine Ophiolites, Western Tethys, Vara unit I* .

ABSTRACT

In the Levanto-Bracco area (Eastern Liguria, Northern Apennine) a beautifully exposed portion of Jurassic gabbro-peridotitic oceanic lithosphere crops out. It forms two north-east vergent subunits belonging to the Vara Unit. One is the Velva subunit, consisting of lherzolitic peridotites covered by ophicalcites, then by Jurassic cherts and Cretaceous pelagites. South westwards (Framura-Levanto), the lherzolitic peridotites pass to gabbros (Bonassola) through a Jurassic tectonic contact, both covered by a composite thick volcano-sedimentary succession. Eastwards the underlying Mt. San Nicolao (Bracco) Subunit include all Bracco gabbroic Massif, one among the best preserved magma chamber of the Jurassic Western Tethys.

The gabbros, well exposed both in Bonassola and the Bracco ridge show evident magmatic stratification marked both by compositional and granulometric banding, cut by veins with hornblende and oligoclase/albite neoblastesis. The Bracco gabbroic Massif (800-1000 m thick) lies upon lherzolitic mantle peridotites and consists of a layered alternation of melatroctolites, troctolites, olivine gabbros, gabbros and plagioclasites. The ultramafic lithotypes are concentrated towards the stratigraphic base of the gabbro. At the top, the gabbroic complex makes transition to the Jurassic sedimentary cover through some intensely fractured and hematitized gabbros, rarely actual gabbro breccias, similar to the ophicalcites that are found at the top of the lherzolites.

According to the different thickness of the volcanic sedimentary cover, the eastern Velva and Mt. San Nicolao subunits have been interpreted as oceanic mantle/crust topographic highs. On the contrary the western (Framura-Levanto) Velva Subunit ophiolitic succession, which shows several hundred meters of basalt flows and pelagic cherts on top, should have formed in a basin low.

In the gabbros (both Bonassola and Bracco) the magmatic banding is characterised by iso-orientation and flattening of minerals, especially plagioclase, with also folding, indicating synmagmatic deformation of the crystal-mush. During cooling, (around 900°-1000°C) the gabbroic massif was affected by HT-LP oceanic metamorphism producing shearing with flaser structures (mylonites) locally associated to a brown hornblende, pyroxene and high-Ca plagioclase paragenesis. Similar structures can be found in the ophicalcitized mantle lherzolites.

These structures are cut by few basalt dykes, with cm to m thickness. These dykes, seem to be contemporaneous to the hornblende and oligoclase veins (formed at 600-500°C), as they crosscut each other. They mark the inception of a brittle regime of deformation in the oceanic crust. In the last phases, the environment became colder (< 400°-300°), and more fractures, cataclastic zones and finally ophicalcites formed.

This tectonic history, from mylonites to ophicalcites, documented in the gabbroic and peridotitic masses has already been interpreted as recording the extensional exhumation of a poorly depleted mantle slice, with rare gabbroic bodies. The interpretations differ from subcontinental lithospheric detachment to various kinds of oceanic exhumation with gravity discharge. The coeval ages of the Bracco gabbros (164 Ma) and the pelagic sediments beneath the massive basalt flows of Levanto (Bayocian-Early Bathonian:169-164 Ma), together with the lack of continental "extensional allochthonous" fragments associated to the lherzolites, exclude, in our view, that this exhumation occurred in a sub-continental lithospheric environment.

As supporting evidence, in the last 20 years, several modern analogues have been found along slow-spreading oceanic ridges (e.g., Atlantis Bank -Southwest Indian Ridge, Atlantis Massif - Mid-Atlantic Ridge), characterized by the exposure of "oceanic core complexes", and along very slow spreading ones (e.g. Gakkel Ridge).

The structures and stratigraphy of the Bracco gabbro Massif and the eastern Velva Unit peridotites fit well the models of exhumation along extensional lithospheric oceanic detachments of modern oceanic core complexes. In particular, they could represent an "Inner Corner" (intersection of the inner side of a ridge and the active termination of a transform fault) of the Western Tethys mid oceanic ridge. The Framura-Levanto "basinal" topography, instead, may have developed in an "Outer Corner" or in a relative depression near the ridge axis in which basalt lavas flowed.

We think that the major lithospheric extensional

detachment surface in the eastern Ligurian ophiolites is represented by the mylonitic zones and by the ophicalcitic 'carapace' that characterize the upper portions of both peridotites and gabbros, whereas the mylonites deeper inside the gabbroic bodies represent minor shears that accommodate the crust-mantle exhumation.

On the metamorphic ophiolites of the western Alps: 40 years after the Penrose Conference

GISELLA REBAY (*), MARIA IOLE SPALLA (**), SILVANA MARTIN (***) & ROGER POWELL (°)

RIASSUNTO

Quaranta anni dopo la Penrose Conference: considerazioni sulle ofilioti metamorfiche delle Alpi occidental.

Con una serie di esempi si intende mostrare qui come sia progredita la maniera di interpretare le ofioliti di alta pressione delle Alpi Occidentali negli ultimi quaranta anni. Il ricorso alla modellizzazione termodinamica delle fasi all'equilibrio combinato con l'analsi srutturale a differenti scale e con una accurata analisi petrografica permette di individuare unità tettono-metamorfiche con una evoluzione metamorfica Alpina uniforme. Questo può consentire la ricostruzione dell'evoluzione completa della litosfera oceanica della Tetide nel dominio alpino.

Key words*: HP ophiolites, HP serpentinites, metagabbro, tectono-metamorphic evolution, Western Alps.*

INTRODUCTION

Ophiolites outcrops offer a unique opportunity to study directly the oceanic lithosphere, as they represent one of the few exposures of otherwise unreachable rock bodies. In the last 40 years relevant progress has been made on the direct observation and study of ocean floor geology, but there still remain many problems to be solved. Ophiolites are mostly found in sutures in collisional chains, and therefore the original relationships amongst rocks are reworked by tectonics and metamorphism. Nonetheless, our ability in unravelling deformation and metamorphic processes has been significantly improved allowing new insights not only in the transformations to which the oceanic rocks have been subjected in subduction zones, but also on their structure.

GEOLOGICAL SETTING

The suture zone of the Western European Alps, deformed under HP-conditions during the Alpine subduction and collision (e.g. DAL PIAZ *et alii*, 2001 and refs therein) is made of metaophiolites and metasediments. This ophiolitic suture, constituted by the Zermatt-Saas and Combin Zones, is tectonically sandwiched between the continental internal massifs and the external nappes respectively belonging to the Penninic and Austroalpine and Helvetic domains (e.g. MARTHALER & STAMPFLI, 1989; DAL PIAZ *et alii*, 2001).

The Zermatt-Saas Zone mainly consists of serpentinite, metagabbros, and metabasalts with minor calcsilicates and quartzites (Fig. 1) (ERNST & DAL PIAZ, 1978; BECCALUVA *et alii*, 1984; PFEIFFER *et alii*, 1989, MARTIN *et alii*, 1994). These rocks preserve HP or UHP mineral assemblages, developed during the Alpine convergence, and overprinted by exhumation-related metamorphism (e.g. ERNST & DAL PIAZ, 1978; REINECKE, 1991; LI *et alii*, 2004; Rebay et al., 2012). The age of the oceanic protoliths spans from 164 to 153 Ma (RUBATTO *et alii*, 1998) and structural and mineral relics show that these protoliths were affected by oceanic metamorphism before the Alpine subduction (e.g. DAL PIAZ *et alii*, 1980, LI *et alii*, 2004). Relict oceanic textures are well documented in the Zermatt-Saas Zone (e.g. BARNICOAT & FRY, 1986).

The Combin unit is mainly made of metasediments (the *Schistes Lustrés* Unit) and metabasalts with blocks of ophiolites metre up to kilometre-sized, scattered into these calcschist-rich series (TRICART & SCHWARTZ, 2006). In the Piedmont Zone the pelagic sediments record a metamorphic evolution under high-P/low-T conditions in the blueschists facies (e.g. POGNANTE, 1991), that, lateron, during exhumation, was re-equilibrated under greenschist facies conditions.

EXAMPLES

Some significant examples of the improvement of our knowledge on the metamorphic ophiolites from the western Alps are here portrayed.

For instance, it has been shown that eclogitised serpentinites from the Valtournanche valley (REBAY *et alii*, in press) have undergone an HP metamorphic evolution while preserving relationships and parageneses that are indicative of an oceanic metamorphic evolution. Here structures and relict parageneses indicate that these mantle rocks underwent a complex oceanic metamorphism involving their almost complete hydration before the subduction. Evidences of such a pre-Alpine evolution, that can be found in serpentinites and enclosed metagabbro, deserve at least a short discussion. Similar relations and parageneses can be observed in the Voltri Group (see REBAY *et alii*, 2004, and refs therein). In both examples this early oceanic evolution has important bearing on the subsequent alpine HP evolution where fluids played again an important role (SCAMBELLURI & RAMPONE, 1999). Metagabbros from the Monviso ophiolite show similar evidences (MESSIGA *et alii*, 1999) of widespread hydration during oceanic evolution.

Moreover, it is relevant the oceanic palaeo-hydrothermal system preserved in the St Marcel Valley (MARTIN *et alii*, 2008; REBAY & POWELL, in press). In this case, different rock-types development of peculiar HP mineral assemblages took place, depending on the bulk rock composition, which varies from mafic to ultramafic and comprises eclogites, glaucophanites, talcschists and chloriteschists. Again, the presence of Cu-sulphide mineralisations and the nearby Mn-Praborna mine testify ocean floor hydrothermal activity (TUMIATI *et alii*, 2010, and refs therin).

In general, a detailed analysis of rocks such as the above mentioned ones, allows, not only the reconstruction of their Alpine metamorphic evolution, but also the detection of the nature and evolution of their oceanic protoliths.

CONCLUSIONS

A multi-scale structural study combined with petrological analysis and thermodynamic modelling in selected areas of the western Alps brought to the conclusion that a large portion of the western Alps ophiolites underwent a widespread hydration due to oceanic metamorphism before being involved in the subduction zone and subjected to metamorphism from HP to UHP type. The reconstruction of the complex Alpine metamorphic evolution allows to reconstruct their oceanic evolution. The determination of the different tectono-metamorphic units in the ophiolites is essential both to understand the nature of the processes taking place in subduction zones, and to decipher the structure and relationships in the oceanic lithosphere before the subduction.

Magmatic-hydrothermal interactions at a fossil slow-spreading centre (Internal Ligurian ophiolites, Italy)

RICCARDO TRIBUZIO (*&**), MARIA ROSARIA RENNA (***), ALBERTO ZANETTI (**) & LUIGI DALLAI (°)

Key words: *Alpine Jurassic ophiolites, albitites, hornblende veins, hornblende trace element compositions, O isotopes.*

The Internal Ligurian ophiolites from the Northern Apennine represent an oceanward domain of the Middle to Upper Jurassic Ligurian Piedmontese basin. These ophiolites contain up to km-scale, MOR-type gabbroic bodies that are structurally and compositionally similar to the gabbroic sequences from the oceanic core complexes of the Mid Atlantic Ridge (SANFILIPPO & TRIBUZIO, 2011). The Internal Ligurian gabbroic bodies record a retrograde, ductile to brittle tectono-metamorphic evolution that started under near solidus conditions. In particular, the onset of the brittle tectonic regime in the gabbros is locally associated with the formation of hornblende-bearing albitite dykes, and veins filled with hornblende and minor plagioclase. The albitite dykes and the hornblende veins show the same elongation direction and form a high angle with respect to the magmatic layering and the shearing foliations of the host gabbros. The development of the hornblende veins is correlated with coronitic hornblende growth at the expenses of the igneous clinopyroxene from the host gabbros. In addition, the gabbroic body considered in this study includes a serpentinised mantle sliver containing a few hornblende-rich gabbroic dykes/sills.

The hornblendes from the albitites and the hornblende-rich gabbros have a homogeneous geochemical signature. In particular, these hornblendes are characterised by low CaO and Al_2O_3, negligible Cl, and high TiO_2, K_2O, REE, Y, Zr and Nb. The incompatible element compositions of calculated melts in equilibrium with the hornblendes from the albitites and the hornblende-rich gabbros are similar to those of the SiO_2-rich plagiogranites from the Alpine Jurassic ophiolites (BORSI *et alii*, 1996). The $\delta^{18}O$ of the hornblendes and coexisting zircons from the hornblende gabbros are consistent with a formation bysilicate melts with negligible seawater contribution. We conclude that the hornblende-rich gabbros and the albitites formed by SiO_2-rich, amphibole-saturated silicate melts. These melts were most likely derived from a high degree of fractional crystallisation of MOR-type basalts.

The vein and the coronitic hornblendes show high CaO and Al_2O_3, significant Cl, and low TiO_2 and K_2O. The concentrations of REE, Y, Zr and Nb, and the $\delta^{18}O$ values are rather variable. Some of these hornblendes have incompatible element patterns similar to those of the clinopyroxenes from the gabbros and have $\delta^{18}O$ values close to seawater. This geochemical signature is attributed to hornblende formation by reaction between migrating seawater-derived fluids and the host gabbros. Conversely, many vein hornblendes show relatively high values of LREE, Nb and $\delta^{18}O$, thereby indicating that their crystallisation required the involvement of both seawater and magmatic components.

Active deformation along the northern margin of the Hyblean Plateau (SE Sicily) from GPS and geological data

BONFORTE ALESSANDRO (*),CATALANO STEFANO (**), MANISCALCO ROSANNA (**), ROMAGNOLI GINO (**), STURIALE GIOVANNI (**) & TORTORICI GIUSEPPE (**)

Key words: *ground deformation, GPS and geological data, Hyblean Plateau, Scordia-Lentini graben, SE Sicily.*

Accurate GPS data and new geological field surveys performed since 1991 on the epicentral area of the December 1990 earthquake across the Scordia-Lentini Graben are here presented in order to test the reliability of a new dynamic model of the region (CATALANO et *alii*, 2010), based on structural and morphological data.

The Hyblean Plateau, located at the southeastern corner of Sicily, represents a buoyant crustal block of the Africa foreland, which is intruded within the frontal areas of the allochthonous Maghrebian thrust belt, along the Nubia-Eurasia convergent margin. The plateau is bordered by roughly N-S trending major tectonic boundaries, inherited from Mesozoic lineaments, that have been characterised by a polyphase Neogene-Quaternary evolution. They are represented by the Malta Escarpment (CARBONE *et alii*, 1982; FINETTI, 1982; GRASSO & LENTINI, 1982), bordering the plateau towards the Ionian Basin, and the Scicli Line (Fig. 1b; GHISETTI & VEZZANI, 1980; GRASSO & REUTHER, 1988; BEN AVRAHAM & GRASSO, 1991, CATALANO *et alii* 2008), controlling the western edge of the plateau.

A diffuse fragmentation of the Nubia-Eurasia tectonic boundary, due to the propagation of distinct extensional belts, has characterised the post-collision evolution of the region. In this frame, the Hyblean Plateau was affected, since about 1.5 Ma B.P., by the propagation of the the roughly N-S trending Siculo-Calabrian Rift Zone (SCRZ in Fig.1a; MONACO & TORTORICI, 2000), an extensional belt that extends from the onshore of southern Calabria to the SE Sicily. In the Hyblean plateau the propagation of the rift zone caused the reactivation of the main previous discontinuity. The earlier SE Sicily branch of the rift zone, in fact, propagated from the Ionian coast to the Scicli Line, causing the collapse of the NE-trending Scordia-Lentini Graben, at the northern margin of the plateau. This extensional basin represents an half-graben, which is controlled by a SE-facing master fault.

(°) INGV – Sezione di Catania

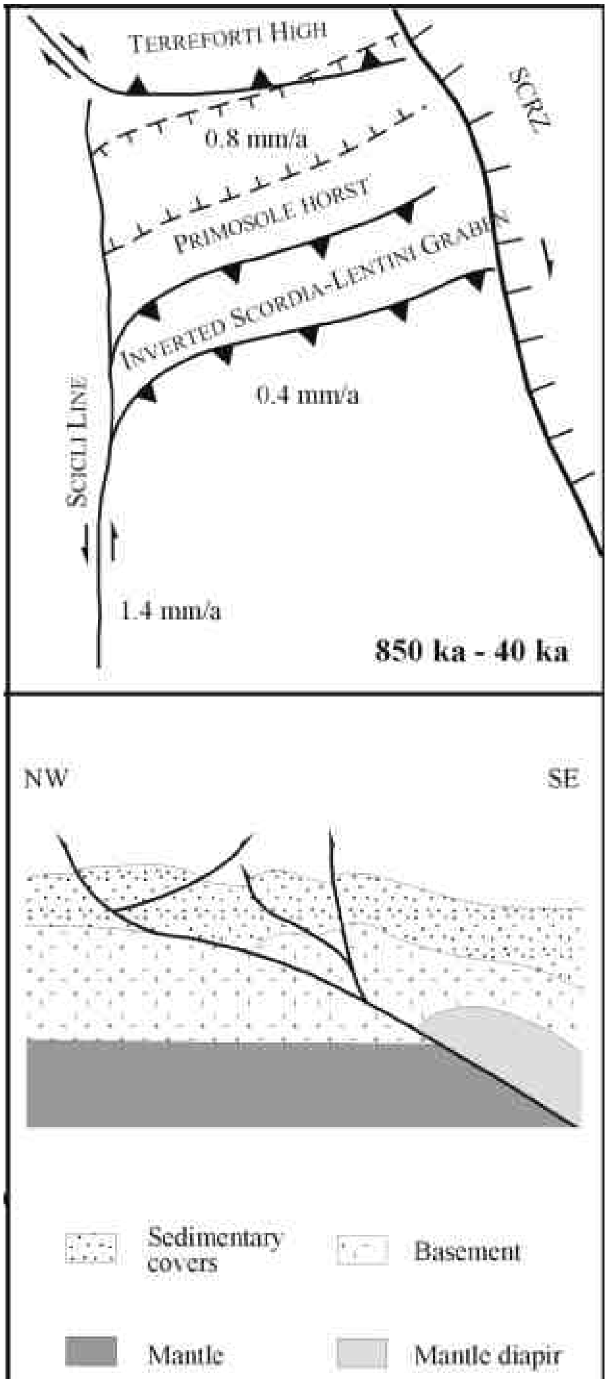

Fig. 2 - Kinematics and dynamics of the Late Quaternary positive tectonic inversion of the northern border of the Hyblean Plateau (after Catalano et alii, 2011, mod.)

The Hyblean branch of the rift zone deactivated as a new extensional belt propagated along the Malta Escarpment, isolating the whole Hyblean Plateau at the footwall of the active rift zone, where a Late Quaternary tectonic inversion affected both the Scicli line, from right- to left-lateral, and the southeastern margin of the associated Scordia-Lentini Graben, from extensional to compressional (BOUSQUET & LANZAFAME, 2004; CATALANO *et alii*, 2008; 2011). This process has been interpreted as the effect of the rift-flank deformation, which triggered a process of Mantle diapirism at the footwall of the active Siculo-Calabrian Rift Zone. According to this model, the Mantle upwelling followed the previous extensional master fault controlling the Scordia-Lentini Graben, causing the NW-ward extrusion of the hangingwall of the fault (Fig. 2). This extrusion has been entirely accommodated by extension along the Avola Fault, on the Ionian side of the block. The analysis of the Late Quaternary marine terraces around the remobilised kinematic block evidenced a clear SW-tilting of the entire region, with a maximum tectonic uplifting concentrated in a narrow belt aligned to the inverted border faults of the Scordia-Lentini Graben, which is consistent with the contractional deformation at the northwestern edge. In the rest of the mobile block, a diffuse NE-SW oriented extension controlled the collapse of basins, which are aligned to the direction of the tectonic extrusion.

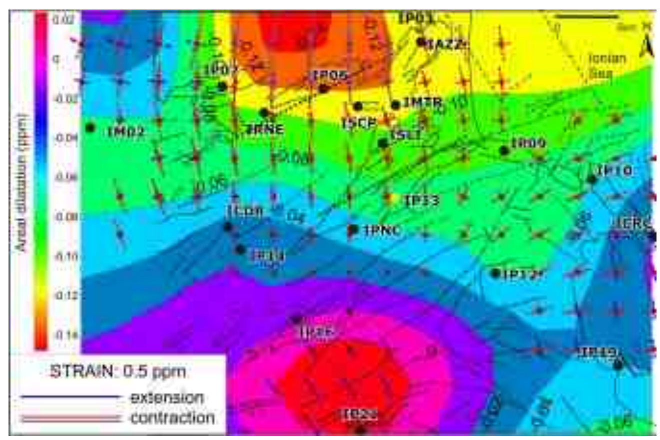

Fig. 3 Geodetic strain parameters calculated from the 2000 and 2005-2006 surveys comparison, on a regularly spaced grid above the northern Hyblean plateau. Arrows indicated the direction of contraction (red or purple, depending on the background color) or extension (blue); solid lines for highly significant data, dashed lines for medium significant data; poorly constrained data are not calculated. Color-coded areas indicate the 2D (areal) dilatation, according to the color scale on the left side.

The GPS data are in good agreement with the long-term evolution of the area. The 2D strain tensor analysis (Fig. 3) evidenced a still active compressive strain, with a main N-S contraction over the Lentini Graben and the Catania Plain, at the footwall of the Hyblean mobile block, associate with a local NNW-SSE extension, concentrated in the area of the ramp anticline, at the hangingwall of the inverted southern border of the graben. These results would suggest that the active deformation of the region can be framed in the Late

Quaternary tectonic evolution in order to constrain the seismogenic potential of the area on the basis of the comparison between the short-term and long-term deformation-rate measured in the region.

Geologically-based seismic zonation of Greece

CAPUTO RICCARDO (*), PAVLIDES SPYROS (^), SOTIRIS SBORAS (*,^), THEODOROS TSAPANOS (^) & ELENI KALOGEROU(^)

INTRODUZIONE

The recently released Greek Database of Seismogenic Sources (GreDaSS) aims at contributing to SHA in Greece. The database contains the crustal seismogenic sources of this area together with their seismotectonic parameters and other supplementary material (*e.g.* images, literature summaries, references list), which can provide the information needed for calculating SHA. The completeness of the database is high both in terms of the sources number and their principal seismotectonic parameters.

An important contribution of GreDaSS to SHA is the enhancement of the seismic zonation of the Aegean Region. Indeed, previous maps were based only on seismological data, ignoring the population, pattern and behavior of seismogenic sources. The homogeneity and the advanced level of completeness of the database allows to support a more realistic seismic zonation consisting of 51 zones of which however, 11 lack at present of completeness in terms of seismogenic sources.

Based on GreDaSS, we estimate the maximum expected magnitude, referred to as M_{geol}. For the same polygons, we also estimate a maximum expected magnitude but based on the recent seismicity following 'classical' approaches. For this purpose, we apply both maximum likelihood method and least squares technique. The historical part of the used catalogue contains only the strongest events, whereas the complete part can be divided into several sub-catalogues each one assumed to be complete above a specified threshold magnitude.

Uncertainty in the determination of magnitudes has also been taken into account. Among the several seismological parameters obtained with the statistical analyses, we focus on the maximum regional magnitude ($M_{reg} = M_{observed} + 1\sigma$). We then compare these seismologically based values with the ones determined from GreDaSS, based on geological information. This comparison shows that the 'classical' seismological approaches provide systematically lower values, which can be explained from the fact that the former methods cannot catch the seismic cycle for most seismogenic source and hence the corresponding zones. Few exceptions occur with the opposite sign, but in these cases, the M_{obs} and then M_{reg} is based on old events whose magnitude is still debated in the literature and possibly overestimated in the used catalog.

One of the added values of GreDaSS is the possibility to determine more likely worst-case scenarios (M_{max}) taking into account the real seismogenic potential of the active faults affecting the region. It should be a good practice in the future to fully exploit and include geological information when performing SHA analyses.

Long-term seismicity predicted by crustal flow in the Mediterranean region

CARAFA MICHELE MATTEO COSIMO (*)

Key words: *earthquakes, geodynamics, long-term seismicity, finite element method.*

INTRODUCTION

The complex morphology of the Mediterranean region has has been complicated by a mix of faulting and distributed permanent deformation, by various stages of active and waning subductions (CARMINATI & DOGLIONI, 2004). Single dataset of accurate measurements such as GPS horizontal velocity or SKS measurements is often not sufficient to resolve without ambiguity the role played by topography or upper mantle.

In BIRD (2003), the Mediterranean region is divided in 4 plates: Eurasia, Africa, Aegean and Anatolia. The latter 2 plates fall inside the Alpine- Himalayan orogen where the term ‘‘orogen’’ in BIRD (2003) is not purely a statement about the nature of the kinematics in that region but a culturally-relative statement that the horizontal velocity field in that region has more degrees of freedom than data at a certain time can constrain. In the same way, the “plate“ concept is a useful approximation rather than literal truth, but it permits to overlook measured or suspected horizontal velocities variation of as much as 2 mm/yr to define any plate.

In this work I tried to solve some issues connected to Mediterranean geodynamics using a different configuration of plates. I considered Adria, northern Greece, Marmara and central Greece microplates (REILINGER et alii, 2006) for the western part of Alpine- Himalayan orogen.

I computed the torques on each surface for each of Mediterranean plates (for both BIRD (2003) plate configuration and this work plate configuration) using a thin-shell finite-element model of the lithosphere that includes the following features: topography, variable heat-flow, variable crust and lithosphere thicknesses derived from seismic data, transient geotherms, nonlinear rheology, and weak faults. Horizontal velocities, long term slip rate and continuum strain rate were computed for several models that differ by the trench resistance and fault friction. The best model was chosen evaluating the misfits between the modelled quantities and the observed geodetic velocities, intraplate stress directions, seismic strain rate and azimuths of mantle seismic anisotropy. The minimum misfit occurs at low values of fault friction and trench resistance around $1x10^{12}$ N/m. The modelled torques can be divided into 3 parts: lithostatic-pressure, side-strength, and basal-strength. Below the plates with subducting slabs, the basal strength represents the sum of net slab-pull and distributed basal shear traction. I found that these forces applied at the base of the lithosphere are mandatory for Mediterranean geodynamics to reproduce horizontal velocities and seismic strain rate. Thus, the plates in Mediterranean region appear to be driven primarily by mantle flow, rather than by topography and associated lithostatic pressures.

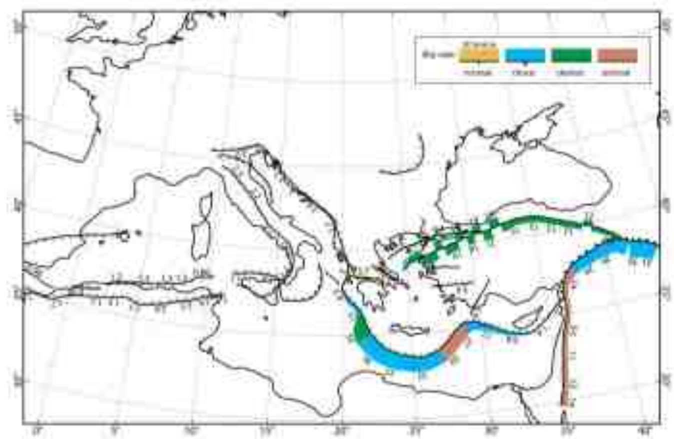

Fig. 1 – Long-term average fault slip rates.

Following the approach of BIRD & LIU (2007) long-term seismicity was predicted from long-term crustal flow (long-term rates of fault slip, *Fig. 1*, and rates of distributed permanent deformation in the crust). The obtained estimates are generally but not always consistent with historic and instrumental catalogs. The seismic hazard inferred from tectonic models (and other similar long-term average models) has to be seen as valuable on the long period. In any case these forecasts should at least be perceived as plausible for buildings

Relationships between fault geometry, slip rate variability and earthquake recurrence in extensional settings

PATIENCE A. COWIE (1), GERALD P. ROBERTS (2), JONATHAN M. BULL (3) & FRANCESCO VISINI (4)

Key words: *fault, earthquake, extensional setting.*

Field observations and modelling indicate that elastic interaction between active faults can lead to variations in earthquake recurrence intervals and fault slip rates measured on timescales of ~10^2 – 10^4 years. Fault geometry strongly influences the nature of the interaction between adjacent structures as it controls the spatial redistribution of stress when rupture occurs. Fault geometry strongly influences the nature of the interaction between adjacent structures as it controls the spatial redistribution of stress when rupture occurs. In this paper, we use a previously published numerical model for elastic interaction between spontaneously growing faults to investigate the relationships between fault geometry, fault slip rate variations and the statistics of earthquake recurrence. These relationships develop and become systematic as a long-term consequence of stress redistribution in individual rupture events even though on short timescales earthquake activity appears to be stochastic. We characterize fault behavior using the coefficient of variation (CV) of earthquake recurrence intervals and introduce a new measure, slip-rate variability (SRV) that takes into account the size and time ordering of slip events. CV generally increases when the strain is partitioned on more than one fault but the relationship between long-term fault slip rate (SR_{mean}) and CV is poorly defined. In contrast, SRV increases systematically where faulting is more distributed and SR_{mean} is lower. To first order, SRV is inversely proportional to SR_{mean}. We also extract earthquake recurrence statistics and compare these to previously published probability density functions used in earthquake forecasting. The histograms of earthquake recurrence vary systematically as a function of fault geometry and are best characterized by a Weibull distribution with fitting parameters that vary from site to site along the fault array. We explain these phenomena in terms of a time-varying, geometrical control on stress loading of individual faults arising from the history of elastic interactions and compare our results with published data on SRV and earthquake recurrence along normal faults in New Zealand and in the Italian Apennines. Our results suggest that palaeoseismic data should be collected and analysed with structural geometry in mind and that information on SRV, CV and SR_{mean} should be integrated with data from earthquake catalogues when evaluating seismic hazard.

Cosmogenic He exposure dating as a tool to calculate slip rates: example from the Pernicana fault system (Mt. Etna)

DAVIDE D'AMATO (*), LUIGIA DI NICOLA (**), BRUNO PACE (*), FRANCESCO VISINI (*), MARK F. STUART (**) & RAFFAELE AZZARO (***)

Key words: *Mt. Etna, Cosmogenic Helium, Pernicana fault, surface exposure dating, seismic hazard.*

INTRODUCTION

Geological record often is the only method, mainly in areas where historical data lacks, to study and quantify the earthquake histories and/or displacement rates of faults. Moreover, in areas such as young volcanic basaltic context, commonly- used dating methods like ^{14}C, K/Ar, $^{40}Ar/^{39}Ar$, can not be used easily (FOEKEN *et alii*, 2009). A recent tool that was successfully used is the surface exposure dating with cosmogenic nuclides. Surfaces exposure dating (SED) through terrestrial in-situ cosmogenic nuclides (TCNs) ^{3}He, ^{21}Ne and ^{36}Cl accumulated in the upper surfaces of flows after eruptions, give us an esteem of the time of exposure and consequently the age of eruptions. In volcanic context the presence of faults may be related to the presence of the same volcano edifice (instability) but also to tectonic regional processes. The variability in fault-slip rate and earthquake clustering within relatively shorts time-intervals can been explained through the changes of stress in the rock volume that contains the fault by processes such as rupture of nearby faults or unrest of the volcano. Therefore, a detailed study on the variability in time and space of fault parameters can provides insights into the mode of interaction between the tectonics and volcanoes processes. Keeping in mind that volcanic areas are often densely populated, a better understanding of slip rate of active faults and modes of interactions is crucial in the effort to quantify volcanic and earthquake hazards.

TECTONIC SETTING

Mount Etna is an active polygenetic basaltic stratovolcano in the north- eastern part of Sicily. It is located in a complex geodynamic position, between the outer front of the late-quaternary south-verging Apennine Maghrebian thrust, and the Late Quaternary east-facing crustal scale normal fault system, which has partially reactivated the Malta Escarpment, a Mesozoic discontinuity that separating the continental crust of Hyblean plateau from the oceanic crust of the Ionian Sea. The tectonic setting of Etna results from the interaction of regional tectonics and local scale volcano related processes. Extensional tectonics, in particular, mainly affects the eastern flank of the Mount Etna, where an eastward sliding of the flank is located (MONACO *et alii*, 2005). Despite of the debating of the causative geodynamic source of the extension, there is a general agree in the surface geometry of the main normal faults bordering the eastern flank of the volcano (fig. 1). The northern end of the "sliding" block is the Pernicana fault, about E-W oriented and characterized by left lateral to normal kinematics. The fault cuts basaltic rocks for a length of about 18 km, with fresh scarps up to 80 m high. Microseismicity and shallow earthquakes (Mmax=4.5, April, 2nd 2010) frequently occur in the central and western sectors of the fault, whereas relevant aseismic creep phenomena affect the eastern segment.

PERNICANA FAULT SYSTEM

The transtensive E-W trending Pernicana fault system delimits the northern part of the unstable eastern flank of Mt. Etna (Fig. 1), over a distance of about 18 km km (AZZARO ET AL., 2012). It consists of several dextral en echelon segments, which shown an average trend of ∼N°80E, arranged in an overall direction of ∼ N°110E. Until the 2002 eruption the Pernicana fault was known to be extend eastward from the NE Etna rift, close to the summit of the Mt. Etna volcano, to the coastline for a length of about 9 km (NERI *et alii*, 2004). About 2km eastward of this termination is located the Fiumefreddo Fault, that with an along strike length of about 3km and an E-W direction has been commonly considered the eastern continuation of the Pernicana fault. The 2002-2003 Etna eruption produced ground fracturing along all the 18 km length of the Pernicana fault system, definitively constraining the total length of the fault system (NERI *et alii*, 2004). The Pernicana Fault System is composed by three main segments: the western, central and eastern segment. The western segment, approximately NE-SW oriented, is commonly named in literature the NE-Rift and/or Piano Provenzana fault (AZZARO, 2004). Here the normal south-east dipping fault, with an escarpment not well exposed or covered from wood and/or younger eruptions, coincides with an

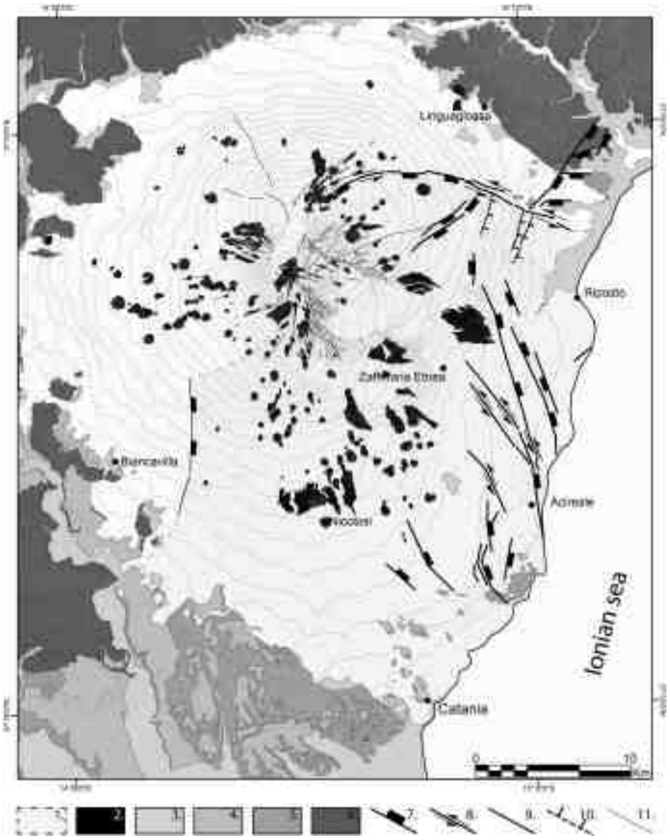

Fig. 1 – Volcano-tectonic map of Mt. Etna (modified from Azzaro et al., 2012): 1. unstable sector, 2. eruptive and effusive activity, 3. Holocene deposits, 4. Fluvial-costal and alluvial terraced deposits (middle-late Pleistocene), 5. Marly clays, sand and conglomerates (early-middle Pleistocene), 6. Tectonic units of the chain and neogene sedimentaru covers (Cretaceous-early Pliocene), 7. normal faults, 8. strike-slip faults, 9. buried fault with evident morphologic scarp, 10. fault with uncertain movement, 11. eruptive fracture.

evident eruptive centres alignment in the NE-SW direction (TIBALDI & GROPPELLI, 2002). High slip rates of 6-18 mm/a have been computed by TIBALDI AND GROPPELLI (2002) by lava flows and pyroclastic deposits displacements younger than 1614 A.D.

The central segment of the Pernicana fault system is E-W oriented, and shows a prevalent normal kinematics. This segment extends for a length of about 5 km, and shows well exposed fault scarp with a maximum height of about 50 m. (Fig. 2). This segment is characterized by the frequent occurrence of seismicity, as the recent 2010 M4.5 earthquake (ALPARONE ET AL., 2012). TIBALDI AND GROPPELLI (2002) computed for this sector two different values of slip rate: 2.7 (+-0.7) cm/yr based on pyroclastic cone displacing and 0.7 (+-0.1) cm/yr based on stone wall displacing. Toward the east the morphological evidence of the fault progressively fades out and the movement, around the Vena and Presa villages, is accommodated by several splays and Riedel shears structures (AZZARO ET AL., 2001).. They show left-lateral displacement and damage the roads and the house in the area between Rocca Campana and Presa. The behavior of the slip rates of this eastern sector of the Pernicana fault system is well constrained in this sector by a leveling network operated from 1980 (OBRIZZO *et alii*, 2001; AZZARO *et alii*, 2001). The geodetic measurements revealed a mean near continuous slip rate of 28 mm/a punctuated by aseismic displacement episodes.

Five lava flows with 16 samples of lava have been collected in order to cover the overall fault length, but here we show the preliminary results from a lava flow and 5 samples of them.

METHODS

Topographic profiles of fault scarps have been made and lavas flow at the hanging-wall have been sampled for SED analysis. Detailed topographic profiles of fault scarps was produced with a Leyca total-station (fig. 2). To dating the lava flows cutted by the faults we collected and dated pyroxene and olivine from samples. Three samples for cosmogenic ^{3}He analysis has been collected from Millicucco lava flow (ML) in Mandra del Re locality (named PER samples) where lava flows are clearly cut by the fault.

Sampling sites do not shown evidence of rolling or shifting after deposition. The samples are not eroded and/or don't show altered surface. No ash, soil or vegetation covers the sites and not shielding is present.

Together with cosmogenic nuclides sampling, we carried out analysis of major elements and rare earth and trace elements aimed to geochemical characterization of the lava flows. This analysis was aimed to recognize possible geochemical variations within a lava flow, and/or signatures common to various lava flows. REE and trace elements have similar physical and chemical properties and they fractionate very gradually between them. Therefore, a fractionation is an effect of very powerful evolutionary phenomena. Conversely, two samples showing similar REE and trace elements patterns are genetically related. We performed this analysis using the ML, sampled at two different localities, Mandra del Re and Rocca Campana.

RESULTS AND DISCUSSIONS

Crush extraction $^3He/^4He$ is from 5.31 to 6.60 Ra (where Ra is the atmospheric $^3He/^4He$: 1.39x10-6), and melted $^3He/^4He$ show very high values (7.49 –22.45 Ra). The combination of both these results indicates that cosmogenic ^{3}He is present in all samples. Minimum exposure ages are calculated using ^{3}He cosmogenic production rate in pyroxene (PR = 120 +- 9.4 at/g yr; GOEHRING *et alii*, 2010) scaled according to DUNAI, 2000. Cosmogenic ^{3}He, hosted in mineral lattice ($^3He_{cos}$), is calculated according to the following formula (CRAIG AND POREDA, 1986):

$$^3He_{cos} = [(^3He/^4He)_{melt} - (^3He/^4He)_{crush}]\,^4He_{melt}.$$

Exposure ages of the samples show a range from 0.9 to 1.2 ka; the weighted exposure age for ML is 1088 ± 96 yr. Geochemical analysis shows a good overlapping of the paths of

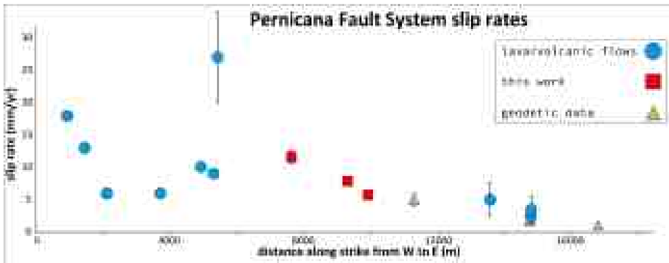

Fig. 2 – Vertical slip rate values of the Pernicana Fault System. Blue circles data from lava flows or volcanic products (Tibaldi & Groppelli, 2002); green triangles datas from geodetic systems or antropic manufact (Tibaldi & Groppelli, 2002); red squares data from this work.

REE and trace elements in all the samples, with errors lower than the detection limit of the analysis. This indicates that the samples collected in Mandra del Re and Rocca Campana localities arise from the same lava flow, and that it is possible to use cosmogenic nuclide dating for the ML lava flow in both areas.

Topographic profiles show a height of the scarp of about 12 m at Mandra del Re, whereas lower heights (8.6 and 6.3 m.) have been observed in two profiles located at Rocca Campana. Using weighted exposure age of 1088 ± 96 yr, the computed average vertical slip rates are: 11.58 ± 1 mm/yr (Mandra del Re), 7.89 ± 0.7 mm/yr (Rocca Campana in correspondence of the highest scarp) and 5.77 ± 0.5 mm/yr (Rocca Campana in correspondence of the shortest scarp). These values are quite close to the available slip-rates calculated using geodetic measurements and displacements of historical manufacts (AZZARO ET AL., 2001, 2012; OBRIZZO, 2001, NERI, 2004). This result highlights the advantage of cosmogenic nuclides dating technique to keep a homogeneous dataset extending the time window of observation for slip rate assessing: from some centuries to many thousands of years.

Fault locking as an indicator of seismogenic potential

DEBORA FINOCCHIO (*°) & SALVATORE BARBA (*)

Key words: *numerical model, earthquakes, seismic hazard.*

INTRODUCTION

The difficulties in determining which faults require the most attention were dramatically obvious in the past few years, when the number of fatalities caused by recent disastrous earthquakes was 100 to 1000 times larger than what expected by the world hazard maps (WYSS et al., 2012). Part of the problem arises from the maximum expected magnitude, as a number of earthquakes occurred during 2001-2011 (http://earthquake.usgs.gov/earthquakes/eqinthenews/) is characterized by 1.3-2.7 magnitude units larger than what predicted by GSHAP (GIARDINI, 1999). As a matter of fact, seismic hazard maps are often constructed by extrapolating from the frequency of small earthquakes the annual probability of large, infrequent earthquakes. But, on the other hand, the capability of active faults to release earthquakes is a time-dependent problem.

The issue of the short length of the earthquake catalogues has been faced by using long-term geological data. Faults that did not generate earthquakes in the historical times can be studied by means of long-term surface offset rates and geomorphic data. However, very long-term fault behavior cannot be directly related to short-term seismic activity. The time dependence can be studied by using numerical models that reconcile short- and long-term fault behavior.

Through the numerical models we can estimate the evolution of the fault (at depth and at the surface) in the interseismic period and simulate the possible coseismic behavior. First, the models can determine the locked or unlocked state of faults; then, such findings can be used as a starting point to determine which fault (or faults) could eventually rupture in a future earthquake. Moreover, we can estimate stress and strain, and thus the loading rate of the faults.

We study and present three faults: The Montello thrust, located in Northern Italy, the Altotiberina fault, located in Central Italy, and the Messina fault, located in Southern Italy. We modeled each fault zone by using different driving forces and different rheological parameters.

MONTELLO (NORTHERN ITALY)

Assessing the seismogenic potential of the Montello thrust system (Southern Alps, Italy) is a debated issue. To clarify this problem, and to understand the locked or unlocked state of the faults, we modeled the interseismic geodetic data available in the region. By means of finite-element analysis, we developed ~160 two-dimensional elastoplastic models and compared the model predictions with the available horizontal GPS velocities and vertical leveling data.

The best model indicates which portions of the studied faults are freely slipping and which are locked (Fig. 1). We found that, rather than the freely slipping Montello thrust, the Bassano thrust may bear a large seismogenic potential, due to the large segment that behaves as locked in the interseismic time.

The unlocked portions of Montello thrust, Montello back-thrust and Bassano thrust are mostly freely slipping in the present time and may generate small earthquakes or other phenomena related to slow fault slip. The locked portions of Montello thrust and Bassano thrust can accumulate stress which may be released during future earthquakes. A very large portion of the Bassano thrust is locked, which suggests the potential for releasing large earthquakes. Bassano thrust is not parameterized as a seismogenic fault for seismic hazard in Italy (BASILI et al., 2008). Thus, future studies of the Bassano thrust are strongly required in order to disprove its hazardous existence or to quantify its present-day slip rate and seismogenic potential.

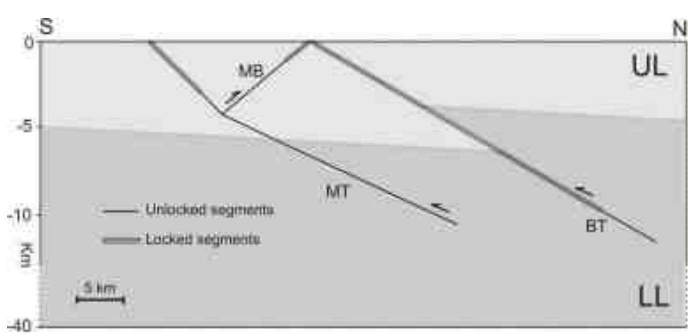

Fig. 1 – Diagram of the model results showing locked and unlocked portions of the Montello thrust (MT), Montello back-thrust (MB) and Bassano thrust (BT). UL, Upper Layer; LL, Lower Layer. The vertical scale is cut at utile depth.

ALTOTIBERINA (CENTRAL ITALY)

The Altotiberina low-angle normal fault in Central Italy is recently undergoing lots of physical investigations. Despite being known since many years, its seismogenetic activity and its relationship with other faults are still debated. We built a 2D elastoplastic finite element model reproducing interseismic deformation of the Altotiberina Fault. The predictions of the model were compared with geodetic velocities, stress orientations and geological data.

The best model was 180 km long and 40 km deep; it presents two layers with different rheological behaviors, two ramps, two faults and four free slip segments. The major contribute at the interseismic deformation on the large scale is due to the basal traction, the contrast of rheological parameters between the upper and lower layers, and the presence of the Altotiberina fault itself, while the local variations (short scale) are due to the antithetic Umbria Valley and Colfiorito faults.

These antithetic faults move freely along the unlocked part. The residual and small locked zone can accumulate stress and generate small earthquakes or other aseismic phenomena. Specifically, the Colfiorito fault ruptured in year 1997 and possibly did not recover yet its locked state. The slip along the Altotiberina Fault is transferred to the surface through the Umbria Valley and Colfiorito faults, which also generates small basins.

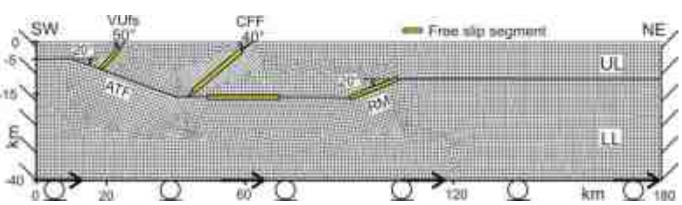

Fig. 2 – Geometry and grid of the best model for the Altotiberina fault (ATF), with the boundary conditions and the free slip segments (yellow rectangles). The circles represent the locked nodes in vertical direction, the lateral bars represent containment edges, and the arrows represent the direction of basal shear tractions (4.3 MPa). UL, Upper Layer; LL, Lower Layer; ATF, Altotiberina Fault; RM, Regional Monocline; CFF, Colfiorito Fault; VUfs, Umbria Valley faults.

MESSINA (SOUTHERN ITALY)

We reproduced through 2D numerical models the 3D analogue model of BONINI *et al.* (2011). The aim is to describe the tectonic evolution of the low angle, blind, normal fault that possibly ruptured during the disastrous 28 December 1908, Mw 7.1 Messina Straits earthquake (VALENSISE & PANTOSTI, 1992). The Messina normal fault is 40 km-long, 30°-dipping and extends between 3 and 12 km depth. The numerical experiments investigated the time evolution of the strain distribution in the hangingwall of the modeled fault, to understand the formation of new structures and more in general to identify a general mechanism of fault generation. We tested the hypothesis of a progressive strain migration from the upper tip of the master fault plane downwards.

The model was 60 cm wide and 13 cm deep. A friction value $\mu=0.1$ was applied on the 30° dipping-plane that represents the Messina fault (the model scale is 1:100,000). The finite-element mesh included 9697 nodes and 9405 quadrilateral elements of variable dimension. We modeled the “sand” of the analogue model as an elastoplastic medium represented by a Lagrangian formulation. The deformation is induced by the sliding backstop; it moves progressively in three displacement steps of 0.50 cm (MS 1), 2.00 cm (MS 2) and 3.50 cm (MS 3; Fig. 3).

Model results show the activation of the entire surface of the master fault. The strain localization at the upper tip point of the master fault suggests that many high angle synthetic and antithetic normal faults can develop. This result is in agreement with the analogue model of BONINI *et al.* (2011), who suggests that all synthetic and antithetic high angle normal faults are directly linked to the low angle master fault and all nucleated during the very early stages of deformation (Fig. 3a,b). By increasing the extension (Fig. 3c), the deformation is transferred towards the deeper part of the master fault plane. Moreover, new faults are to be developed to the central part of the model.

FINAL REMARKS

The results of the numerical model principally depend on the boundary conditions. Indeed, the principal step to build the model is to know the forces driving the deformation. The second important thing is using a realistic description of the medium.

We showed that describing the present-day behavior of known and supposed seismogenic faults requires a modeling approach which includes the boundary conditions, the neighboring faults, the decollement layer and the present-day interseismic data. A complete description of the interseismic stage, along the lines shown here, allows determining the seismogenic potential of known faults.

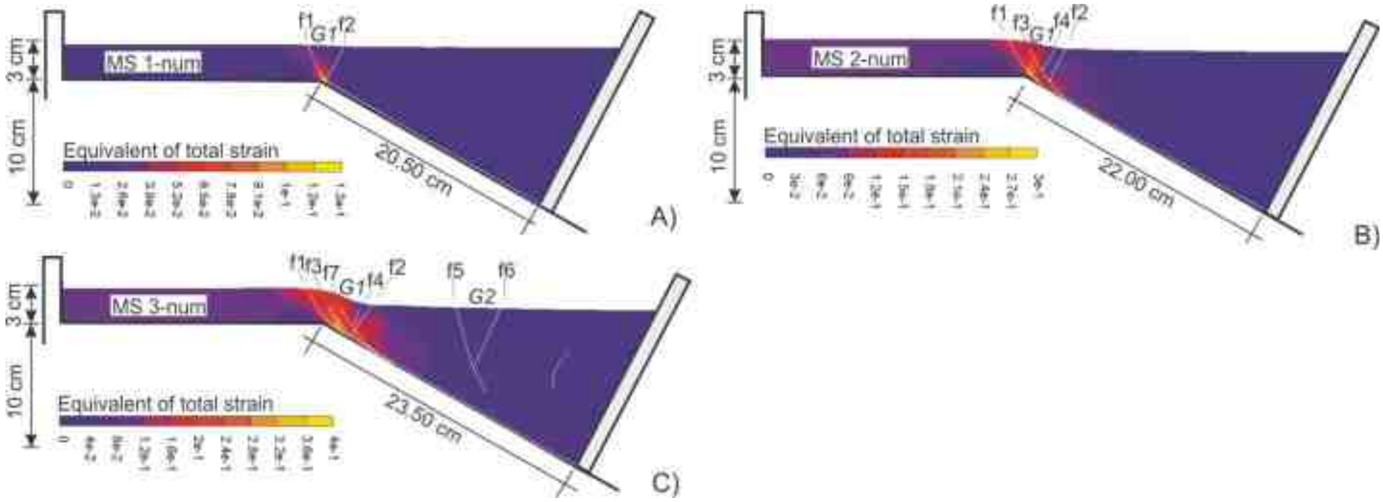

Fig. 3 – Equivalent of total strain calculated in three steps (MS 1= 0.5 cm; MS 2=2 cm; MS 3 = 3.5 cm). The white dashed lines labeled as f represent the faults obtained by BONINI *et al*. (2011).

October 23, 2011 Van Earthquake (Mw=7.1), Turkey : Was it improbable or unexpected?

LEVENT GÜLEN (*)

Key words: *Seismotectonics, Earthquake, Blind Fault, Lake Van, Turkey*

The tectonics of the Lake Van region is dominated by the active convergence of the Arabian and Eurasian plates. These plates act as converging jaws of a huge wise and the eastern Anatolia represents a crush zone which consists of numerous blocks forming a crustal mosaic in between. The effects of continental collision and the continuing plate convergence extends all the way north towards Caucasus as evidenced by seismic activity and GPS measurements.

Fault plane solutions obtained from many earthquakes occurred in the region indicate that the active convergence is taken up primarily as folding and thrusting along the Bitlis-Zagros belt and along the Caucaus, but as mostly oblique-slip faulting through a network of conjugate set of faults within eastern Anatolia.

The October 23, 2011 Van Earthquake (Mw=7.2) occurred on Van thrust fault that extends for 27 km on land in E-W direction between Lake Van and Lake Erçek. The surface fault rupture of the Van thrust was mapped by EMRE *et al.* (2011) after the Van Earthquake and maximum 10 cm vertical displacements have been documented along a northward dipping fault plane. Most of these observed displacements developed several days after the occurence of the main shock suggesting that the Van thrust fault is a blind thrust.

We inverted the teleseismic body waves recorded by 35 stations to model the source process of the 23 October 2011 Van Earthquake using the method of KIKUCHI AND KANAMORI (1991). The rupture process can be satisfactorily modeled with two subevents that have seismic moments of 3.47×10^{19} Nm and 2.34×10^{19} Nm, respectively corresponding to a total seismic moment of 4.59×10^{19} Nm (GÜLEN ET AL., 2012).

A number of normal faults forming half graben structures within the Lake Van basin were mapped earlier by seismic reflection studies (WONG AND FINCKH, 1978). Recently an E-W trending reverse fault was delineated within the Lake Van basin based on seismic reflection data obtained during the PaleoVan Project (TOKER, 2011). This reverse fault has a total length of 35 km and it is the westward continuation of the Van Thrust Fault. The tectonic relationship between the half grabens and the Van Thrust/Reverse fault is not clear and it needs to be investigated.

Although the Van Thrust fault was not mapped previously, based on the seismotectonic setting of the Lake Van region, which is situated just to the north of the continental collision boundary between the Arabian and the Eurasian plates and the ongoing active continental convergence evidenced by seismic activity and GPS results, we can conclude that the October 23, 2011 Van Earthquake was not a surprise.

Multi-disciplinary Approach to the Study of the Pernicana Fault System, Mt. Etna, Sicily: Integration of Structural, Geodetic and Seismological Data

SIMONA PUGLISI (*), MIMMO PALANO (**) , CARMELO MONACO (°), ENRICO TAVARNELLI (*) & SALVATORE ALPARONE (**)

Key words: *Pernicana Fault System, Mt. Etna, structural geology, geodesy, seismology.*

ABSTRACT

This contribution investigates the Pernicana Fault System (PFS), a seismogenic structure that dissects Mt. Etna (Sicily). The study was carried out through a multidisciplinary approach based on integration of structural, geodetic and seismological data, with the aim to produce a consistent model for this complex sector of the volcano edifice.

The PFS is a W-E trending fault array, organized into segments arranged *en-échelon*, and displays a dominantly left lateral component of strike-slip. From West to East it joins the NE-Rift (1900 m a.s.l.), crossing Piano Provenzana and Piano Pernicana, and reaches Rocca Pignatello (1050 m a.s.l.) and Rocca Campana (900 m a.s.l.) where the fault branches out SE-wards into two fault segments. The former shows a roughly N105°E orientation from Rocca Pignatello to Rocca Campana, where the fault rotates to N090°E and terminates without morphological evidence; the latter propagates downhill from Rocca Campana with a roughly N120°E orientation. During the 2002-03 Mt. Etna eruption, an intense ground-fracturing phenomenon affected the entire NE flank, allowing to identify the development of the N120°E fault segment and to trace it down to the Ionian coast.

The work has been carried out with different approaches: structural analysis, to identify the kinematics and geometry of the fault system through the study of well-recognized structural marker; seismology, based on the analysis of focal mechanisms in order to unravel the dynamics of the system, and space geodesy, in order to infer the recent ground motions due to slip along the PFS.

Three main segments are recognised within the PFS: a western, a central and an eastern segment. The western and eastern segments indicate dominantly transtensional kinematics, with both important normal and strike-slip displacements, whereas the central segment best illustrates the effects of the strike-slip component. This segment was monitored with local networks based on GPS techniques since early 1997. GPS data indicate daily displacement vectors up to 50 cm as recorded during the first days of the 2002-03 eruptive event of the Mt. Etna volcano. These data collectively indicate a sliding towards SE of the southern block identified by the PFS.

The analysis of focal mechanisms is in general agreement with data inferred from structural analysis and GPS techniques, indicating a good kinematic and dynamic consistency. The eastern segment of the PFS is characterised by a low seismic activity and by the lack of recent earthquakes, therefore outlining that this part of the PFS is dominated by aseismic creep.

The brittle-ductile transition as the switch for earthquakes

FEDERICA RIGUZZI (*), SALVATORE BARBA (*), EUGENIO CARMINATI (°), MATTIA CRESPI (^), ROBERTO DEVOTI (*), CARLO DOGLIONI (°), GRAZIA PIETRANTONIO (*) & ANNA RITA PISANI (*)

Key words: *brittle-ductile transition, fault activation, earthquake, strain rate*

In extensional, compressional and strike-slip earthquakes, faults activate in areas of high strain-rate gradients along the segments with lower strain rates. The example of the Italian seismicity of the last years shows that as the strain rate increases, the magnitude of the expected earthquake decreases. Moreover fluid discharge variations are frequent at the coseismic stage. To explain these evidences, we modelled a fault locked in the brittle shallow layer, constantly shearing in the ductile deeper crust. The episodic locking-unlocking behavior in the brittle upper crust marks the seismic cycle. This behavior should correspond to the sudden release of the elastic energy accumulated during the interseismic period in the volume of rocks along the fault above the brittle-ductile transition (BDT) due to the differential behaviour between the two layers. During the interseismic period, in tensional tectonics, a stretched band antithetic to a normal fault forms above the BDT (Fig. 1). During the coseismic stage, fractures close, and fluids are expelled. In compressional tectonics, the mechanism reverses: during the interseismic stage, an over-compressed band should form above the BDT; this band dilates while rebounding during the coseismic stage and attracts fluids locally (Fig. 1). Along strike-slip faults, the locked segment corresponds to a horizontal decollement on the BDT plane. Outside the tip lines of the locked brittle segment, both the brittle and ductile layers move together because of their more efficient welding. At the tip lines, two opposed couples of subvertical bands are inferred, one in the dilation/compression and one in the compression/dilation. This deformation inverts during the coseismic stage. In the stratigraphy of the crust there may be more than one BDT, as a function of the lithologic contrasts, the thermal regime and the fluids pressure. The magnitude of the earthquake can be measured in terms of volume of rocks displaced rather than on the length of the related fault (Fig. 2). This model is one possible mechanism for controlling the seismic cycle, and gives insights for the parameters to be monitored in earthquake forecasting. For example, moving along active faults in Italy, the magnitude of earthquakes during the last years increases as the strain rate decreases. Locked faults can now be monitored by space geodesy, and the areas where the strain rate is lower can be the focus for testing the parameters that may vary prior to the occurrence of a major earthquake, e.g., the variation in fluids discharge, thermal and geochemical anomalies, acoustic emissions, electromagnetic signals, low or moderate seismic clusters, etc. It is worth noting that each different tectonic setting (tensional, contractional, strike-slip) has its own signatures.

(^) DICEA, Università Sapienza, Roma

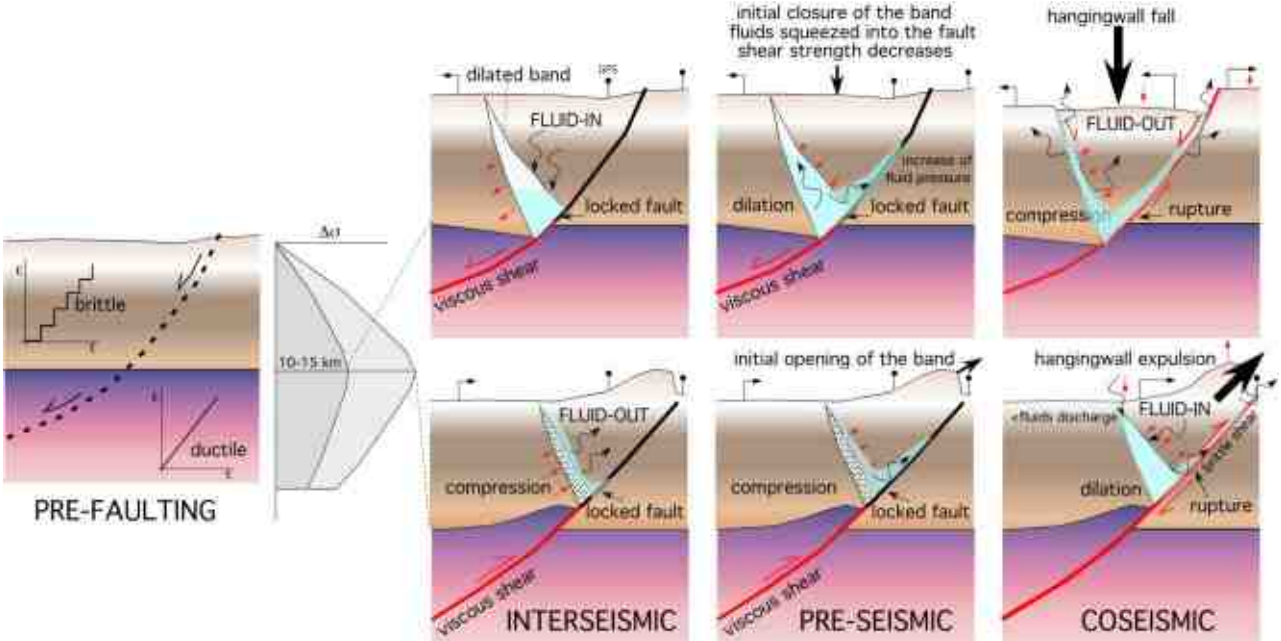

Fig. 1 – Assuming a simplified two-layer crustal rheology, the ductile lower crust is characterized by a constant strain rate whereas the brittle upper crust displays episodic locking-unlocking behavior. Tensional and compressional faults generate opposite kinematics and mechanical evolutions. In the tensional tectonic environment, the triangle of crust above the BDT remains "suspended" while a dilated area forms during the interseismic period. Fluids may enter the fractured volume. Once shear stress along the locked part of the fault becomes larger than fault strength, the hangingwall will begin to collapse, increasing the fluid pressure into the fault gouge. This mechanism is self-supporting because it decreases fault strength, facilitating the final fall of the hangingwall and generating the mainshock. Conversely, during the interseismic period, along a thrust plane an over-compressed band separates the ductile shear from the overlying locked fault segment. The hangingwall is eventually expelled during the coseismic period. Fluids discharge behaves differently as a function of the tectonic field.

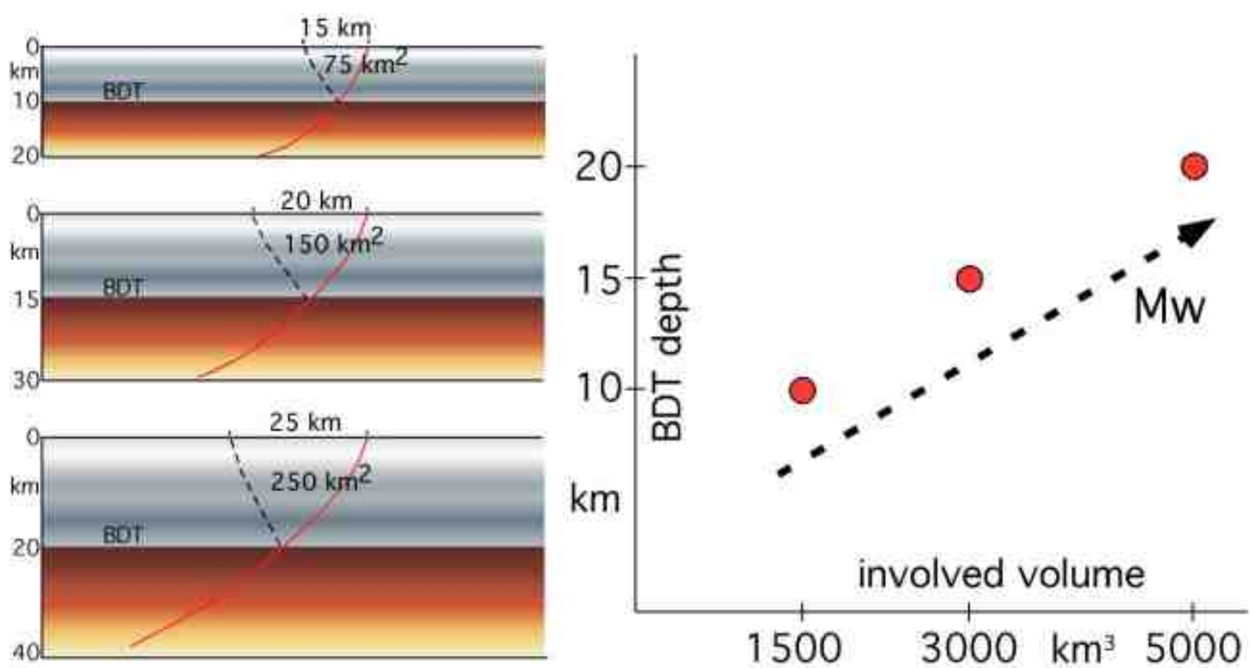

Fig. 2 – Assuming similar fault length and accumulated slip, the deepening of the brittle–ductile transition depth determines an increase of the volume involved during the earthquake, and hence of its magnitude. High geothermal flux generates a shallow BDT, i.e., smaller volume above BTD and lower seismic energy release.

Earthquake hazard from *in situ* ^{36}Cl exposure dating of elapsed time and Coulomb stress transfer

GERALD ROBERTS (1), PATIENCE COWIE (2), RICHARD PHILLIPS (3), KEN MCCAFFREY (4), PETER SAMMONDS (5), JOHN MCCLOSKEY (6), SULEYMAN NALBANT (6), STEWART FREEMAN (7)

The elapsed time since the last earthquake on an active fault is one of the key parameters needed to calculate its probability of rupturing in a given time period in the future. However, the elapsed time is unknown for many active faults. This talk describes a new method for measuring the elapsed time using *in situ* ^{36}Cl cosmogenic dating of emergent normal fault planes in Italy.

In addition to providing the elapsed time parameter for probabilistic seismic hazard analysis, ^{36}Cl dating can provide insights into changes in probability of rupture due to Coulomb stress transfer. Active faults experience earthquake rupture due to stress transfer from neighbouring earthquakes only if the fault in question is close to its failure stress. We lack knowledge of which faults are close to their failure stress, because, again, the elapsed time since the last earthquake is not known for many faults. Thus, at present it is not possible to interpret calculations of Coulomb stress transfer in terms of the probability of impending earthquakes.

This talk describes initial results from active normal faults in central Italy whose geometry and slip-rates are well known, where we are attempting to measure the elapsed time since the last earthquake(s), normalised to the fault slip-rates, using ^{36}Cl cosmogenic exposure dating, because this is a proxy for how close a fault is to its failure stress. Our long-term project will combine elapsed time with calculations of stress transfer from historical and palaeoseismic earthquakes to reveal which faults are candidates for imminent rupture, in the hope that end-users will be able to prepare and increase social/economic resilience to earthquakes, and to change the way the earthquake community views and uses stress transfer modelling.

We will present results concerning the geometry, kinematics and rates of extension, with preliminary results from ^{36}Cl cosmogenic dating, but are not yet able to present results from Coulomb modelling.

Historical tsunamis and paleotsunami deposits on eastern Sicily

BARBANO M.S. (*), DE MARTINI P.M. (**), PANTOSTI D. (**), PIRROTTA C. (*) , SMEDILE A. (**) & PINZI S. (**)

Key words: *eastern Sicily*, *paleo-tsunami*, *tsunami hazard*.

INTRODUCTION

The Mediterranean Sea has one of the longest historical records of tsunami occurrences worldwide. In fact, more than three hundred events have been reported since 1300 BC to have occurred in this region (SOLOVIEV *et alii*, 2000). Although exceptionally long, the historical dataset of Italy, concerns the past two millennia (TINTI *et alii*, 2007 and references therein) and only for the last one to three hundred years the reports fully describe tsunami effects providing for each affected site run-up values and limit of flooded coasts. Therefore, the geological evidence of tsunami related deposits could provide a much longer record that can be extended back in time for the past 5-6 ka. The knowledge of the distribution and characteristics of paleotsunami deposits, linked to both near and far sources, could represent a useful tool for a robust local tsunami hazard assessment.

With the aim of contributing to a better understanding of the tsunami potential of eastern Sicily, we integrate an unique set of published data on paleotsunami deposits recently collected by different authors along the ~230 km stretch of coast facing the Ionian Sea (Fig. 1). Geological evidence for paleotsunamis is then used to reconstruct a history of tsunami inundations in the region, to highlight unknown potential inundation extents, and also to define if the nature of the causative sources is local, regional, or basin-wide.

METHOD

Several studies describing geological evidence of tsunami deposits along eastern Sicily coasts, both inland and offshore, have been recently published (DE MARTINI *et alii*, 2012 and references therein).

In the above mentioned papers an original combination of historical, archaeological, geomorphologic, stratigraphic, paleontological and geochronologic approaches, has been used to recognize and characterize paleotsunami deposits.

A paleotsunami deposit inland consists in a high-energy marine deposit that is allochthonous to the local stratigraphy and shows morphologic, sedimentologic and paleontological characteristics compatible with the tsunami action/modification. Thus, a thin layer of sand, coarse sand or pebbles, with sharp basal contacts, containing shell debris, marine benthic and planktonic foraminifera, and vegetal remains is a good potential candidate. When this layer is sandwiched in low-energy continental deposits with distinct faunal associations, its tsunami origin can be confidently stated. Also, a paleotsunami deposit can be represented by boulders transported from a submerged rock platform and deposited inland. Differently, offshore signatures of paleotsunamis were recognized identifying as tsunami proxies rare layers of displaced fauna (*i.e.*, not consistent with the water depth of the sampling site) coupled with concentration of vegetal

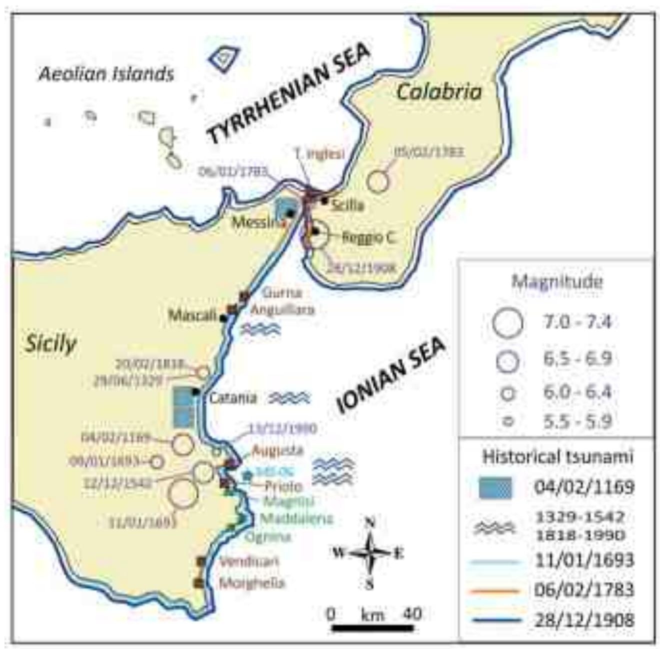

Fig. 1 – Main tsunamigenic historical earthquakes and inundated areas by regional tsunamis. Mascali, Catania and Augusta were also hit by the 1329, 1818, and 1542 and 1990 local tsunamis, respectively. Scilla and Torre Faro are related to the 1783 tsunami probably triggered by a submarine landslide. Sites are shown with brown squares and with green triangles when studied by our group or by other researchers, respectively. The light blue star shows the sediment gravity core (MS-06) location (from DE MARTINI *et alii*, 2012).

remains and peculiar sedimentary changes, in very low-energy mud deposits (SMEDILE *et alii*, 2011).

RESULTS AND DISCUSSION

Integrating information gathered from a single 6.7 m-long offshore piston core, 69 inland boreholes (down to a maximum depth of 5.8 m), an archeological exposure (PANTOSTI *et alii*, 2008), a natural outcrop near Ognina (SCHICCHITANO *et alii*, 2010) and several displaced boulders (at Vendicari, BARBANO *et alii*, 2010; Ognina, Magnisi and Maddalena Peninsulas, SCHICCHITANO *et alii*, 2007), we obtain evidence for 38 tsunami deposits (Table 1) at 11 different sites (Fig. 1). These are spanning in time from 5200 yrs B.P. to the present and show an average inundation distance from the present coastline of 400 m with a maximum of 1200 m. The age of these events is constrained thanks to 49 ^{14}C and 4 OSL datings, together with tephrochronology and archaeological estimates (at Torre degli Inglesi and Ognina sites). The results are summarized in Table 1, where historical tsunamis are also reported (TINTI *et alii*, 2007).

The integration of all the existing data for this stretch of Sicilian coast provides a unique reference (1) to test if the tsunami deposits age interpretations made by the different authors are coherent, and (2) to evaluate the minimum extent of coastline hit by each correlated event.

Comparing the tsunami deposits ages with known historical events allow us to verify if the tsunami effects confirm their local or regional/basin-wide origin (Table 1). The 1783 and 17 A.D. tsunami deposits were found only at Torre degli Inglesi site (at the northern tip of Sicily, PANTOSTI *et alii*, 2008) and are likely related to a source located near Scilla (Fig. 1, on the Tyrrhenian coast of Calabria – see BOZZANO *et alii*, 2011). A deposit that could be related to the 1542 tsunami was found at the Anguillara site, ca. 70 km north of the area indicated as flooded in the contemporary reports (Augusta, see Fig. 1). At the other sites of Gurna, Augusta offshore and Priolo there is only evidence for one event in the time interval including both 1542 and 1693. We consider more likely the fact that these traces are related to the large 1693 tsunami.

As for the regional historical tsunamis, geological traces of the 1908 event were found at 5 sites (Table 1) for a total minimum inundated coastline extent of ca. 160 km. The 1908 geological record comprises both sandy-bioclastic layers and boulders and can be interpreted as evidence for very energetic waves. Similarly, the 1693 tsunami was recognized at 7 sites (Table 1) suggesting that the hit coastline was at least 130 km-long. Also in this case, the evidence for the 1693 tsunami includes both coarse sand layers and megaclasts. Finally, the 1169 tsunami seems to duplicate the 1693 event (Table 1), reaching a total minimum hit shore length of 130 km.

Traces of the 365 A.D. basin-wide event (e.g. STIROS, 2001) were detected at 5 sites (Table 1) for a total minimum coastline length of ca. 160 km, comparable to the 1908 tsunami. Differently, signatures of the ca. 1600 B.C. Santorini tsunami were found at two sites only in the Augusta Bay (Table 1). In spite of the fact that this should have been a huge event, its evidence is limited at two sites likely because of the difficulty in reaching in the cored sediments an age comparable to that of the Santorini event.

Exploring the most obvious age correlations among those tsunami deposits that are not reported in the historical records (because lost or pre-historical), we found at more than one site two potentially unknown tsunamis that hit the Augusta Bay in the B.C. period: the events are dated at 975-800 B.C. and at 700-500 B.C. For these two events it is not possible to confidently set a regional importance, because of the limited number of sites exploring through this age, and thus we are forced to consider them as local events. Surprisingly, one unknown tsunami was discovered also in the A.D. period in the age range 650-770 A.D. at 4 sites (Table 1) implying at least 145 km of coastline affected. If compared to the events discussed above (1908, 1693, 1169), this tsunami seems to have regional significance and, being a "missed" event in the historical dataset, may turn out to have also a basin-wide importance if found at other sites in the Mediterranean sea.

For tsunami hazard purposes it is also relevant to compare the historical reports on the inundation distance, existing only for the past ~300 yrs, with the geologically observed values, considering the influence of tectonic vertical changes or sea-level rise on the shoreline position in this time frame negligible. For the 1908 tsunami, the comparison can be done for instance at the Anguillara and Vendicari-Morghella sites where we observed the 1908 deposits at a distance of 280 and 380 m from the present shoreline, respectively, whereas at localities within ca. 15 km historical reports account for 200 and 15 m, respectively. The 1693 tsunami was reported to have inundated the Gurna-Anguillara area for 1500 m inland, whereas our geological data yield a minimum of 380 m. Historical data in the Augusta Bay area report inundation of 165 m, whereas at the Priolo site we found the 1693 tsunami deposits up to 530 m inland (DE MARTINI *et alii*, 2012).

CONCLUSION

By integrating geological data on paleotsunami deposits found at 11 distinct sites along the ca. 230 km-long coast of eastern Sicily, we reconstructed a geological tsunami record of the region, substantially extending back in time the historical catalogue. Based on 38 distinct tsunami deposits (from fine sand to boulders) and thanks to several chronological constraints we calculated an average tsunami recurrence interval for the investigated sites ranging between 320 and 840 yrs. Several tsunami deposits are related to known historical events, including those originated far to the east (the 365 A.D. Crete and ca. 3600 B.P. Santorini basin-wide events).

Moreover, the comparison of the ages of these events together with the location of the relative site along the coastline of eastern Sicily allowed us discriminating between tsunamis characterized by a relatively short length of inundated coast (<40 km) and those with a long affected coastline (>130 km) that can be rated as of regional importance. It was also possible to suggest the occurrence of two possibly local unknown tsunamis in the Augusta Bay area during the first millennium B.C. and, quite surprisingly, of one regional unknown tsunami, occurred in the age interval 650-770 A.D. By including this latter tsunami in the dataset presented above, we can estimate an eastern Sicily average recurrence interval for strong tsunamis of ~ 400 yrs in the past 2 ka. Furthermore, the comparison between the historical inundation distance from the shore at few specific sites and the geologically observed minimum values suggests that the historical data tend to underestimate the tsunami ingressions, also by an order of magnitude. Finally, after this work, we do believe, even stronger than before, that the combination of historical and geological data can be very effective in reconstructing the tsunami history of a specific region as well as in providing robust parameters to be used in tsunami hazard estimate and scenario modelling.

The seismic landscape of the Monferrato Arc - NW Po Plain (N Italy)

LIVIO BONADEO (*), ALESSANDRO M. MICHETTI (*), FABIO BRUNAMONTE (*), GIANFRANCO FIORASO (**), FRANZ LIVIO (*), FRANCESCA FERRARIO (*), LEONELLO SERVA (***), EUTIZIO VITTORI (****).

Key words: *Active compressional tectonics, paleoseismology, seismic hazard, Po Plain foredeep, seismic landscape, uplift rates.*

It is commonly thought that the Po Plain is an area of low seismic hazard. This conclusion is essentially a combination of two factors, 1) the historical record of earthquakes, that shows a relatively small number of events of moderate magnitude, and only two significant earthquakes, occurred in the Middle Ages; and 2) the lack of *ad hoc* research on the geology of earthquakes in the study area; although many papers are highlighting local Quaternary tectonics, only very few of them discuss the observed evidence in term of seismic hazard. As illustrated by the May 20, 2012, M6 earthquake in Emilia, the low seismic hazard of the Po Plain is not a real physical feature of this region. In fact, it is a misleading result of analyses based on a largely incomplete database. In this note we argue that the Monferrato Arc basically shares the same seismic landscape of the Ferrara Arc, and therefore it is characterized by a similar earthquake potential, at least in terms of maximum magnitude.

The Monferrato Arc (often defined as "Thrust Frontale Padano" in the Italian literature; referred to as "TFP" in the following and in Figs. 1 and 2), belonging to the northern sector of the Apennines, is located in the westernmost Po Plain, bounded to the W and to the N by the Western Alps, and to the S by the Ligurian Alps (Fig.1). In the W Po Plain the Alps-Apennines junction is characterized by a complex architecture. The metamorphic Penninic Units of the Western Ligurian Alps are tectonically juxtaposed against the non-metamorphic Ligurian Units of the Apennines, along an E-W striking regional fault zone, just south of the Torino-Monferrato hills.

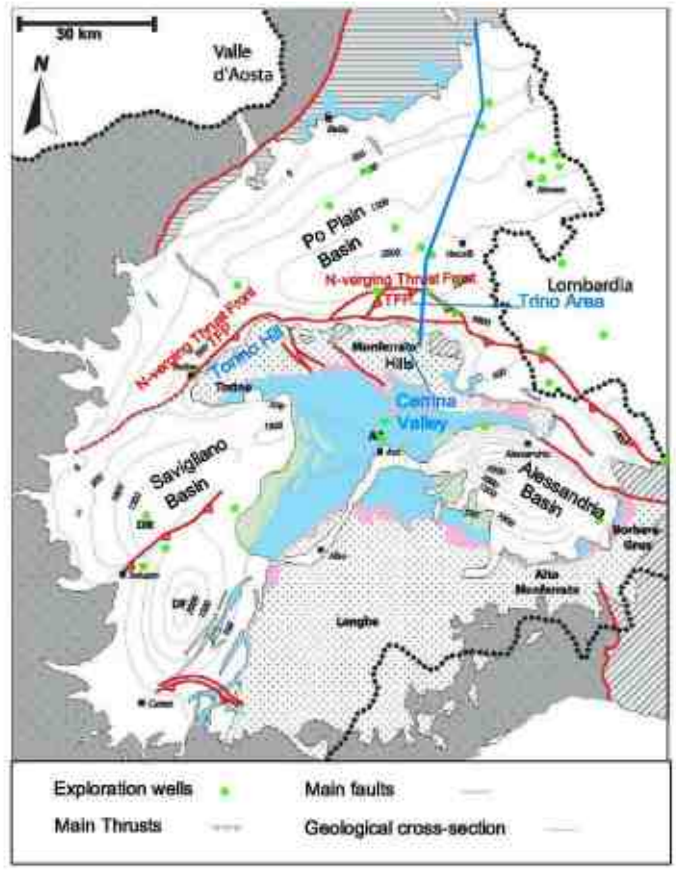

Fig. 1 – Monferrato Arc. The north-verging thrust front (TFP) is buried beneath the alluvial surface of the Po Plain, bounding the northern slope of the Torino and Monferrato Hills.

The Monferrato area exposes a sequence of Upper Eocene to Tortonian deposits, lying on a substratum of Ligurian Units. Along the adjacent Torino Hill, a sequence of terrigenous units of Upper Eocene to Tortonian is outcropping. The Torino Hill lies on the hangingwall anticline of an out-of-sequence, N-verging, breakthrough thrust. Conversely, beneath the Monferrato Hills an important imbricate and north-verging thrust sheet develops. The Rio Freddo Deformation Zone, a NW striking transpressive fault zone (Piana & Polino, 1994; 1995), separates the Torino Hill and Monferrato structures.

This work has been in part funded by grants from the Operational Programme Cross Border Cooperation INTERREG IT / CH 2007-2013 - project "SITINET: census, networking and development of geological and archaeological sites" ID 7621984. Progetto cofinanziato dal FESR – Fondo Europeo per lo Sviluppo Regionale. "Le opportunità non hanno confini".

Available seismic lines highlight a considerable lowering in tectonic activity since Oligocene along the junction between Alps and Apennines and a contemporary progressive activation of out of sequence N-verging thrusts from W to the E (e.g., Falletti *et al.* 1995; Mosca *et al.* 2009). These structures cutoff older alpine thrusts along the so-called "Torino hill structural belt" (Mosca 2006; TFP in Fig. 1 and 2). New data made available by the CARG Project (Dela Pierre *et al.* 2003a; 2003b; Festa *et al.* 2009a; 2009b) clearly document the progressive offset of stratigraphic units and geomorphic paleosurfaces across the TFP during the Pliocene and Quaternary, as already hypothesized by pioneering work from Carraro *et al.* (1995).

Geomorphic evidence of recent activity can be found first of all in the isolated relief of Trino Vercellese, sticking out from the Po Plain just north of the Monferrato Hills (Figs. 2 and 3). The small Trino Hill, only ca. 20 m higher than the surrounding alluvial plain, is in fact the outcropping crest of a mostly buried anticline belonging to the TFP (Gruppo di Studio del Quaternario Padano 1976).

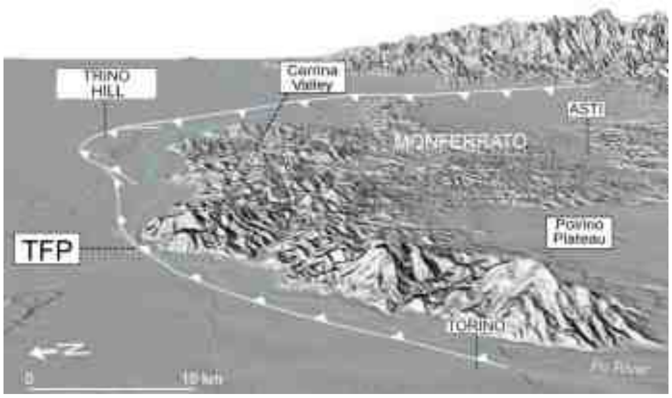

Fig. 2 – Digital Elevation Model and structural features of the Monferrato Arc; view to the East.

Moreover, on the N slope of the Torino Hill, uplifted middle to late Pleistocene fluvial terraces and relics of meandering river courses are present (Vezzoli *et al.* 2010). On these basis, Barbero *et al.* (2007) estimated an uplift rate of 0.8 to 1 mm/yr (Fig. 4); a value consistent with geodetic leveling undertaken in the period 1897-1957 and identifying a contemporary uplift rate of ca. 3 mm/yr for the whole Torino Hill sector (Arca & Beretta 1985). Beneath the Torino metropolitan area, thrust faults belonging to the TFP reach the surface and bedrock in the hangingwall is generally only a few meters below the topographic surface. Above the bedrock, only a thin cover of Latest Pleistocene to Holocene fluvial sediments is present. In this case depositional and/or erosional processes haven't been able to keep pace with tectonic uplift: in the inner sector of the range older features are progressively more uplifted while in the adjacent sector of the plain only incipient relief (e.g., the Trino isolated relief) or terraces are present.

A complex rearrangement of fluvial drainage during the Mid Pleistocene to Holocene, including combing and diversion of major rivers (e.g., Gruppo di Studio del Quaternario Padano 1976; Forno, 1982; Dela Pierre *et al.* 2003b), testifies an important recent tectonic activity of the TFP. For instance, the Cerrina Valley, located at the northern fringe of Monferrato Hills and now drained by the Stura Stream, has to be related to a paleo-Dora Baltea River course that was successively diverted by the northward migration of the mountain front (e.g., Giraudi 1981; Carraro *et al.* 1995). Fluvial deposits outcropping in the Cerrina Valley are related to a catchment located in the western Alps, and valley morphology is clearly oversized compared with the present-day Stura Stream flow rate. The diversion is related to the beginning of Mid Pleistocene, based on pedostratigraphy of paleo-Dora Baltea fluvial deposits (Dela Pierre *et al.*, 2003b). Calculated minimum uplift rate is ca. 0.5 mm/yr (Fig. 4).

The Po River drained eastward, south of the Torino and Monferrato hills, until the end of late Pleistocene, as testified by a) the age of the oldest fluvial deposits, ascribed to Po River, N of Torino Hill and b) clear traces of a huge meandering river preserved on Poirino Plateau (e.g., Carraro 1976; Forno 1982). The Po River diversion was caused by the growing of W-plunging folds (Torino anticline and Asti syncline) whose amplification caused a W-ward tilting of Poirino Plateau itself. This tilting was initially compensated by an E-ward increasing in river erosion and by a progressively S-ward migration of the meandering belt; finally, tilting won and Po River was diverted N of Torino Hill. Tilting uplifted the western sector of Poirino Plateau of ca. 40-60 m over a distance of ca. 20 km. The process can be indirectly dated to Mid Pleistocene, based on Torino Hill contemporary uplifting (Boano *et al.* 2004). Moreover a dated fluvial outcrop, located in the easternmost sector of the Poirino Plateau, ascribable to a paleo-Po Piver course, postdates the river diversion and the subsequent plateau erosion at 45 – 40 Ka B.P. (Alessio *et al.* 1982). The Po River diversion caused, in turn, a change in the Tanaro River course, flowing from S to N and abruptly turning to the E just south of the Poirino plateau; the river flows into an ancient paleo-Po River course, just SE of the Asti Hills.

In the Torino Hill and Monferrato area, therefore, unequivocal geologic and geomorphic evidence points out surface deformation and/or faulting at rates higher than those of the local depositional/erosional morphogenic processes (Carraro *et al.* 1994). The relations between tectonics and sedimentation across the Monferrato Arc, and uplift rates estimated across the TFP at several locations, are illustrated in Figure 4, based on the recent revision published in Irace *et al.* (2009).

Structural styles, ongoing shortening form GPS data and Late Quaternary rates of folding and faulting in the Monferrato Arc are therefore consistent with those documented along structures capable of M6 or larger earthquakes.

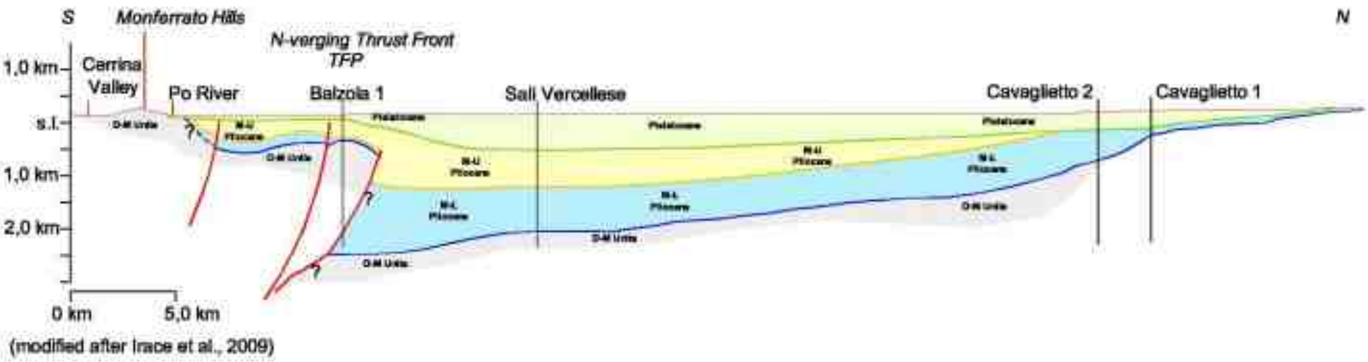

Fig. 3 – Geological cross-section of the Trino Vercellese Area (Monferrato Hill eastern sector) based on detailed lithostratigraphic (exploration wells) and geophysical (seismic lines) data, fully described in Irace *et al.* (2009).

We conclude that A) strong earthquakes such as those occurred on Christmas 1222 south of Brescia (likely along the Capriano del Colle capable fault; Livio et al., 2009) and on May 20, 2012 near Finale Emilia (along the Mirandola capable fault; Scrocca et al. 2007) earthquakes, though very rare, must be considered credible events along all the Quaternary faults throughout the whole Po Plain foredeep, and in particular along the Monferrato Arc, at least until we learn from geological and geophysical studies how/if the Quaternary tectonic structures near Brescia and Mirandola are truly different from those in other areas such as, for example, the Trino Vercellese structure or the Torino hill, B) the late Quaternary - and especially Holocene - history of deformation and the local seismic landscape are far more valuable tools in estimating seismic hazard than has generally been appreciated until now in Italy - as well as in most parts of the world. The lack of significant earthquakes for the last eight centuries in the Garda region, and for longer elsewhere, must prompt an effort to much deeper understanding of the actual seismic potential in one of the most populated and economically developed areas of Europe.

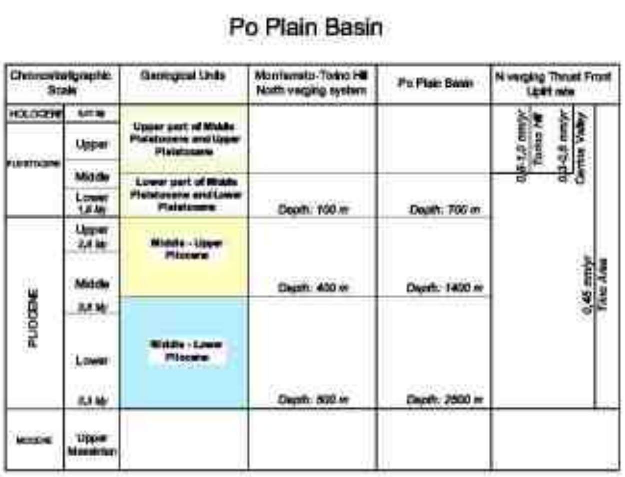

Fig. 4 – Relations between tectonics and sedimentation across the Monferrato Arc during the Plio-Quaternary (modified after Irace et al. 2009), and related uplift rates over different sectors along the TFP, and over different Plio-Quaternary time windows.

Zoning Surface Rupture Hazard along Normal Faults

PAOLO BONCIO (*), PAOLO GALLI (**), GIUSEPPE NASO (**) & ALBERTO PIZZI (*)

Key words: *Surface Fault Rupture Hazard, Normal Fault.*

We propose general criteria for delineating zones of surface fault rupture hazard (SFRH) along active normal faults. Our proposal, which is explicitly inspired to the Californian Alquist-Priolo Earthquake Fault Zoning Act, considers: 1) the observation of surface faulting in populated areas affected by the 2009 Mw 6.3 L'Aquila earthquake in central Italy; and 2) data collected from the literature for several normal faulting earthquake surface ruptures worldwide.

The analyzed data provide insights on the general criteria for shaping zones of SFRH along active normal faults. This is useful for 1) addressing policies aimed at mitigating the SFRH in the Italian Apennines and in areas with a comparable seismotectonic setting that do not already have specific regulations, and 2) providing a case study that might help in defining basic criteria for determining earthquake fault zones and fault setbacks along active normal faults, even for countries or local authorities that already have regulations for SFRH.

Both earthquake fault zone (EFZ) and fault setback (S) are needed to adequately account for the likely SFRH across an active normal fault. The EFZ should include the main fault and the possible active branches of the main fault. Following the Alquist-Priolo Earthquake Fault Zoning Act, the EFZ should be a regulatory zone within which detailed investigations are required prior to building structures for human occupancy. The S is the fault-avoidance zone within which critical facilities and structures for human occupancy cannot be built. While detailed geological investigations prior to building structures for human occupancy can better define the local hazard, minimum requirements for the shape and width of EFZ and S are a necessary starting point.

The 2009 L'Aquila earthquake is one of the smaller earthquakes with ground surface rupture (Mw 6.3), offering the opportunity to set these minimum requirements for normal faults on the basis of direct observations. The conclusions based on these observations are strengthened by the comparison with surface rupture data collected for normal faulting earthquakes worldwide.

Both EFZ and S should be asymmetrically shaped around the trace of the active fault. A S of 15 m is a reasonable value for the footwall, provided that the fault is traced on a detailed map (e.g., 1:5,000 scale). On the hanging wall, a more precautionary S of 40 m is suggested. Observation suggests a minimum width of 150 m for the EFZ on the hanging wall, in order to account for possible active branches of the main fault. A minimum EFZ width of 30 m on the footwall seems to us sufficient for faults mapped in detail.

Rupture zone widths observed globally during moderate-to-large normal faulting earthquakes indicate that the choice of an asymmetric zone around the main fault is reasonable and the proposed widths of the S and EFZ are statistically reasonable values. These data also suggest that other factors must be considered, such as fault kinematics and fault complexities. The width of the rupture zone seems to be systematically wider for oblique-slip faults, indicating that the proposed values are particularly suited for dip-slip normal faults. During large earthquakes, the rupture can cross large (i.e., km-scale) geometric complexities, producing rupture zones much wider than for simple fault traces. This suggests that the width of the EFZ must be flexible, widening in zones of fault complexity (e.g., as large as the separation zone between en échelon segments).

The criteria and examples presented here may be useful in evaluating the potential for SFRH. On the other hand, they cannot be considered operational instruments (e.g., in official construction regulations) until they are at least discussed with other specialists involved in the problem, such as engineers and planners. We hope this scientific contribution will promote discussion, hopefully with operational implications. This is particularly important for countries that do not have explicit and comprehensive codes and/or regulations against SFRH, such as Italy.

Downtown faults

FRANCESCA R. CINTI (*) & LUIGI CUCCI (*)

Key words: *Hazard from Surface faulting, Liquefaction and Tsunami, Urban areas, Seismogenic Faults, Calabria, Southern Italy.*

INTRODUCTION

We show some examples of faults located at or very close to urban settlements and discuss their potentiality for affecting houses, infrastructures and population. Moreover we report some examples of direct effects on settlements from earthquakes worldwide and some specific mitigation actions taken to increase the level of community resilience. In particular, an overview of the fault lines recognized as Quaternary active faults within the Calabria region is discussed respect to the urban distribution. We also overlap the distribution of moderate to large historical and instrumental earthquakes that pose the Calabria territory in a relevant ranking for surface faulting hazard. Based on this rank and on the high density building stocks, on the presence of critical infrastructures (e.g. facilities for telecommunication, public health, water supply, electricity generation) and on the remarkable cultural heritage, the surface faulting risk incoming on the Calabrians is extreme.

Finally, we wish to underline some critical "geological" issues for earthquake mitigation of the risk:

-A detailed knowledge of the fault lines at or very close to the urban areas should be well defined including characterization of the slip at specific sites and also make it available to the community.

-The planning of infrastructure textures should be driven by the seismic/geological information to reduce the economic losses in case of surface faulting, wave inundation, and liquefaction.

-Increase the consciousness of the population for living in a territory devoted to a number of natural hazards, this to be ready to mitigate the effects.

The contribution of airborne LiDAR data to the assessment of surface faulting hazard

RICCARDO CIVICO (*), DANIELA PANTOSTI (*), STEFANO PUCCI (*) & PAOLO MARCO DE MARTINI (*)

Key words: *LiDAR, surface faulting hazard, 2009 L'Aquila earthquake*

Surface faulting is the breaking of the ground surface directly related to coseismic slip along a fault in case of moderate to strong earthquakes (generally for M > 5.5) and is commonly confined to a relatively narrow zone a few meters to few tens of meters wide. However, in some cases a fault can rupture the surface along multiple splays, distributing the deformation across a zone hundreds of meters wide (BONCIO *et alii*, 2012 and references therein).

As the other natural hazards, although scarcely considered, the surface faulting hazard can have a relevant societal impact because it determines a substantial risk where urban areas and/or important infrastructures, facilities and lifelines are developed or planned in correspondence of an active fault trace.

In central Italy, although a significant number of active faults able to produce surface ruptures were recognized and mapped at different scales and with variable accuracy, the assessment of surface faulting hazard is often a difficult task because of: a) lack of detailed map of active faults at a national level; b) the frequent complex geometrical pattern of active tectonic structures related to inherited structural and deformational style.

By a practical point of view, the exact identification of active fault traces is the first task to be accomplished for assessing surface faulting hazard. This is done by means of the direct observation of geomorphic and tectonic features that are related to the present tectonic activity.

The occurrence of the 6 April 2009 Mw 6.3 2009 L'Aquila earthquake strongly highlighted how critical is a deep knowledge of the location and characterization of the active faults and also of their secondary splays to prevent damage directly related to surface faulting.

In fact, during the April 6 mainshock, coseismic surface ruptures occurred along several splays that are part of the complex fault system that is the expression of the earthquake causative fault at the surface (Paganica fault – PF thereinafter). Buildings and lifelines located across or near the coseismic surface ruptures suffered significant damage (e.g. the Paganica-Tempera aqueduct pipe broke because crossed by coseismic surface faulting). Even secondary splays had a role in the damage distribution in the area. (EMERGEO WORKING GROUP 2009; FALCUCCI *et alii* 2009; BONCIO *et alii* 2010).

Prior to the 2009 earthquake, the PF was reported in the official geological maps as a single, simple fault trace affecting Middle to Late Pleistocene continental deposits (Geological Map of Italy, scale 1:50.000, sheet 359, L'Aquila, APAT, 2005).

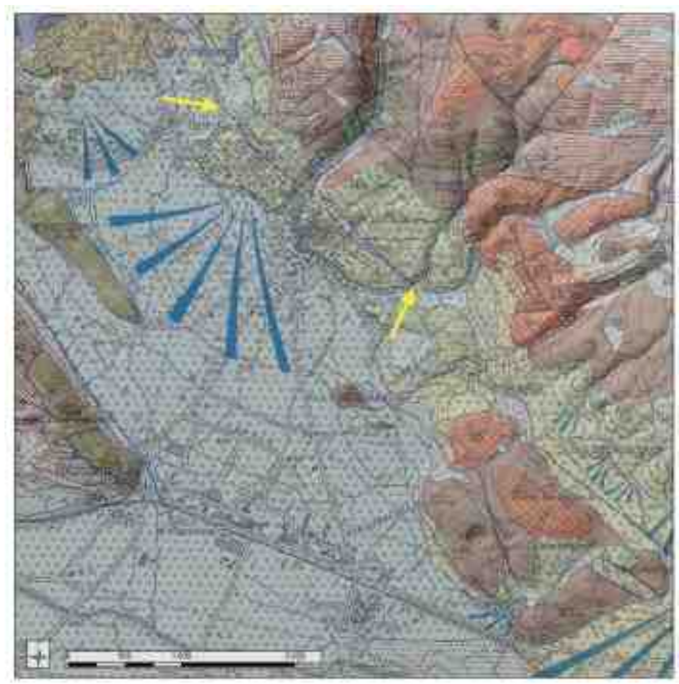

Fig. 1 – Trace of the Paganica Fault (blue line between yellow arrows) as reported by the Geological Map of Italy, scale 1:50.000, sheet 359, L'Aquila (APAT, 2005).

The complexity of the 2009 coseismic surface breaks highlighted the need for a substantial refinement of the PF mapping, including minor and hidden active fault traces despite they have or have not ruptured in 2009. This with the aim of defining all the fault splays capable of displacement in the future earthquakes and especially to pinpoint those that have a higher potential to slip.

In doing this, we took advantage of the availability of an airborne LiDAR (light detection and ranging) survey performed in the area hit by the 2009 earthquake.

LiDAR is an optical remote sensing technology that uses laser light to measure distances with high accuracy and high resolution and that is capable of revealing the ground surface even in highly vegetated areas. Moreover, the high-resolution topographic data stored in the LiDAR-derived Digital Elevation Models (DEMs)

(*) Istituto Nazionale di Geofisica e Vulcanologia, Rome, Italy.

may be digitally manipulated to enhance and reveal subtle topographic features, something not possible with most aerial photographs, satellite imagery, or lower-resolution digital elevation data.

High-resolution topographic data such as airborne LiDAR have recently been deployed to qualitatively and quantitatively analyze landscapes resulting from tectonic, hillslope, fluvial, biologic, and anthropogenic activity. Earth-science applications of LiDAR include identification of faults (HAUGERUD *et alii* 2003, CUNNINGHAM *et alii* 2006, KONDO *et alii* 2008, ARROWSMITH and ZIELKE 2009, HUNTER *et alii* 2011), characterization of the geometry of fault scarps (BEGG and MOUSLOPOULOU 2010, DELONG *et alii* 2010, HILLEY *et alii* 2010, BRUNORI *et alii* 2012) and estimates of slip-rate of active faults (FRANKEL *et alii* 2007, AMOS *et alii* 2010).

The airborne LiDAR survey of the study area was commissioned by the Italian Civil Protection Department and was performed a few days after the 6 April 2009 mainshock by the Civil Protection of Friuli Venezia Giulia (Italy) using an Optech ALTM 3100 EA Airborne Laser Terrain Mapper System, with vertical errors <0.2 m and horizontal errors <0.54 m. The original LiDAR bare-earth point cloud was processed in order to obtain a regular 1 x 1 m DEM and several derivative digital maps (shaded relief, slope, aspect, etc.).

Figure 2 compares the resolution of traditional photogrammetry-generated (5 m resolution - figure 2a) and LiDAR-generated shaded reliefs (figure 2b) and highlights how the very high-resolution (1m) LiDAR-derived data can be an effective tool in representing the landscape morphology with unprecedented detail.

In figure 2, the LiDAR-derived shaded relief allows to display, among others, some subtle landforms like fault-related scarps and peculiar drainage patterns (e.g. fluvial entrenchment that may testify the location of uplifted fault footwall) of an area close to the San Gregorio village.

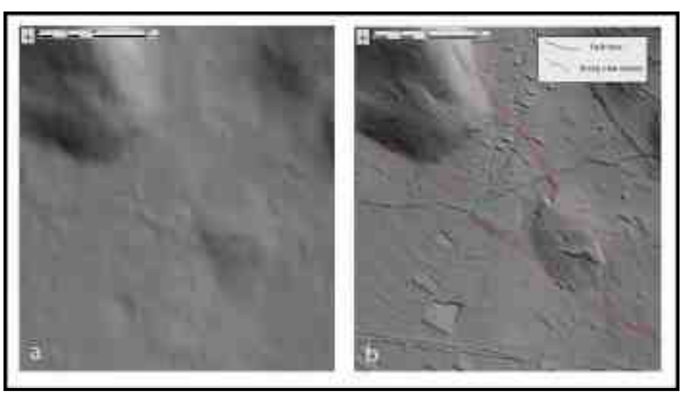

Fig. 2 – Comparison between 5m resolution (a) and 1-m resolution (b) shaded reliefs.

By extensively using the LiDAR-derived high resolution topographic data, we performed morphological analysis and mapping at a 1:10.000 scale, to identify and map all the existing active tectonic structures in the study area, as well as to characterize their predominant behavior.

Figure 3 encompasses the same area of figure 1 and highlights how the LiDAR-derived data can substantially increase our confidence in locating and tracing most of the active fault traces.

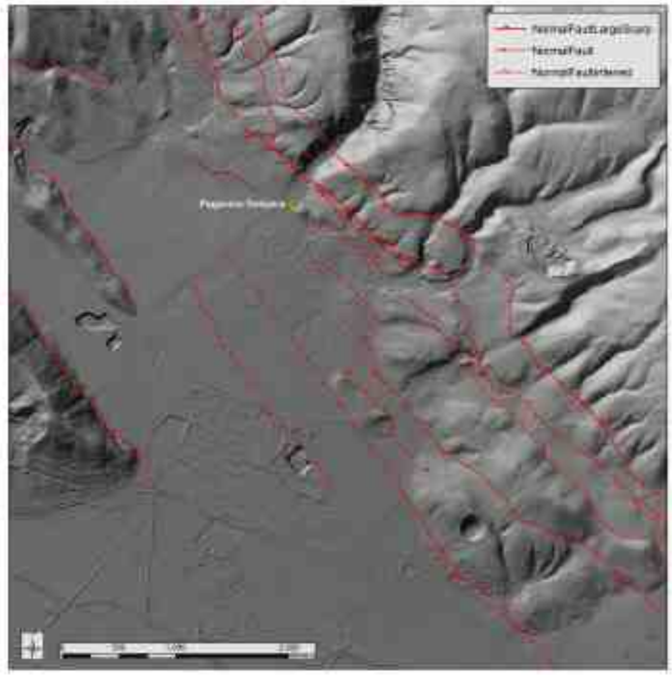

Fig. 3 - LiDAR-derived shaded relief showing the surface structural setting of the Paganica fault (same area of figure 1).

At the LiDAR resolution, the surface structural setting of the PF appears to be much more complex than expected from the geological map (figure 1) but also from previous detailed works (BAGNAIA *et alii* 1992, VEZZANI and GHISETTI 1998, BONCIO *et alii* 2004), being characterized by the presence of several normal parallel fault splays both synthetic and antithetic.

The L'Aquila experience, as well as those developed from other parts of the World, shows that LiDAR data offer a unique opportunity to improve our knowledge about the location of fault splays related to an active structure, the reconstruction of its overall geometry and extent, and for its characterization. Under this light, fault mapping integrating LiDAR to the other traditional approaches, is certainly an innovative and effective tool that represents the first input for starting, in Italy too, a reliable assessment of surface faulting hazard following standardized or regional methodologies (e.g. Eurocode 8, 2003; BONCIO *et alii* 2012).

In this paper we are going to present some key areas where LiDAR data analysis contributed to a better imaging of the location of the active fault splays relevant to existing and developing urban centers, industrial areas and main infrastructures (roads, railways, pipelines, etc.) in the area hit by the April 6 2009 earthquake.

Active normal faulting, rupture segmentation and structural "complexities": insight from geological, paleoseismological and seismological data along the middle Aterno river valley, in the 2009 L'Aquila earthquake region (Central Italy)

STEFANO GORI (*), EMANUELA FALCUCCI (*), MARCO MORO (*), MICHELE SAROLI (*;°), CLAUDIO CHIARABBA (*), GIANDOMENICO FUBELLI (+), FABRIZIO GALADINI (*)

Key words: *central Apennines, active normal faulting, Middle Aterno valley-Subequana valley fault system, San Demetrio-San Mauro faults, 2009 L'Aquila earthquake.*

INTRODUCTION

The eastern flank of the middle Aterno river valley is affected by the NW-SE trending Middle Aterno Valley fault system (hereafter MAVF) (Fig.1). This tectonic structure, characterised by normal kinematics, is about 20 km long and represents the surface expression of a seismogenic source potentially responsible for earthquakes with M of up to 6.5-7, which is presently considered as "a seismic gap" (e.g. GALADINI AND GALLI, 2000; PACE *et alii*, 2006), i.e. no large magnitude historical seismic event (e.g. WORKING GROUP CPTI, 2011) can be attributed to the activation the MAVF.

We investigated the Quaternary activity of the fault system by performing geological field surveys aimed at identifying continental deposits affected by the fault movements; as for the Holocene activity, we also made classical paleoseismological investigations (trenches) to collect information about the recent kinematic behaviour of the MAVF.

GEOLOGICAL AND PALEOSEISMOLOGICAL ANALYSES

Two excavations have been performed across the fault, close to the village of Roccapreturo. We identified two subsequent surface faulting episodes in the late Holocene.

The chronology of the events, as well as the displacement per event, is highly consistent with that of the displacement episodes identified along the Subequana Valley fault (hereafter SVF) by FALCUCCI *et alii* (2011) (Fig.1). This corroborates the hypothesis made by the mentioned authors of a hard linkage between the MAVF and the SVF. The obtained results define a recurrence interval for the MAVF-SVF system in the order of 2000-2300 years and an elapsed time since the last activation of about 2000-2200 years.

STRUCTURAL SETTING OF THE NORTHEN SECTOR OF THE MVAF

As for the definition of the total surface extent of the fault system – to be utilised for defining the maximum expected magnitude of an earthquake determined by this tectonic structure (e.g. WELLS AND COPPERSMITH, 1994) – useful information has been obtained by mapping the segments that compose the MAVF-SVF system. In particular, we focused on the northernmost termination of the structure which, according to GALADINI AND GALLI (2000), is represented by a sector affected by a dense net of parallel, few-km-long fault strands (Fig.1). Among these, the San Demetrio and San Mauro faults (hereafter SDF and SMF, respectively) are known (e.g. BOSI AND BERTINI, 1970; BERTINI AND BOSI, 1993; GIACCIO *et alii*, 2011) and related to the MAVF by GALADINI AND GALLI (2000). Conversely, it has been proposed that the SDF and SMF are part of a longer fault system comprising the Paganica fault (hereafter PF; Fig.1) – i.e. the causative fault of the 2009 L'Aquila seismic event (Mw 6.1; e.g. CHIARALUCE *et alii*, 2011) – that activated during the earthquake (GALLI *et alii*, 2010; 2011) or that can activate during seismic events stronger than the 2009 one (e.g. CALDERONI *et alii*, 2011). In this perspective, it must be noted that, however, geological and coseismic geodetic (GPS and InSAR) observations suggested that the SDF exclusively activated during the 2009 earthquake as a secondary/sympathetic structure and that this fault and the PF have been probably characterised by a different kinematic history (GORI *et alii*, in press).

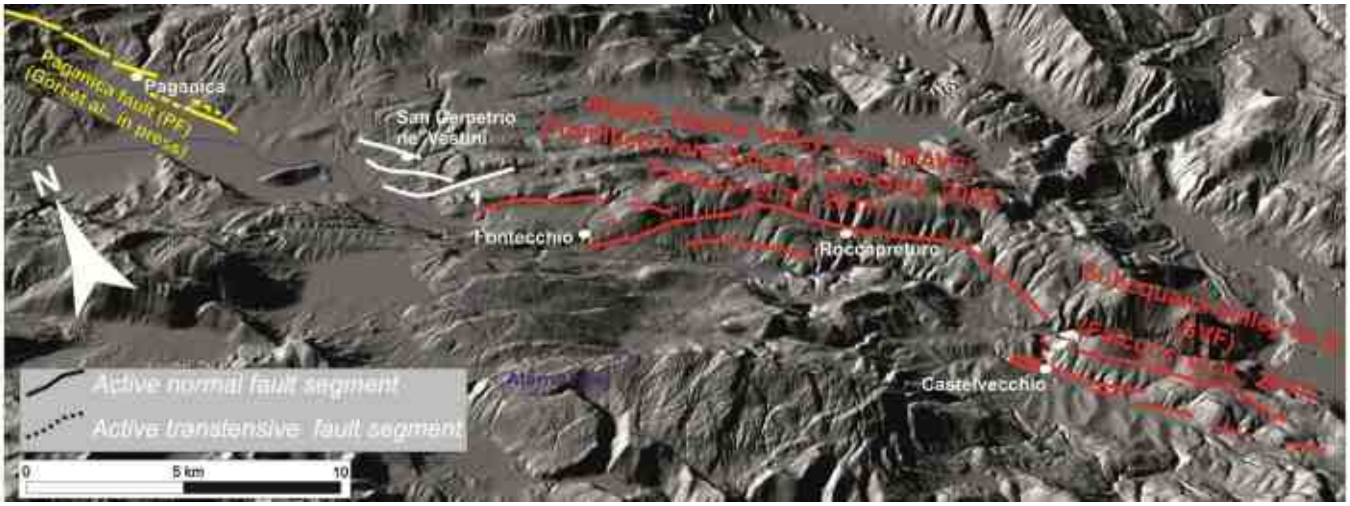

Fig. 1 – Structural setting of the middle Aterno river valley. The Paganica fault, yellow lines; The Middle Aterno Valley fault-Subequana Valley fault system, red lines; fault segments whose attribution is still under debate, white lines.

SEISMOLOGICAL OBSERVATIONS

This being settled, we analysed the seismic sequence occurred after the April 6 2009 mainshock with the aim of casting light on the extension towards north of the MAVF. The hypocentres localisation confirms that the rupture along the PF did not extend south of San Gregorio, and that it did not include the SDF and SMF area, as indicated in previous works (FALCUCCI *et alii*, 2009; BONCIO *et alii*, 2010; GORI *et alii*, in press); moreover, within this light, it is worth noting that the activation events identified along the MAVF-SVF system are chronologically mismatching with those recognised along the PF (GALLI *et alii*, 2010; MORO *et alii*, 2010; CINTI *et alii*, 2011). Furthermore, the seismological data fit the observations obtained by means of geological and geodetic data (GORI *et alii*, in press), depicting a complex structural setting in the sector comprised between the MAVF-SVF system and the PF, i.e. the area of the SDF and SMF, influenced by pre-existing structural features.

Key words: *Active tectonics, Southern Alps, Paleoseismology*

INTRODUCTION

Here we focus on new paleoseismological evidence on the first observation of late Pleistocene to Holocene paleoseismic surface faulting in the Po Plain, identified at the Monte Netto site (LIVIO *et alii*, 2009), located ca. 10 km S of Brescia, in the area where the highest damage from the Christmas 1222 earthquake have been recorded (GUIDOBONI & COMASTRI, 2005).

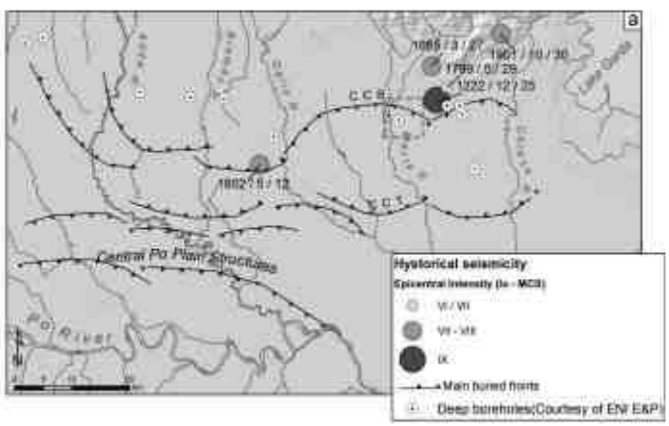

Fig. 1 – Structural map of the buried structures in the study area. The dashed box indicates the Monte Netto site, where exploratory trenches were excavated. Abbreviations: CCB: Capriano del Colle backthrust; CCT, Capriano del Colle thrust.

Fig. 2 - On the top of Monte Netto, 10 km S of Brescia, new quarry works in 2007 exposed a Late Pleistocene to Holocene fluvial (FS) and loess (LS) sequence affected by growth folding and surface faulting and seismic induced liquefaction features (B).

Monte Netto is a small hill, ca. 30 m higher than the surrounding piedmont plain, which represent the top of a growing fault-related fold belonging to the Quaternary frontal sector of the Southern Alps; the causative deep structure is a N-verging back thrust, well imaged in the industrial seismic reflection profiles kindly made available by ENI E&P (CCB in Fig. 1; e.g., LIVIO *et alii* 2009).

PALEOSEIMICS INVESTIGATIONS

New trenching investigations have been conducted at the Cava Danesi of Monte Netto in October 2009, focused on the 1:10 scale analysis of the upper part of the 7 m high mid-

Midland Valley MOVE® suite software has been used for model construction and fault/fold restoration

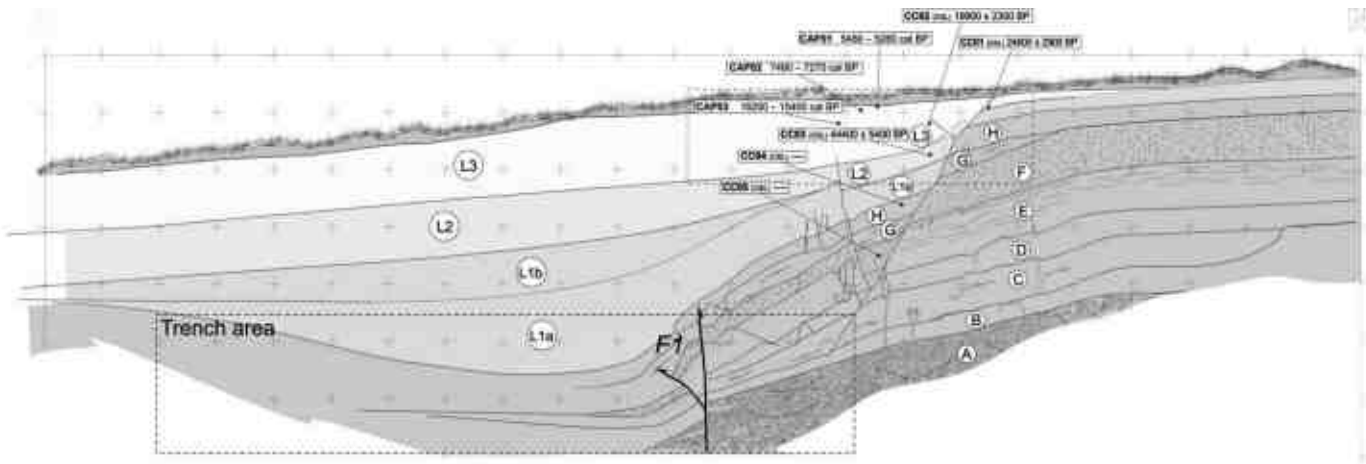

Fig. 3 – Log of the trench excavated in the Monte Netto area. Grid spacing is 1 m. Dashed boxes indicate the area that has been trenched (western wall). The fluvial sequence has been divided into 8 different stratigraphic units (A to H) and a sequence of four loess-paleosols cover has been divided into 4 different pedo-stratigraphic units, based on sedimentological and pedological characteristics. Dating labels refers to CC series, which indicate OSL samples, and CAP series, which are 14C AMS samples. Archaeological dating available in the Monte Netto site (Cremaschi, 1975) is consistent with our new analyses.

Pleistocene to Holocene stratigraphic section exposed along the quarry walls. The section exposes a sequence of early-to-late Pleistocene fluvial sediments; loess strata cap the sequence on the top of the hill (Fig.2 and 3). Decametric secondary anticline gently fold the fluvial sequence and evidence of paleoseismicity is also provided by the observation of paleoliquefaction features near the graben (Fig. 2c). In particular, we excavated a ca. 2 m deep trench across the graben that affects the crest of a decametric anticline due to paleoseismic bending-moment faulting (Fig. 3).

DATINGS AND AGE ESTIMATES

Eight samples were collected and analyzed from five units to constrain ages of alluvial and loessic sediments exposed in the trench (Fig. 3). AMS ^{14}C samples indicate that all units in the trench exposures are Holocene in age.

The samples provided for OSL analysis were prepared in the laboratory at Innsbruck. Approximately 20 g of each sample was removed for water content measurement and dosimetric analyses. The remainder of the sample was prepared for OSL analysis following standard techniques (WINTLE, 1997).

The luminescence analysis was undertaken using the double single-aliquot regenerative-dose (SAR) protocol (BANERJEE *et alii*, 2001; ROBERTS & WINTLE, 2001) with a preheat of 220°C for 10s, and a cutheat of 160°C

The D_e values were obtained from the blue LED stimulated measurements, and thus is based on the quartz component of the polymineral fine-grain mixture.

The D_e was measured for 24 aliquots of samples 8/CC01-03. From the D_e dataset of 24 values for each sample, the burial dose was calculated using the Central Age Model (GALBRAITH *et alii*, 1999). Luminescense results indicate an Upper Pleistocene aggradation for loess strata. The described loess-paleosols series can be tentatively correlated with the well established marine oxygen-isotope stages (MIS) sequence integrating constraints coming from OSL and 14C AMS datings and on some archeological findings. These correlations suggest that the sequence would represent a complete stratigraphic recording of cold/warm climate stages, for northern Italy, starting from MIS 7 to present (Fig. 3).

- Soil I developed on Unit H to the south and on Unit L1 to the north. Its formation started during MIS 7 warm stage (243- 191 Ka);
- Unit L1b deposited during MIS 6 (191 – 130 Ka) and Soil II developed during the following warm oscillation (“Eemian” MIS 5e – 130 – 114 Ka);
- then a long polyphasic and polycyclic cold phase followed (MIS 5d – 2) and Units L2 and L3 deposited. Soils III and IV developed during interstadials and the whole Holocene.

L2 deposition is constrained by an OSL ca. 44 ka dating, to MIS 4 cold phase and 14C AMS and OSL datings both bracket ages for Unit L3 deposition. Two archeological findings strengthen these correlations: a Paleolithic “*levellois*”, probably Mousterian core artifact found in Unit L1 and another flint chip found in Unit L3.

RESULTS

The trench walls allowed to identify 3 discrete events of graben reactivation, interpreted as generated by 3 strong paleoearthquakes (Fig. 4). These paleoearthquakes occurred between ca. 45 kyr B.P. and ca. 5 kyr B.P., based on OSL and AMS dating of stratigraphic units sampled on the main quarry walls, and mapped also in the October 2009 trench. The post 5 kyr B.P. stratigraphy is missing at the trench site, due to plowing and reworking. These data indicate an average recurrence interval of ca. 15 ka., which obviously should be considered as a maximum interval, since some paleo-events could be missing or not recorded due to the discontinuous nature of the sedimentation at the site.

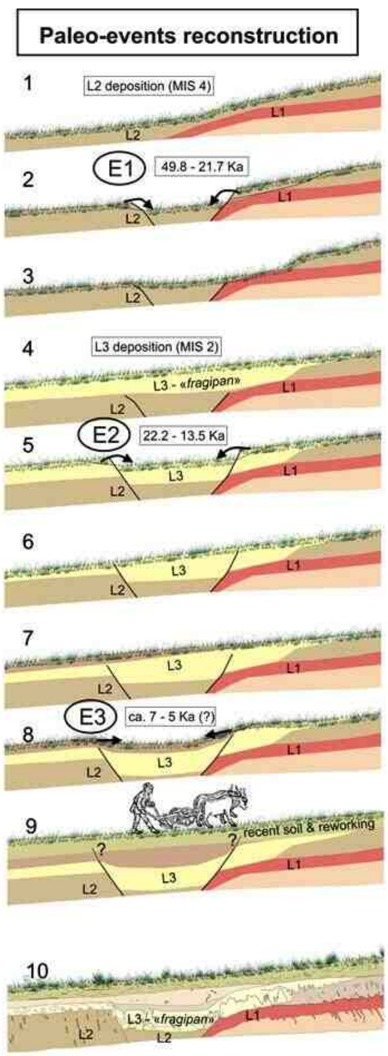

Fig. 4 – Step diagram illustrating the paleoseismic history of the Monte Netto site, as reconstructed through the paleo-events recorded in the analyzed section. E1, E2 and E3 indicate the paleoevents; ages are bracketed by dated horizons.

The paleoseismic evidence at Monte Netto, clearly related to the growth of a recent compressional structure, is significant for the assessment of the threshold for coseismic surface rupture along capable faults in the Po Plain foredeep. Ongoing investigation in the epicentral area of the May 20, 2012, M6 Finale Emilia earthquake, characterized by a very similar structural setting and crustal stress environment, will allow to compare modern and paleoseismic ground effects from the two sites, thus providing a calibration for the earthquake magnitude needed to generate tectonic surface rupture in this region.

Sub-bottom Chirp analysis for active tectonics and seismo-induced features investigation: application in the Augusta Bay (Italy)

C. PIRROTTA *, M.S. BARBANO*, D. PANTOSTI **, P.M. DE MARTINI **

Key words: *active fault, chirp sonar, earthquake, Ionian Sea, seismically- induced slump.*

INTRODUZIONE

The Augusta Bay, located along the Ionian coast of Sicily, is a NNW-SSE trending tectonic depression delimited by Quaternary faults (Fig. 1) some of them showing recent activity (BF, PMF and MEF in Fig. 1) (CARBONE *et alii*, 2011; ARGNANI and BONAZZI, 2005). In the past this area was affected by strong earthquakes (1169 and 1693, magnitude ~ 7.0; CPTI Working Group, 2004) as well as moderate close- located events (1542, M ~ 6.2; 1848 and 1990 M ~ 5.5; CPTI Working Group, 2004). Some of these earthquakes (e.g. the 1169, 1542 and 1693events) were followed by tsunamis that flooded the Augusta Bay as well.

Even if the location of the seismogenic sources of eastern Sicily is still controversial in the scientific community, most of the active tectonics evidence is located offshore in the Ionian Sea, likely related to the NNW-SSE striking Malta Escarpment fault system activity (e.g. BIANCA *et alii*, 1999; ARGNANI *et alii*, 2012). In proximity of the Augusta Bay the faults of the Malta Escarpment system run very close to the coast (see the segment MEF in Fig. 1) and they cause seafloor faulting and the development of sedimentary basins (ARGNANI and BONAZZI, 2005).

The Augusta Bay is a key area to clarify possible Malta Escarpment fault system activity and its relations with the tectonic structures detected onshore. Thus, the offshore basin was chosen as a natural laboratory to develop paleoseismological and active tectonics studies through a geophysical campaign based on high resolution sub-bottom Chirp technique. This method is particularly suited to this kind of studies because the signal penetrates very well into the soft young sediments and gives back high resolution images that may show recent and superficial sedimentary and tectonic structures. Moreover, it offers the possibility of exploring a continuous and well-preserved offshore sedimentary record with a detail comparable to inland outcrop observations.

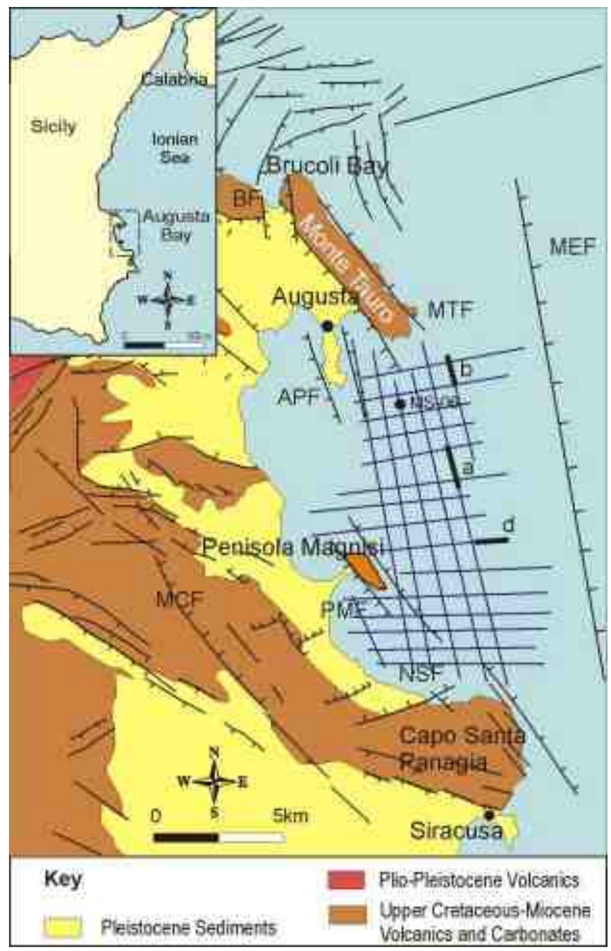

Fig. 1 – Geological sketch map of the Augusta Basin showing bordering Quaternary faults indicated as: BF = Brucoli Faults; MTF = Mt Tauro Faults; APF = Augusta Peninsula Faults; MCF = Mt Climiti Fault; MPF = Magnisi Peninsula Faults; NSF = North Siracusa Fault; MEF = Malta Escarpment Fault; blue lines indicate the sub-bottom chirp profile grid; black tracts refer to the chirp section shown in Fig. 2; MS06 is the sediment core performed by SMEDILE *et alii* (2011). Inset at the top left locates the study area in eastern Sicily.

METHOD

Chirp profiles (Fig. 1) were acquired during a cruise performed in Summer 2007, within a collaboration among INGV (Istituto Nazionale di Geofisica e Vulcanologia), Geological Department of Catania University and CNR-ISMAR (Istituto di Scienze Marine). Geophysical data were caught using a deep-towed Chirpsonar (Datasonics SIS-1000) operating at a frequency of 3-7 kHz. The instrument also included an ADSL link from the tow-fish to the topside computers. The deployment configuration was complemented with an onboard motion sensor and a global positioning system (GPS) receiver to measure real position for every shot. The surveyed grid covers an area of 90 km^2 and consists of 22 ~N-S and ~E-W striking lines, with average line spacing of 1 km and 0.45 m of shot interval. Acquired seismic data were converted into standard SEG-Y, corrected and processed using the seismic processing software package SeisPrho (GASPERINI and STANGHELLINI, 2009).

RESULTS AND DISCUSSION

The seismostratigraphic analysis highlighted two main reflectors. A lower reflector (R1) characterized by high reflectivity values (between 1 and 1.5) (Fig. 2a) represents the top surface of the bedrock (Seismo-Unit-A). This reflector, on the basis of its seismostratigraphic characteristics, likely images the limestone of Miocene and/or Pleistocene age cropping out inland (Fig. 1). The R1 reflector is a wide erosion surface, locally irregularly shaped with high and low reliefs. Since the penultimate highstand terrace (MIS 3.3, age ~ 60 ka) outcrops inland, close to the Augusta Bay, R1 likely represents the erosion surface formed between 60 and 19 ka BP (the Last Glacial Maximum, LGM). A semitransparent homogeneous sequence of sediments (Seismo-Unit B, Fig. 2a) lies on this surface. In the north-eastern part of the basin it reaches a maximum thickness of 35 m. The top surface of Seismo-Unit B, R2 reflector, has average reflectivity values between 0.1 and 0.6, suggesting that this deposit is made of unconsolidated very fine sediments. Low reflectivity values also allow the penetration of the signal into Seismo-Unit B, where thin higher reflectivity levels shape aggradational geometry and almost horizontal stratification (Fig. 2a). A prominent high-amplitude reflector (Rt) (average reflectivity between 0.12 and 0.56), representing an 'acoustic anomaly', is observed into Seismo-Unit B between 3 m and 10 m b.s.f. (below seafloor) (Fig. 2a).

The analysis of a 6.7 m-long sediment core (MS-06), sampled in the northern part of the Augusta Basin (Fig. 1), confirms that Seismo-Unit B represents the sedimentary record post-dating the LGM and allows to relate Rt reflector to a coarse ash level originated during the 122 AD Plinian Etna eruption (SMEDILE *et alii*., 2011).

Morphobathymetric map of the basin (Fig. 2b), obtained processing and combining Chirp profiles, shows a rather articulated morphology. The basin can be divided into a northern and southern sector comprising mostly highlands and a central sector that is a morphological low showing a more complex geometry.

Morphobathymetric analysis also allowed to observe two marine abrasion platforms with their related inner/outer edges, Ms1 and Ms2 (Fig. 2b) that can be tentatively correlated with two minor high stands occurred between 60 ka and the LGM time: the first at 45 ka BP and the latter at 30ka BP.

Combining Chirp profile and morphobatimetric analyses normal faulting and active deformation were observed into the basin. The main detected features are shown in Fig. 2b. Some faults appear to be still active as they rejuvenate scarps bounding asymmetric basins, cause seafloor up-warping, displacement of the two marine abrasion surfaces (Ms1 and Ms2) and development of growth strata in the post-LGM sedimentary sequence. As an example Nf4 produces seafloor down-warping and active deformation with growth strata geometry development into Seismo-Unit B (Fig. 2 c and 2d). Gas clouds, often observed in proximity of some faults, are a further evidence of the activity of these faults acting as preferential emission path. Considering the age of the younger displaced marine abrasion surface (Ms2) and that active faults cause ~ 15- 20 m of dislocation, we can obtain an slip rate of ~ 0.5- 0.7 mm/y since 30 ka for these structures. Also, some faults seem to be the offshore prosecution of those bordering emerged sectors: Cf1 can be the prosecution of the fault bordering the Augusta Peninsula to the east (APF in Fig.1), Sf4 of one of the faults affecting Capo Santa Panagia and f1 of the structure bordering the Magnisi Peninsula to the west (MPF in Fig. 1).

Soft sediment deformations (slumping), involving the post-LGM sediments, were found at the foot of some scarps (Fig. 2e and 2f). The observation of the geometry and shape of the echo-types, together with morphobathymetric analysis of the Augusta Basin, allowed us to exclude wave action, contour currents, and turbidity flows as triggering mechanisms. Therefore, earthquake shaking seems to be the most likely process responsible for slump formation. At least two different slumped bodies, lying unconformably and with different deformation style and shape, are observed. The lower body (A) appears more intensely deformed with wringer folds, the uppermost body (B) appears more weakly deformed, showing still the typical stratification of the Seismo-Unit-B, and also encompass the Rt reflector (Fig. 2e and 2f). Given their different deformation degree and unconformable setting, these two deformed bodies can be related at least to two different seismic shaking, occurred before and after the deposition of the 122 AD tephra layer. These events had sources near enough and released sufficient energy to produce the above described deformations at the study area. The presence of slumped bodies in the vicinity of faults suggests a tectonic instability of the basin and it also confirms the hypothesis that these faults may have been activated during recent earthquakes.

CONCLUSIONS

The faults we detected in the Augusta Basin have not sizes suitable for generating earthquakes of magnitude M > 7.0 such as the 1693 main-shock. On the other hand, they might have generated the moderate events occurred in the area (e.g. the 1542, 1848 and 1990 quakes).

Orientation and kinematics of these faults are compatible with the Malta Escarpment fault system of which they can be the westernmost traces. This hypothesis puts forward that the Malta Escarpment fault system can be active at least in the sector of the Augusta Basin and responsible for some of the strong historical earthquakes of south-eastern Sicily.

Our results are also significant for seismo-geological hazard evaluation. This is of high relevance not only because the Augusta Bay is a densely populated area, but it also covers an important role for the economic and industrial framework of Sicily and hosts an Army Naval base.

Seismically-induced re-activation of landslides along the Southern Calabria Tyrrhenian coast: co-seismic displacements computed by a spectrum compatibility approach

BOZZANO F. (*), ESPOSITO C. (*), MARTINI G. (**), MARTINO S. (*), PRESTININZI A. (*), RINALDIS D. (**), ROMEO R.W. (***), SCARASCIA MUGNOZZA G. (*)

Key words: *Seismically-induced landslides, susceptibility analysis, Newmark's displacements, spectrum-compatible reference inputs, Southern Italy*.

INTRODUCTION

Expected co-seismic displacements of slopes are commonly computed by applying Newmark's sliding block method; based on this approach, some empirical equations were proposed by solving multivariate co-relations (Jibson et al., 1998; Romeo, 2000; Hsieh & Lee, 2011) to provide the Newmark's displacements (D_N) for known values of critical acceleration and ground-shaking parameters (i.e. PGA or Arias intensity). Probabilistic seismic landslide hazard-mapping procedures for Newmark's co-seismic slope displacements was applied so far by many Authors (Jibson et al., 2000; Saygili & Rathje, 2009; Romeo et al., 2011); nevertheless, these applications are generally referred to slope failures, i.e. not specifically devoted to analyse co-seismic displacements due to re-activation of pre-existing landslide masses. The here considered South-Tyrrhenian Calabria represents a significant test site since it is exposed to high magnitude earthquakes (related to Southern Italy seismogenetic source areas), as proved by the catastrophic earthquakes in 1783 ("Terremoto delle Calabrie" earthquake - M_w=6.5+) and in 1908 ("Reggio and Messina" earthquake - M_w=7.0). To perform this study natural time-histories compatible with the expected response spectra were specifically derived for each landslide mass and for each considered earthquake scenario, as an alternative to a PGA shaking map; moreover, it was also taken into account the role of pore water pressures within the slopes by considering a variation of the r_u parameter along the landslide sliding surface.

LANDSLIDE INVENTORY

The geological setting of the study-area is characterized by outcroppings of cemented rocks and granular deposits ascribable to the Ercinic-Holocene time interval. The Paleozoic basement is part of the Aspromonte metamorphic unit. Also a thick succession of terrigenous transgressive deposits widely outcrop in the study area and it includes conglomerates, marls and sands, ascribable to the Tortonian-Pliocene time interval, passing to sands and gravel of the Pliocene-Holocene time interval and including marine terrace deposits. The intense tectonic evolution of this area is responsible for intense jointing of the rock masses which can be observed astride the main fault lines.

Several landslides affect the study area because of the morphological features of the relief (i.e. deepening rivers, cliff slopes) as well as of the geomechanical properties of the outcropping rock masses (i.e. highly jointed rock masses or poorly cemented granular deposits). 175 landslides were recognized so far, including 57 falls and 118 sliding, over an area of about 45 km^2. More in particular, the sliding mechanisms include 94 roto-translational landslides and 24 translational landslides. The percentage Landsliding Index computed for the study area is almost equal to 6%. Moreover, about 80% of all the recognized landslides involves the metamorphic substratum, among which about 57% is represented by roto-translational landslides and 51% by falls.

HISTORICAL EARTHQUAKETRIGGERED LANDSLIDES

The ground effects historically documented were derived from the CEDIT catalogue (Martino et al., 2012), whose reports the ground failures triggered by the largest Italian earthquakes. In the investigated area, the catalogue reports 12 localities where seismically-induced landslides occurred, referring to the following municipalities: Bagnara Calabra, Favazzina, Fiumara, Palmi, Ruffino, Sansone, Sant'Agata, Sant'Anna di Seminara, San Procopio, Scilla, Seminara, Sinopoli. The total reported landslides amount to 21, referring to the following earthquakes: 1783, 1894, 1905 and 1908. In table 1 the number of landslides triggered by each earthquake related to the seismogeneic source are reported. The largest number of documented landslides refers to the February 5th 1783 earthquake, while the smallest number refers to the November 11th 1894 earthquake. In the same table the relative frequency of reactivated landslides based on the numerical analysis described hereafter is shown; the inversion between the estimated reactivation of landslides and the documented ones that can be observed between the 1783 and 1908 earthquake, may be possibly interpreted as a source effect determined by the location of the investigated area on the hanging-wall as it regards the 1783 earthquake source, and on the foot-wall as it regards the 1908 earthquake source, whose effect has been neglected in the simulation of time-histories.

SCENARIOS OF SEISMICALLY-INDUCED LANDSLIDE RE-ACTIVATIONS

In order to derive re-activation scenarios of earthquake-induced landslide, 6 seismogenetic source areas were considered here, based on the INGV on-line Database of Individual Seismogenetic Sources (DISS); moreover, another source was hypothesized in this study, located in the Tyrrhenian sea off-shore and constrained by the numerous earthquakes recorded by the National Accelerometric Network. The 7 selected seismic sources are reported in the following Table 1.

Name	Reference earthquake	M_w	EPD km	CDT	NMK
Aspromonte NW	6/2/1783	5.3	6	-	18
Scilla off-shore	16/11/1984	5.3	5	4	20
Aspromonte NE	16/11/ 1984	5.8	18		20
Subduction	-	6.0	>100	-	9
Gulf of Patti	15/4/ 1978	6.1	81	-	11
Gioia Tauro	5/2/ 1783	6.6	30	9	42
Strait of Messina	28/12/ 1908	7.0	27	6	57

Tab.1 – Considered seismic sources (M_w from DISS-database) and related epicentral distances (EPD) from the study area, CEDIT documented landslides (CDT) and here obtained re-activations by Newmark's approach (NMK).

To each seismogenetic source was attributed the uniform hazard spectrum (UHS), corresponding to a recurrence time of 475 years, i.e. to a probability of exceedance of 10% in 50 years, except for the here hypothesized off-shore Tyrrhenian source to which a recurrence time of 2475 years, i.e. a probability of exceedance of 2% in 50 years, was attributed due to the lack of a reference earthquake. A selection of UHS adjacent to each seismogenetic source was performed and a final UHS at the 90th percentile was calculated. In order to characterize the possible ground-motion generated by each seismogenetic source, a selection of natural accelerometric records was obtained by consulting both the European (Ambraseyes et al., 2000) and some global database of accelerometric records (COSMOS - http://db.cosmos-eq.org; PEER - http://peer.berkeley.edu/smcat; Kyoshin Network K-NET - http://www-k-net.bosai.go.jp/k-net/index.en.shtml). Moreover, in order to derive the possible accelerometric time-history at each recognized landslide, i.e. in correspondence with its centroid, the Sabetta & Pugliese (1996) attenuation law was used to calculate the local response spectra by measuring the epicentral distance of the landslide centroid and by using different empirical attenuation functions referred to 14 frequency values within 0.25 and 25 Hz.

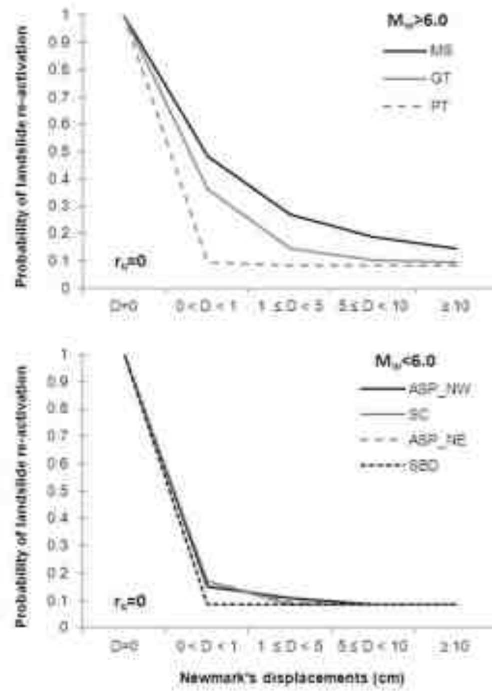

Fig.1 – Probability of seismic landslide re-activation in the case of M_w>6 (up) and M_w<6 (down) earthquake scenarios for r_u=0. Key to legend: MS – Strait of Messina; GT – Gioia Tauro; PT –Gulf of Patti; ASP_NW – Aspromonte NW; SC – Scilla; ASP_NE – Aspromonte NE; SBO – Subduction.

The selected accelerometric records selected for each seimogenetic source were adapted to the response spectra calculated by attenuation law, on the basis of the procedure performed by the WES RASCAL CODE (Naeim & Lew, 1995). According to this procedure, the response spectrum of each time-history was modified by an original algorythm (Rinaldis et al., 2011) subtracting and/or adding contributions to the frequency content of the selected natural time-history.

To evaluate the slope stability of the existing landslide masses under dynamic conditions a limit equilibrium analysis was carried out for the roto-translational landslides only, by applying the Bishop's method.

On this basis, a slope stability analysis for seismically-induced reactivation was performed by deterministic scenarios, which were obtained considering the aforementioned 7 seismic sources and the time-histories derived by the previously described procedure. The co-seismic displacements for all the roto-translational landslides were computed by applying the sliding-block Newmark's method in relation to the different considered sources as well as to different values of r_u.

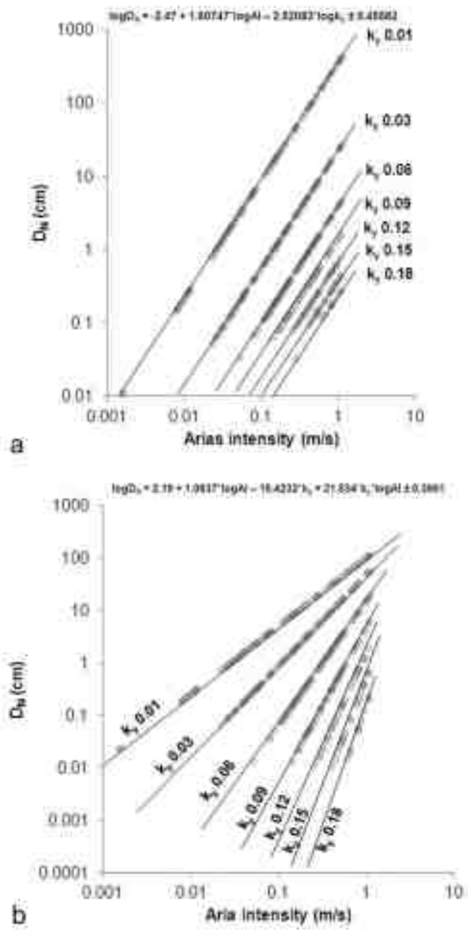

Fig.2 – Empirical co-relations among Arias intensity, k_y and D_N obtained for the study area, according to the regression equations by Jibson et al. (1998) (a) and by Hsieh and Lee (2011) (b).

The landslides reactivations were distinguished from collapse events in relation to the reached values of displacements according to Romeo (2000). As expected, the strongest scenario is represented by the Strait of Messina source for which the percentage of reactivated landslide area range from 33% up to 89%, considering r_u varying from 0 up to 0.4.

As it results from this analysis, the highest earthquake scenario (i.e. the Strait of Messina one) implies a probability of 50% of producing not zero co-seismic displacements; more in particular, the probability of landslide collapses is equal to about 25%. This probability decreases to about 10% for the M_w=6.1 Gulf of Patti earthquake scenario as well as for all the other M_w<6 earthquake scenarios. On the opposite, the probability of failure increases up to 50% for the Strait of Messina earthquake scenario by assuming a value of r_u=0.2.

A multivariate linear regression was carried out, according to Jibson et al.(1998) and Hsieh & Lee (2011), with the aim of producing specific regression equations for this area. Good fit was achieved with respect to the literature data, in fact the relation obtained utilizing the Jibson (1998) model is characterized by a R^2 of 0.79 while the relation by Hsieh and Lee (2011) model corresponds to a R^2 of 0.86 (Fig.2).

Large landslides and recently uplifted antiforms in the Northern Apennines (Italy): the Ossella landslide (T. Mozzola Valley)

ALESSANDRO CHELLI (*), CLAUDIO TELLINI (*), ANDREA RUFFINI(**) & PAOLO VESCOVI (*)

Key words: *Deep-Seated Gravitational Slope Deformation, large landslide, neotectonic activity, Northern Apennines, Italy.*

INTRODUCTION

The Northern Apennines is an active NW-SE trending fold-and-thrust belt originated during the Late Cretaceous to Present convergence between the European and African plates.

Evidence of neotectonic activity in the Northern Apennines is testified by earthquakes (BOSCHI *et alii*, 1997; INGV, 2010) and several geomorphic features which testify that the Apennines experienced uplift since the Pliocene, with a remarkable increase in the uplift rate in Late Pliocene and Middle-Late Pleistocene (BARTOLINI *et alii*, 2003; BALESTRIERI *et alii*, 2003 and references therein). Moreover, surface and subsurface geological data also indicate that the evolution of the last 1.0 Myr of the Northern Apennines is mainly due to vertical movements (ARGNANI *et alii*, 2003).

In a recent paper starting from a multidisciplinary approach (through the use of subsurface, thermochronological, structural and geomorphological data), CARLINI *et alii* (in press) concluded that the tectonic evolution occurred since the Upper Miocene in the area between the T. Enza and R. Taro catchments (Parma Province), may be related to the activity of five embricated thrust faults and related antiforms that represent the latest orogenic structures.

From the geomorphologic perspective, one of the principal effects of the neotectonic vertical movements in the mountain chains are the slope processes. They are the response to the stress induced by the topographic growing resulting from the tectonic uplift. In mountain evolution, the landsliding exerts a primary control on the planform development, incision history and sediment discharge of watersheds (KORUP *et alii*, 2010).

For the area between the T. Enza and R. Taro catchments, the large landslides and Deep-Seated Gravitational Slope Deformations (DSGSDs), with a surface more than $1x10^6$ m^2, were extracted from the Landslide Inventory Map of the Parma Province (PROVINCIA DI PARMA, 2007). Besides a structural-tectonic map of the area, compiled from existing and new data, was made. Geologic cross-sections, perpendicular to the main Apennines structures, have highlighted the spatial arrangement of the uplifted antiforms due to the recent evolution of the mountain chain. The comparison between the large landslides inventory map and the geologic-structural map highlighted the spatial correlation among several large landslides and recent antiforms (CHELLI *et alii*, in press) (Fig. 1).

Nevertheless, the meaning of the relationships between landslides and tectonic structures, namely tectonic activity, passes through the connection between landslides and tectonic features.

The aim of the paper is to show the results of a geologic and geomorphologic study performed in correspondence of the slopes involved in large landslides in the valley of T. Mozzola, a tributary of the R. Taro, focusing on the Ossella landslide (Fig. 2), just in correspondence of the confluence between the T. Mozzola and the river. These landslides are in correspondence of the axis of a recent antiform considered in CHELLI *et alii* (in press).

METHODS AND RESULTS

The geological survey performed in the study area permitted to reconstruct the structures of the T. Mozzola Valley, where Ligurian rock complexes outcrop. In details, in the slope of the Ossella landslide the Mt Caio Flysch tectonic unit outcrops, represented by the marly calcareous flysch itself and by the Ossella mélange made by dark argillites. On the opposite side of the valley the Mt. Ottone tectonic unit, represented by the *Argille a blocchi* (argillites with blocks of calcilutites), and the *Media Val Taro* tectonic unit, represented by Mt. Rizzone *Argille a palombini* (argillites and thin calcareous beds) and Scabiazza Sandstones (thin layers of clay and sandstones), overthrusted the Mt. Caio Flysch tectonic unit.

In correspondence of slope of Ossella landslide (Fig. 2), the unit of Mt. Caio Flysch is involved in at least two series of folds. The hinge of the first phase folds plunges N125° while for the folds of the second phase the plunge of the hinge is N260°. Besides at least two fault systems were recognized: the first one with strike

Work partially performed thanks to FIL2009 (Head: A. Chelli) University of Parma.

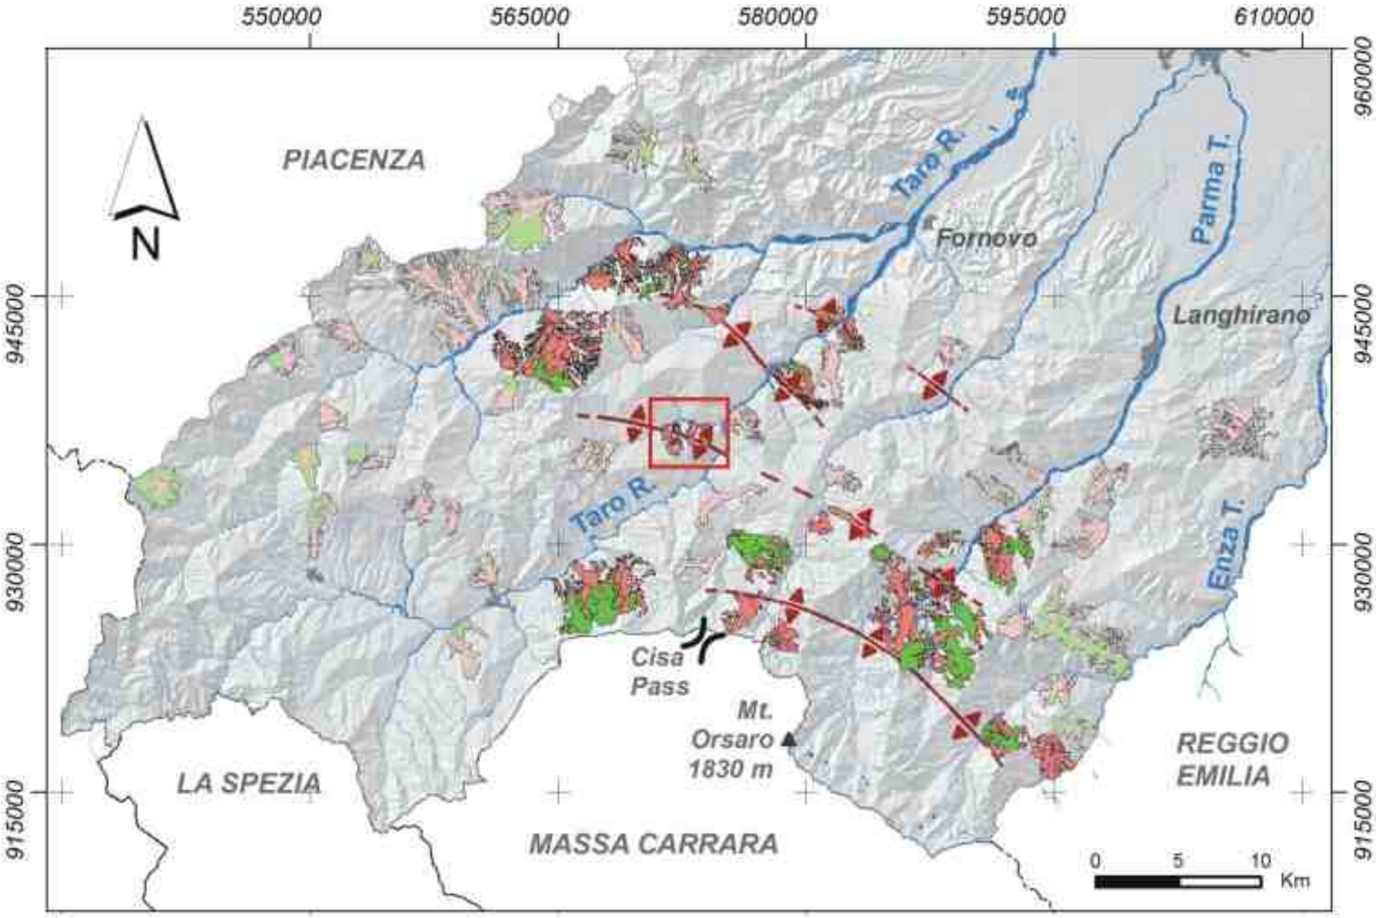

Fig. 1 – The inventory map of large landslides (pink colour) and DSGSDs (green colour). The slope processes spatially related to the recent antiforms (the axes of antiforms are shown as red line with triangles) are in shining colours. The investigated area is pointed out by the red box (modified after CHELLI *et alii*, in press).

N-S and dipping towards E, the second one with strike ENE-WSW and dipping towards N.

A detailed survey has been performed investigating the discontinuities of the outcropping rocks. Different families of discontinuities were found that correlate with the different phases of rock deformation and folding.

The Ossella landslide, as revealed thanks to the detailed geomorphological survey, is a large complex and composite (rock slide-earth flow) landslide. It has had a first known reactivation in 1954 and subsequent several phases of activity, even if only partial, during the second half of XX century and the first years of the XXI century.

SUMMARY

The study performed has highlighted the relationships among the Ossella landslide and the tectonic features recognized in the area that are due to the antiform structure already shown in CHELLI *et alii* (in press) as spatial related to several large landslides. In details, this antiform has developed during the post-collisional tectonic phase occurred in this portion of the Northern Apennines, moreover responsible of the well-known tectonic window of *Ghiare di Berceto* (for this last structure see VESCOVI coord., 2002). The Ossella landslide is just at the N rim of the Ghiare tectonic window, an area characterized by uplift during the recent tectonic phases of the Apennines, as testified by the presence of the fault pertaining to the NS system that runs parallel to the left flank of the landslide and that represents the tectonic element along which occurred the uplift of the rock block on which the Ossella landslide developed.

So, the results of the case study seem support the occurrence of relationships among large landslides and recent tectonic activity in this part of the Northern Apennines and the evidence that large landslides can occur as response to the topographic disequilibria induced in the slope by the tectonic vertical movement. In details, the landslides can act as the main processes removing the material from the slope subjected to tectonic uplift contributing to shaping the mountain slope.

Fig. 2 – The landscape view of the right side of the T. Mozzola Valley. The Ossella landslide is recognizable in the centre of the photograph. The left flank of the landslide (on the right for the reader) is morphologically controlled by a fault.

A large-scale landslide in the recently uplifted coastal area between Moneglia and Punta Rospo (Eastern Liguria, Italy)

F. FACCINI[1], M. FIRPO[1], A. ROBBIANO[2] & A. ROCCATI[2]

Key words: *Landslide, Monitoring activities, Geohazard, Ligurian Apennine.*

In this work the results of geomorphological and engineering-geological studies conducted along the eastern Ligurian coast between Moneglia and Deiva Marina, on the administrative boundary of Genova and La Spezia provinces, are presented.

The studied area is historically affected by instability phenomena, which cause evident effects on buildings and structures: in this sector the Lemeglio landslide is well known in scientific literature from the end of XIX century, mainly due to the railway construction, up to recent studies (Federici et al., 2004; Gorziglia et al., 2007).

Infact, compared to the other Ligurian coastal landslides, the Lemeglio landslide - the largest in Eastern Liguria - has preserved almost intact its geomorphic features, and it was only partially affected by man-made landforms (Maifredi & Nosengo, 1975).

Several new data derived from drilling activities, geophysical surveys, geotechnical and hydrogeological monitoring, radar interferometry data, and original geologic and geomorphologic survey, provide an integrated analysis of the area; the results are not completely according to the more recent studies and suggest a new interpretation of the phenomena.

In addition to the methods listed above, the photo-interpretation and historical maps comparison have allowed evaluating about the activity and morphological changes over the past 200 years.

The geology of the area is characterized by two Formations: the Scisti Zonati (weak siltstone and clayey shales with sandstone layers) and the overlying Arenarie of Mt. Gottero (sandstones with thin interlayers of shales). The Scisti Zonati are tectonically deformed, intensively folded with NE-SW axis oriented, orthogonal to the coastline; the sandstones, with various orientation of bedding planes, mainly dipping southwards (ISPRA & Regione Liguria, 2012).

This stretch of eastern Ligurian coast is clearly affected by distensive neotectonics in an area where recent uplift has given origin to steep coastal cliffs; a direct fault system mainly directed NW-SE, which shapes the coastline, can be easily recognized.

[1] Di.S.T.A.V., Università degli Studi di Genova (Italia)

[2] Geologo (Ph.D.), collaboratore esterno

Normal faults are clearly identified on the sea bottom, but can be recognized on the mainland only through geomorphologic elements. Another normal faults system, featuring a direction orthogonal to the coastline, is present and often determines large mass movements (Federici, 1980).

The geomorphological survey carried out, has been stretched inland to the entire area included inside a triangle, whose vertices are the mouth of the Bisagno stream, Punta Rospo and Mt. Crocetta - wider than the area previously studied.

This has allowed to highlight a wide range of landforms and processes due to gravity, running waters and wave action.

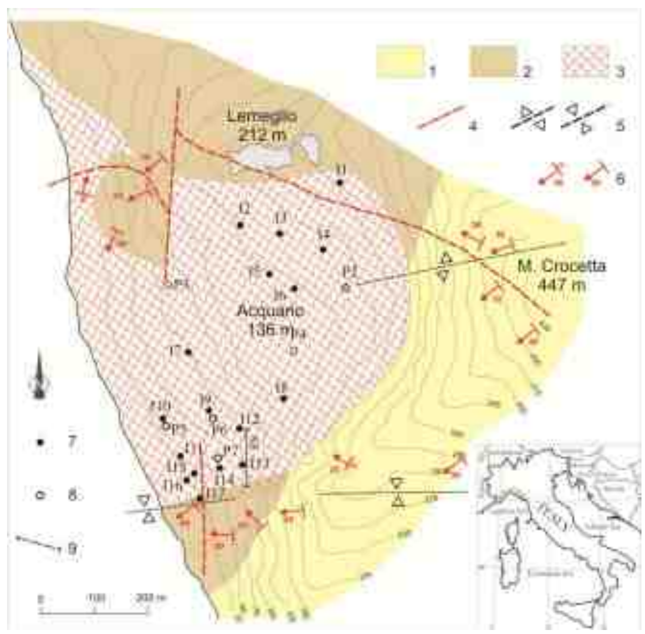

Fig. 1 - Engineering geological sketch map of Lemeglio landslide: 1) clayey shales with sandstone layers; 2) sandstones with thin interlayers of shales; 3) landslide; 4) fault; 5) anticlinal and sinclinal axis; 6) bedding planes, normal and overturned; 7) inclinometric case; 8) piezometric case; 9) seismic refraction survey

In the studied area have been recognized and mapped several morpho-tectonic evidences, related to the watersheds (altimetric discontinuities), to the slopes (edge of scarps, reverse slope), to water courses (straight patterns, step or longitudinal profile anomalies) and to general character (saddle, fans, closed depression, tectonic lineations).

The main landslide, well-identified for over thirty years, lies in the central portion of the slope, between Mt. Crocetta, Lemeglio hamlet and Punta Rospo (Terranova, 1987; Cevasco

Fig. 2 - Lemeglio coastal zone in an old map (1815-1823, Stati Sardi di Terraferma), in Google earth (Image 2012 digital Globe) and sketch map of anomalous areas and Permanent Scatterers (1992-2000 data aquired by ERS sensor along descending orbit T208_Genova)

et al., 2000), while in the northern sector, along the Fosso del Mandola catchment, other smaller landslides have been identified.

In the main landslide body several drillings were performed and allowed to detect a thickness of the slumped mass of more than 50 m in the area dubbed "Acquario”. In order to obtain geotechnical and hydrogeological data, the drillings were set up with inclinometric cases, piezometers and wells.

The landslide mass is still showing evidences of displacement, which has caused undulated road surfaces, deformation of the dry-stone walls enclosing the terraces, structural damage in buildings, including newer ones. Since the toe of the slumped body is sited along the coast line, when Libeccio sea storms strike from the southwest, wave action can be considered a triggering feature as well. .

The integrated assessment of the structural cracks in building and the anomalous areas identified by permanent scatterers interferometry SAR (PSInSAR™) data shows ground deformation of few centimeters per year along the ridge where Lemeglio hamlet lies and in the Fosso del Mandola catchment.

All collected data allow to recognize a large-scale landslide affecting the whole studied area and connected to the well-known landslide causes (geological, morphological, physical and human). Some neotectonic aspects and the watershed instability on which stands Lemeglio village indicate a deep-seated gravitational slope deformation (Dramis, Sorriso-Valvo, 1994; Agliardi et al., 2001).

The evolutionary model is complex: several sets of tectonic lineations oriented NW-SE resemble a rock block slide (Dikau et al., 1996) or a rotational sagging (Hutchinson, 1988); the stratigraphic model determines a geomechanical contrast between the hard rock sandstones, at the slope top, and the weak shales, at the bottom, and, consequently, may also allow a lateral spreading component, stressed by the lack of contrast by the landslide toe.

At the same time, the groundwater circulation influences mass movements because of the permeability contrast between the

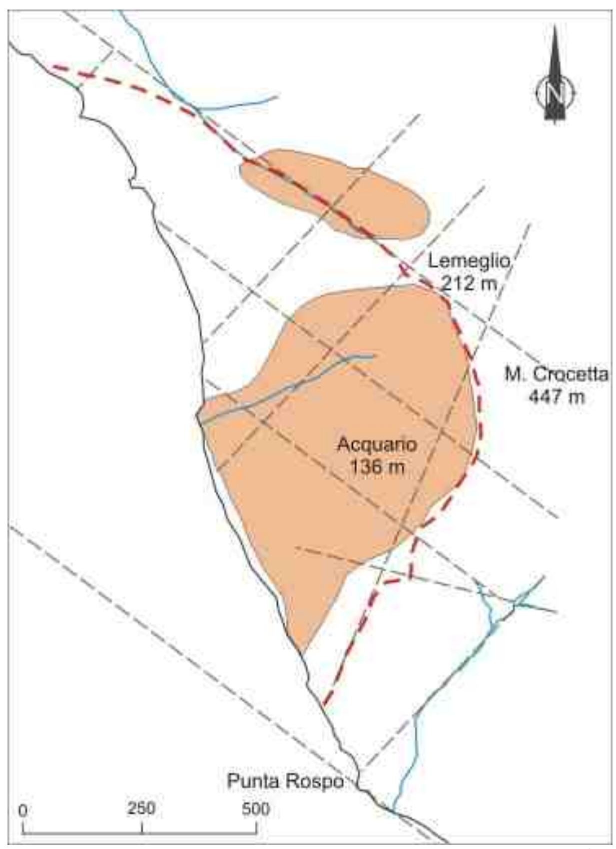

Fig. 3 - Neotectonic sketch map: red dashed line is the contour of the idenfied large-scale landslide, orange area are the well-known landslides, brown dashed line are direct fault or tectonic lineation

two rock masses along the shales-sandstones and shales-landslide separation surfaces .

In terms of geomorphological hazard - referring to what is currently assumed in land-planning - actually the most important problems of the Lemeglio landslide are mainly due to displacement velocity, consisting in rock falls (in the Arenarie di M. Gottero) from the main landslide scarp, which has determined the lithological nature of the rock blocks in the landslide body.

As a final remark, considering the high value of this area, mostly for its tourist fruition, it should be advisable to plan monitoring activities, taking into account the geomorphologic evolution model and the connected geological risk related to each sector.

Tectonic-gravitational deep-seated failures and macro-landslides in Scilla and Punta Pezzo area (Southern Calabria - Italy)

GUERRICCHIO A. (*), DOGLIONI A. (**) & SIMEONE V. (**)

Key words: *Calabria region, DSGSD, gravitational deformations, Scilla, tectonic deformations.*

INTRODUCTION

The Tyrrhenian coastline in the area of the town of Scilla close to Reggio Calabria (Fig. 1) has several geomorphic anomalies that can be ascribed to deep-seated tectonic-gravitational failures and deformations (Fig. 2) (GUERRICCHIO & MELIDORO, 1998). These movements from Melia highland involve the zone between Scilla toward N and Cape Pezzo (Punta Pezzo) toward W (Fig. 2). These failures affect the morphology of the whole area and the trend of the coastline.

Here the term tectonic-gravitational failure is used for deep-seated failure inducing deformations and displacements driven both by tectonic uplift and gravity. These failures for their amplitude and upthrow cannot be easily identified as fault or Deep-Seated Gravitational Slope Deformation DSGSD sensu stricto, even if deeply affecting the hydrographic network in the studied area.

The evidence of this failure is in some large trenches, where the main streams of the area are located. These streams are deep and show irregular paths cut in crystalline rocks, without relevant fans at their outlets. Therefore they cannot be related only to erosional processes. Evidence of the deep-seated tectonic-gravitational failure is also related to the sequence of morphological steps, mainly in the direction NNE-SSW, cutting the continuity of the crystalline rock mass toward WSW.

Fig. 1 - Google earth image of the studied area).

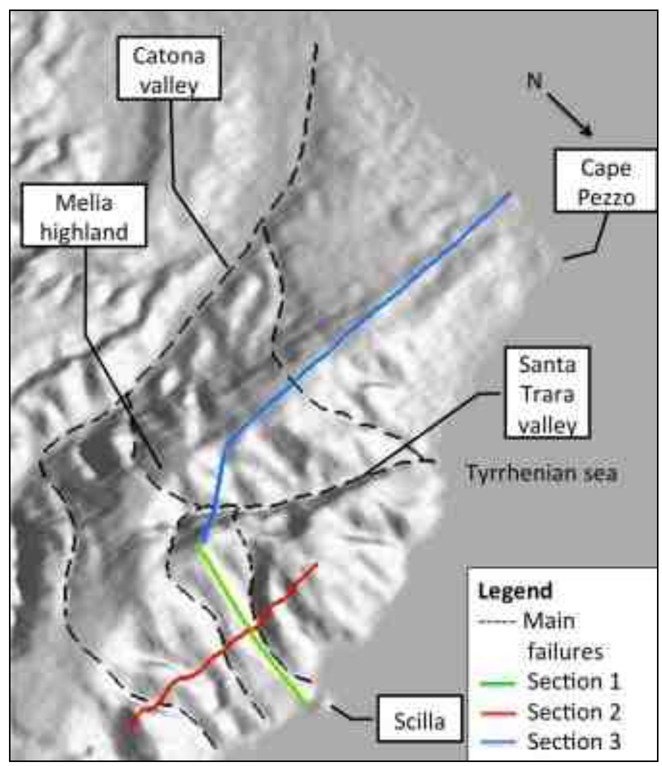

Fig. 2 - DEM of the studied territory with the evidence of the main tectonic gravitational failure and of the geological section.

GEOLOGICAL STRUCTURE AND TECTONIC-GRAVITATIONAL DEEP-SEATED FAILURE

It is not easy to recognize the original geological structural order, due to the large failures and deformations involving this area. These strongly disturbed the original layout of biotitic schist and gneiss crystalline rock of the basement of Aspromonte Units (AMODIO MORELLI *et alii*, 1976).

All the failures and tectonic slope gravitational deformations of the studied area were driven by a first large failure developing according to a horseshoe pattern along S. Trara and Catona valleys (Fig. 2).

This main failure developed together several other minor deep-seated failures along the crest between Tyrrhenian sea and Catona valley. This failure allowed for the decompression of all rock masses on the East side of S.Trara creating a large opening at the level of N-S line between Scilla and Melia highland (Figs. 2 and 3).

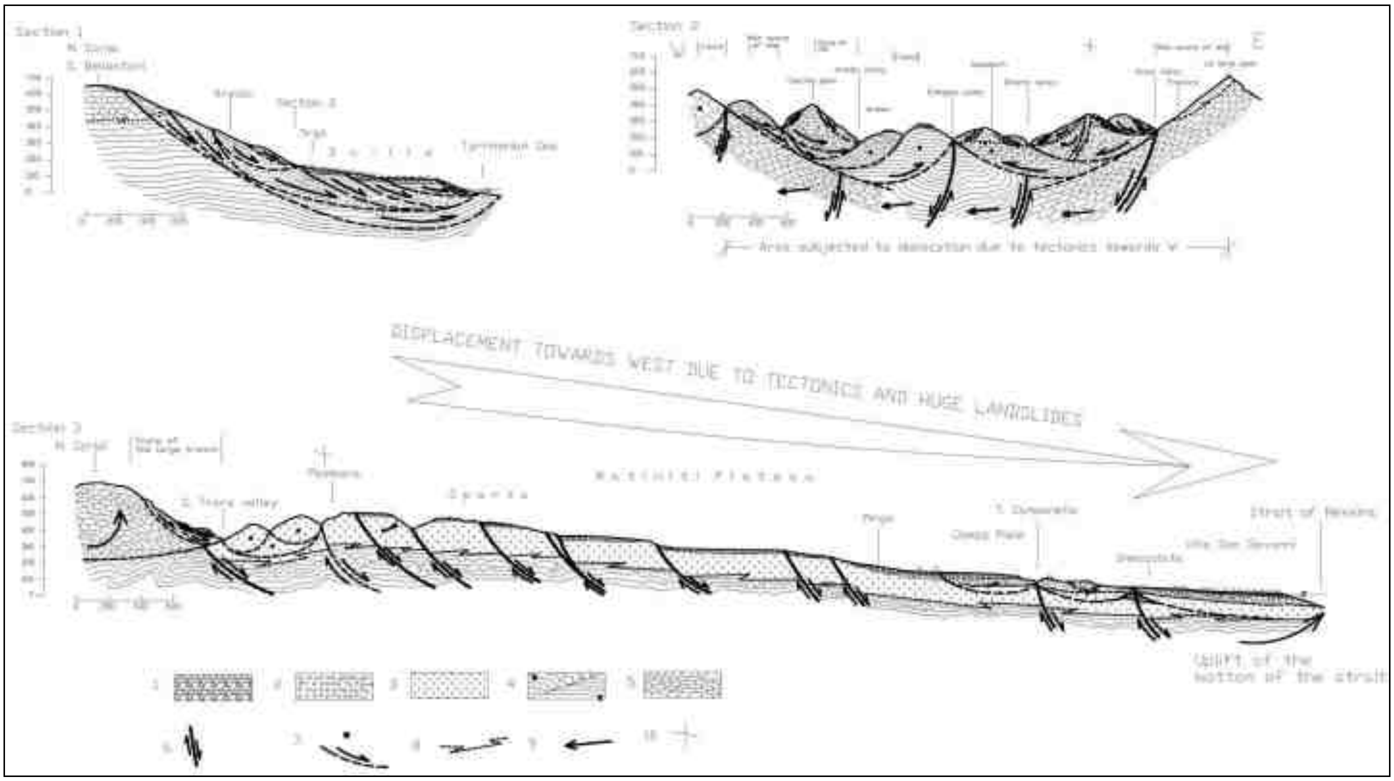

Fig. 3 – Geological section
1. Detrital deposits, gravels sands conglomerate and silts (Holocene, Pleistocene)
2. Conglomerates, grey-brown sands, sometimes sandstone or marly-silty clay (Pliocene);
3. Biotitic granite, strongly weathered overlying or intruded in basement metamorphic rocks
4. Biotitic schist sometimes with a gneiss aspect and with several intrusion of granite an pegmatite rocks Paleozoic;
5. Quartz feldspatic gneiss with inclusion of schist and granite;
6. Tectonic-gravitational failure (deep);
7. Simplified pattern of the failure surface and main movement direction.
8. Progressive and uncertain geological contact
9. Direction of the deep sited main movement
10. Direction change of the section

These failures develop in the biotitic schist of the metamorphic basement creating the deep-seated tectonic gravitational movement that disarranged also the middle Pleistocene deposits and terraces. They created the large opening (trenches) where the main stream network is located

The displacement toward West related to the deep-seated tectonics creates a large opening according the line between Melia Highland and Scilla (Fig. 2 and Fig. 4 red full arrow) making it possible the collapse of the large Scilla landslide (Fig. 3 Sects. 1 and 2). On the two side of the opening there are the scarp (S_A and S_B) of the macro-slide (NEMCKOK, 1972) of A and B whose masses move toward the center of the opening with a "pincher" movement favored by the cleavage of the metamorphic rocks on both side of the large basin due to the gravitational failure opening (Fig. 3 - Sect. 2).

In the central part, the bodies of the landslide (C in Fig. 4)

Fig. 4. View of Scilla landslide with the evidence of the main landslide body

involve biotitic schist and the continental covers of the ancient Tyrrhenian fan. These bodies enlarge downstream in the bodies Da, Db, Dc, Dd and in Scilla foreland, E, creating the peculiar coastline profile

Toward West the main failure created the large opening of Santa Trara valley. All the crests between Tyrrhenian sea and Catona valley lay on EW direction (Fig. 3 Sect. 3), cut by several failures creating small morphological steps related to tectonic-gravitational deformations fragmenting all the crest to Villa S. Giovanni town.

In all these displacements and failures, it is noteworthy the influence of schist rocks of the basement, provided with lower stiffness with respect to the overlying gneiss and granite rocks. It is also possible to assume that like in other zone of Calabria region (GUERRICCHIO *et alii*, 2007), there is a more deep and less stiff phyllite unit, which conditioned the large tectonic gravitational movements.

DUMAS & RAFFY (2004) showed how the marine terraces existing at multiple levels are discontinuous and disarticulated, even if it does not seem that the zone was subjected to severe reactivation of the main fault system later than Middle Pleistocene.

The discontinuity of marine terraces and the difficulties in correlating the different parts of terraces, are here assumed due to the large tectonic-gravitational failure and displacements created by the severe tectonic uplift.

CONCLUSIVE REMARKS

Tectonic-gravitational failures appear quite deep and involve quaternary deposits but also the metamorphic basement allowing to interpret the severe discontinuity of marine terraces. The interpretation here proposed provides an explanation of the irregularities of morphological forms and hydrographic network. This cannot be correlated only to surficial erosion, as well as of the irregularities of the coastline profile, but as in many other part of the Italian territory (GUERRICHIO, 2000) must be interpret as the result of the jointed effects of tectonic and gravitational deformations.

Preliminary remarks on gravitational tectonic deformations and DSGSD in mount Poro headland (Calabria - South Italy)

GUERRICCHIO A. (*) & SIMEONE V. (**)

Key words: *Calabria region, DSGSD, gravitational deformations, Mount Poro headland, tectonic deformations.*

INTRODUCTION

The Northern and South-Western slopes of mount Poro headland (maximum elevation 750 m a.m.s.l.), (Fig. 1), are characterized by morphologies, which seem quite surprising in relation to lithology of the strength of the involved granitic relative basement. In fact, it is constituted by "granite rock masses of mount Poro" (CALABRIA GEOLOGICAL MAP, 1971; AMODIO MORELLI *et alii*, 1976), "Polia Copanello and Stilo Units" according to LORENZONI *et alii* (1983). This relative basement is overlied by the sequence of Miocene (Tortonian and Messinian) and Pleistocene marine deposits.

In the Bouguer anomalies map (CARROZZO *et alii*, 1986), (Fig. 2), positive anomalies of the gravity, between +120 mGal and +130 mGal, are clearly evident in the continental part reaching the +140 close to the coastline. These anomalies are in good agreement with the severe uplift of the central part of mount Poro headland that induced a large tension crack in granitic "basement" from Spilinga toward W till to Torre Ruffa (Fig. 3). This crack, afterword occupied by the Raffa, Brattirò and Ortocara streams ("fiumare"), is so deep in granitic rocks that it cannot be related only to erosion phenomena, also for the absence of a relevant fan at its outlet. This uplift of the headland and its tectonic history (GUERRICCHIO, 2000) induced deep seated gravitational tectonic failures. It is possible to delineate almost three main large and deep seated bodies involving the granite "basement", displaced in consequence of tectonic-gravitational effects and DSGSD (Fig. 1). These failures were also probably favored by the presence, under the granitic rocks, of more deformable rocks, like biotitic schists at a relatively low depth, as it happens in other areas of Calabria Region (GUERRICCHIO *et alii*, 1997).

The southern one of the three main bodies is here called Capo Vaticano body. It was subjected to an anticlockwise rotation with a W and WSW vergence (Fig. 1) due to the opening of the large crack of Spilinga. The second one, called Cresta di Gallo-Drupia-Tropea body, has a movement toward WNW (Fig. 1). The northern one, involving an area of more than 100 km^2 (Fig. 1) is here called Cessaniti-Favelloni-Briatico body. It has flatter morphologies and it is characterized by the presence of large zones where Miocene and Plio-Pleistocene marine deposits outcrop. This body is subjected to severe displacements toward NNE originating a deformation of the coastline profile for a length of about 15 km with a maximum displacement toward NNE between Bivona-Porto Salvo e P. della Tonnara-V.gio Baia Paradiso. The empting morphologies of the upslope seem to delineate the main scarp of a quite deep large macro-slide (NEMCOK, 1972). Within the main bodies of the these large deep seated tectonic gravitation movements there are a lot of secondary scarps, deep seated landslides and gravitational slope deformations. They involve both the crystalline relative basement and the overlying deposits of Miocene, Pliocene and Pleistocene marine terraces. These are mainly constituted by Tortonian deposits, made by sand and sandstone, with the presence of clypeasters, which are topped by arenaceous banks, for a total depth of 150 m. In these deposits are sometimes clearly evident sub-vertical scarps of large ancient landslide.

Locally Pleistocene terraces are back-tilted in consequence of failures related to landslides or to the uplift of the toe of large deep-seated landslides. An interesting example of these phenomena is observable is in the more advanced zone of Capo Vaticano, where an area of about 1 km^2 is back-tilted by a severe uplift of the western bound of the terraces, then granite rocks strongly crushed, crop out due to uplifting the movement. This example shows how the area of Tyrrhenian terraces is quite

Fig. 1 – Mount Poro headland. The arrows point out the displacement directions of the three main deep seated gravitational slope deformations.

(*) Calabria University – Department of Soil Defense – Cosenza – Italy.

(**)Technical University of Bari – Department of Civil Engineering and Architecture – Bari – Italy.

deformed both in elevation and in plan with respect to its original profile. Also if it is not immediately evident, specially between Briatico and Tropea, terraces are strongly deformed. Here it is assumed that displacements induced by deep-seated tectonic gravitational movements started in late Miocene lower Pliocene,

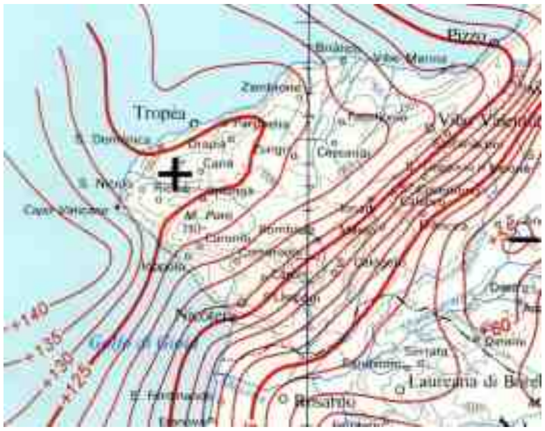

Fig. 2 – Bouguer anomalies in mount Poro area (after CARROZZO *et alii*, 1986)

and still continue today.

The three large displaced bodies are detached by the less disturbed "stable" horst elements of Poro headland. The main one is the granitic rock crest of mount Poro (711 m a.s.l.) elongated according the direction Caroniti-Joppolo-Comerconi. On the north-eastern part of this crest, there is the deep failure of the first body displaced toward W and WSW (Spilinga-Ricadi-Capo Vaticano). Its right bound is along the small discontinuous crest of Zungri (600 m a.s.l.) and Cresta di Gallo (661 m. a.s.l.)

The low magnitude of the earthquakes measured in Poro area may be related, also for their irregular distribution (Fig. 4), just to that gravitational movements still continuing. The low energy of these earthquakes makes it possible to suppose that their failure depths are related to gravitational failures instead of tectonic ones.

Fig. 3 – Google earth image showing the large crack of Spilinga, that generated the Vaticano Cape and Tropea DSGSDs.

DSGSD and big landslides between the territories of Paola-San Lucido and Rende-Cosenza (Calabria Region - Italy)

M. PONTE (*), A. GUERRICCHIO (**) & G. FORTUNATO (*)

Key words: *Deep Seated Gravitational Slope Deformations, Calabria, Catena Costiera.*

The middle-southern part of Catena Costiera between the territories of Paola-San Lucido at West and Rende-Cosenza at East (Calabria – Fig. 1 from Google Earth, 2012) is involved by gravitational deformations at various scales, ranging from DSGSDs to big landslides and slides. They have been produced also in consequence of some left transcurrent faults, directed NNE – SSW, that interrupt in two points the continuity of the north-south axis of the Catena Costiera; the first one starts in the Falconara Albanese territory and it goes toward S.Fili, S. Vincenzo la Costa and Montalto Uffugo, the second one starts from the Paola territory and proceeds toward San Benedetto Ullano (Fig. 1).

In the high-grade metamorphic alpin units, which represent the backbone of Catena Costiera in the study area, DSGSDs are very widespread, so that water courses develop in their ruptures with typical "horse-shoe" patterns. High scarps, trenches, knee-deformations and bulgings in the maximum compression zones are also present, especially in the western part of the study area toward Tirrenian Sea.

San Lucido-Paola area represents a clear example of "continuum" between neo-tectonic structures and DSGSDs, big landslides and slides.

In the eastern part of the study area, toward the Crati River valley, it is possible to distinguish between gravitational mass movements, which include "en enchelon" structures, and big

(*) Dipartimento di Scienze della Terra Università della Calabria
(**) Dipartimento di Difesa del Suolo Università della Calabria

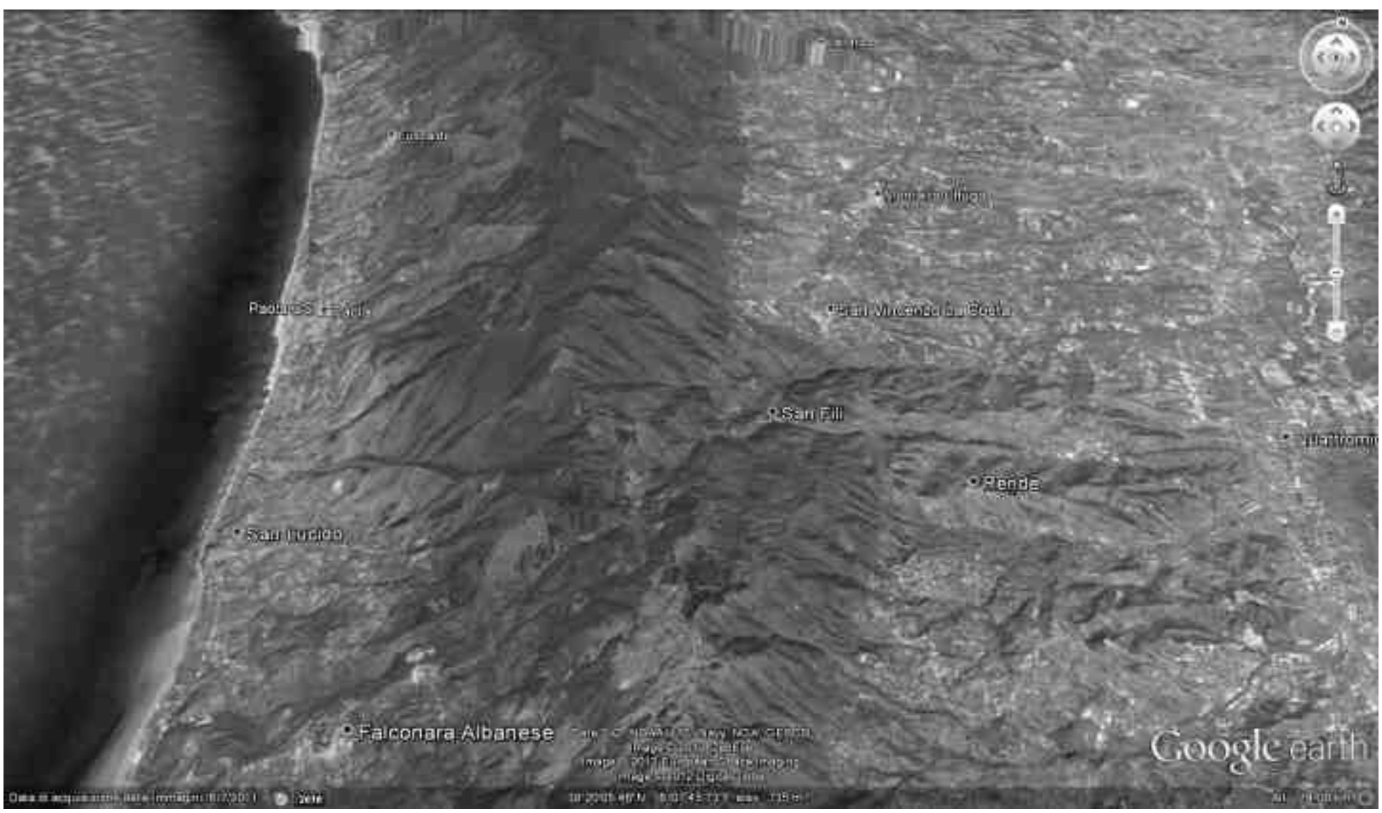

Fig. 1– The image poits out the two left transcurrent faults, directed NNE – SSW, that interrupt the continuity of the north-south axis of the Catena Costiera; the first one starts in the Falconara Albanese territory and it goes toward S.Fili and S. Vincenzo la Costa Montalto Uffugo, the second one starts from the Paola territory and proceeds toward San Benedetto Ullano (Google Earth, 2012).

landslides in accordance of main tectonic lines, which involve both metamorphic units of the basement and plastic Tertiary and Quaternary rocks.

The remaining part of the Catena Costiera is involved by deformations due to "scissor-like" gravitational tectonic movements, characterized by clockwise rotations, and also induced by the uplift of Cocuzzo Mount.. To these movements is to be ascribed the wide lateral expansion toward East, i.e. toward the Crati River valley, of the same metamorphic masses which produced the movement of the overhanging Tertiary and Quaternary sedimentary units.

Finally, is to be highlighted that, due to the widespread presence of tectonic ruptures in the metamorphic units of the basement and in the sedimentary Miocene and Plio-Pleistocene units, the study area is affected by high seismic and landslide hazard, as well shown by the deep gravitational deformations which occurred during the 1783 earthquake.

Deep Seated Slope Deformations and Large Rockslides: from geological modeling to risk management

G. SCARASCIA MUGNOZZA (*), A. PRESTININZI (*), F. BOZZANO (*), S. MARTINO (*), C. ESPOSITO (*), G. BIANCHI FASANI (*) & A. BRETSCHNEIDER (*)

Key words: *Gravity driven slope deformations, geological model, numerical model, management, monitoring, rock slide.*

INTRODUCTION

In this review paper new insights about Deep Seated Slope Deformations (DSSDs) are drawn from remarkable examples in Central and Southern Apennines. The presented results derive from studies developed over the last 20 years and carried out by the research group DES and CERI La Sapienza. Such research activities focused on: geological and geomorphological field survey, analogical scaled modeling, numerical modeling, slope deformation monitoring.

Based on the so far achieved knowledge about such complex slope processes, main topics dealt in this paper are represented by:

- Influence of structural settings on different types of DSSDs
- Evolutionary stages related to creep processes
- Massive rock slope failure and large rockslides
- Rock mass properties characterization
- Appropriate numerical modeling approach
- Monitoring and alert systems

The mentioned topics are discussed to address some key-points in view of effective risk management and mitigation measures.

DSSD TYPES, MODELING AND MONITORING

DSSDs are gravity driven deformation processes, which involve large rock mass volumes along a whole slope or a significant part of it, which develop according to stress-strain-time relationships which can be referred to creep mechanisms. Typical geomorphic evidences are trench, anti-slope scarp, double ridge, tension crack in the uppermost section of the slope and bulge in the lowermost one. DSSDs have very long evolution times, in the order of thousands of years, and can evolve in catastrophic slope failure through mechanisms typical of large rockslides.

Among other factors, DSSDs can be grouped according to local structural setting conditions. We recognize DSSDs in fault-slope related settings and non fault-slope related ones. The first ones are ascribed to thrust front or normal fault-slopes

Fig. 1 – View of the Sgurgola village lying upon huge limestone blocks detached from the lower part of the slope and scattered near the thrust front.

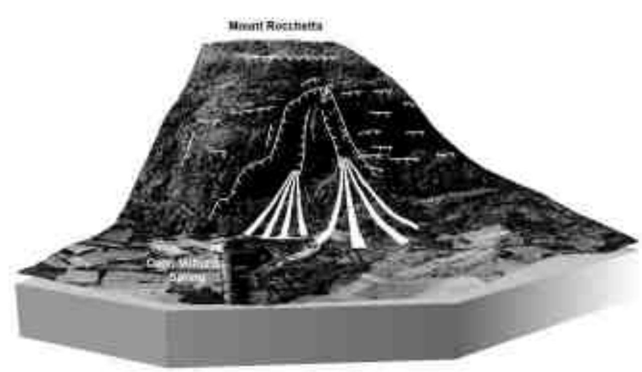

Fig. 2 – DEM of Mount Rocchetta slope section affected by DSSD; related trenches and scarps are outlined with white continuous lines

(*) Dipartimento di Scienze della Terra; Centro di Ricerca CERI – Sapienza Università di Roma.

while the latter are mainly developed in metamorphic-intrusive rocks. Some case examples are given, making reference to significantly different structural setting, geometries, geomorphic signatures along the slope, deformation characters and evolutionary conditions, as well as to the influence of groundwater circulation within rock mass.

With specific reference to such conditions, Sgurgola and Roccatagliata case histories are ascribable to slope featured by thrust front setting, while Maiella and Genzana western slopes are referred to DSSDs along normal fault slope. Other case examples come from slope where crystalline-metamorphic rocks mainly outcrop (Mt. Granieri, Calabria).

In addition, northern slopes of Mt. Nuria and Mt. Rocchetta are two examples of DSSDs strictly influenced by groundwater circulation within karst aquifer close to springs with large discharge.

Rock slopes: from the analysis to the definition of the risk mitigation works. The "Scilla Rupe" case (RC, Italy)

ALIPERTA A. (*), INFANTINO S. (*), LA TORRE A. (*), MANDAGLIO G. (***), MANDAGLIO M. C. (****) & PELLEGRINO A. (*****)

Keywords: *rock slope, landslide, vulnerability, risk mitigation.*

ABSTRACT

The problem of the instabilities on the Scilla Rupe (RC,Italy, Fig.1) known for a long period, determines an hazard situation on the surrounding areas (exiting historical buildings and downstream structures). The Rupe has been classified as a landslide risk area with from high to very high level inside the Hydrogeological Plan of the Calabria region (PAI,2001) because several vulnerabilities, such as "Ruffo di Calabria" castle upstream and the homonymous strategic platform and the Chianalea village downstream, there are.

In order to analyze in detail the Rupe, a specific study on the safety measures and the risk mitigation by means of the structural works has been developed using a specific regional activity programming (OPCM 3734- General Plan of the works for the soil protection in Calabria, 2010).

The applied methodology is based on detailed geological researches, on the geomorphologic and hydrogeological analyses, on the mineralogical and petrographic analyses, on physical-mechanical laboratory tests and on *in situ* investigations. In particular, laser scanning technologies have been used and a detailed geostructural relief has been performed in order to analyze spatially the geomechanics data .

On the basis of structural, morphological and geomechanical setting, some "zones marked by a homogeneous behavior" were identify (Fig. 2); every one is characterized by a distinctive geological-evolutionary model of slope, on which to develop appropriate and consistent risk mitigation actions.

The used multidisciplinary approach focused on the construction of geomechanical asset, at the mass scale, and on the individuation of the potentially unstable rock blocks. The proposed approach improves the traditional approaches bas on the geometric reconstruction of the structural asset of rock slopes.

The developed investigations allowed to define a strongly diaclased and fractured crystalline-metamorphic rock mass. The larger litoclasi and fractures reduce strongly the spatial continuity of the rock along the Rupe.

Fondi OPCM 3734/- Piano Generale degli interventi di difesa del suolo in Calabria, 2010.

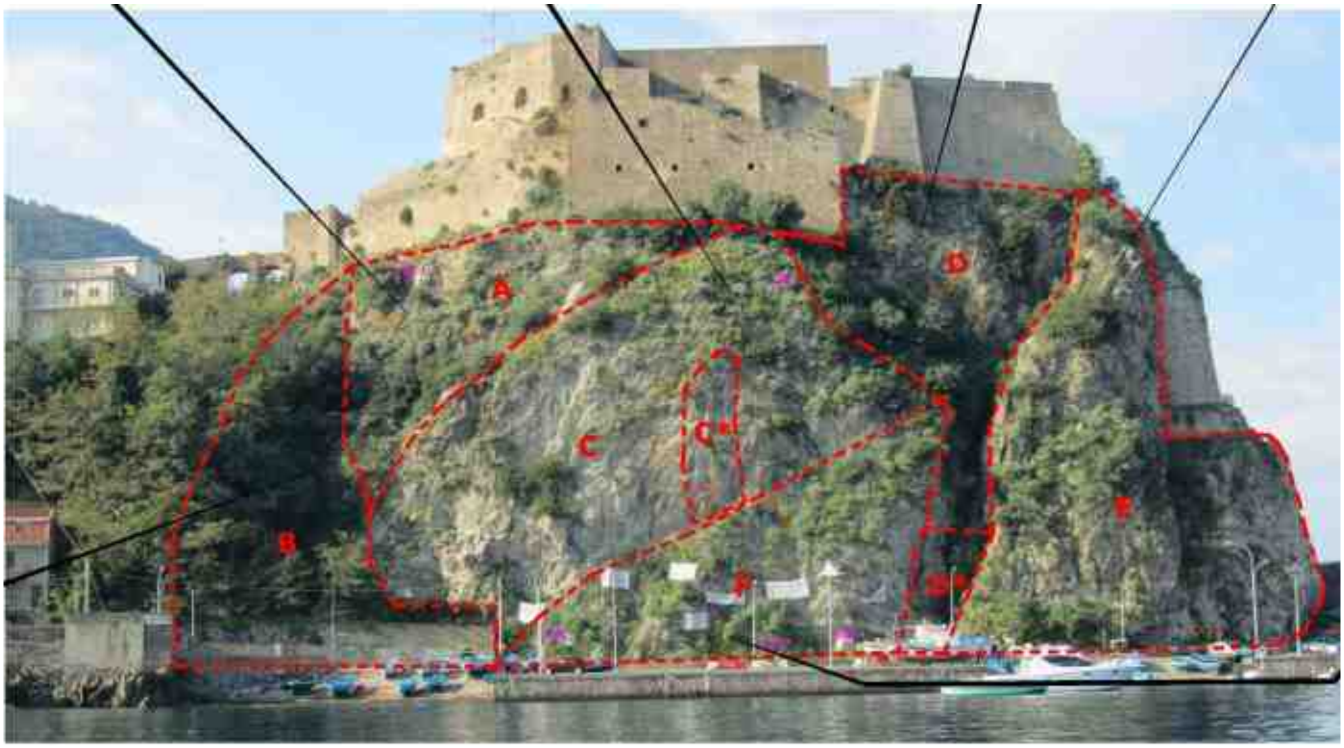

Fig. 2- Scheme of the “zones marked by a homogeneous behavior”.

Considering each homogeneous zone, the safety measures, that will be performed, will aim to: reduce the detaching and shallow fall from the wall of the fissured rock blocks, stabilize the rock mass of bedrock (rock fall and rock slock slide), such as the large wedge retained by the barbacane- underpinning. In fact, in these cases, rock volumes can slope along preferential slip surfaces and further accelerations can be generated if earthquakes or water infiltrations occur.

Finally, the obtained data have been integrated with stability analyses of rock slopes, where the geological-technical model of slope has been divided in analytical failure models corresponding to the physical situation of the Rupe in order to demonstrate the effectiveness of the works (ante and post-operam analyses).

The improvement of historical database on damaging hydrogeological events in the case of Apulia (Southern Italy)

BASSO ALESSIA (°), LONIGRO TERESA (*) & POLEMIO MAURIZIO (°)

Key words: *Apulia, natural hazard, flood, landslide*

INTRODUCTION

Historical database about landslides and floods are an important tool for the comprehension of the evolution of a study area or for the estimation of risk scenarios as a basis for Civil Protection purposes (BLAHUT *et alii*, 2011). Many researchers have shown the usefulness of historical data in the study of past events (BARNIKEL & BECHT, 2003; GLASER & STANGL, 2004; PETRUCCI AND POLEMIO 2009).

Starting from these milestones, the aim of this work is to collect historical data about DHEs, Damaging Hydrogeological Events (PETRUCCI & POLEMIO, 2003), mainly floods and landslides, in order to improve the existing available databases in the area of Apulia, a southern Italian region .

Data about the occurrence of floods or landslides are available consulting historical documents, national databases, scientific publications, technical reports, and all kind of documents from which it is possible to collect information about the occurrence of DHEs. For this study the main DHE database is represented by the AVI (the acronym means Italian damaged areas) database (http://avi.gndci.cnr.it). The AVI project was a special program promoted by the Italian Civil Protection to gather information on sites hit by landslides or floods in Italy during the period 1918 to 1996. The main sources of data for Apulia were newspapers.

Unfortunately the collection of historical data presents some limitations. First of all the temporal extension of database is limited because not all events are registered, especially the oldest and the ones occurred in not easily accessible areas or in areas not covered by newspapers. This is particularly true for events with a low magnitude that can be significant only at local scale, focalizing the attention of local newspapers.

A previous research (POLEMIO & LONIGRO, 2011) showed that Apulian DHE data could be affected by an underestimation of the number of events for the oldest periods (when not all events were registered) and an overestimation for the recent years due to the redundancy of information sources. The former problem can only partially solved, continuously trying to find more historical sources of data (as an example studying municipal, parochial, and/or private archives); the latter can be simply solved deleting redundant records.

With regard to DHEs, the AVI database reports 800 flood events and 140 landslide events in Apulia.

Since our research purposes are defined at a local scale, it was necessary to improve the AVI database, expanding the temporal range. For this purpose, further data were collected searching in the archives of regional libraries, especially working on sources of the National Library in Bari, Apulian chief town. Each available newspaper distributed in Apulia was analyzed since 1876 to 1952 with a gap from 1878 to 1881. 62 headings were considered, the majority of them were regional and local newspapers and only few newspapers had a national circulation. About 700 useful news from 17 different local newspapers were found from 1876 to 1951 (Fig. 1).

The collected news were studied in order to obtain new validated records. After the collection of these data our database was expanded from 1876 to 1996.

A further integration of our database was made up to 2006 by consulting newspapers, publications and technical reports.

The final database covers a period of 130 years (1876-2006).

Each DHE corresponds to a record of the database. For each DHE there is an accurate description about its geographical position (including municipality and watershed), temporal information (basically date and duration), the type of the event (basically flood or landslide), the kind of damages produced by the DHEs (describing damages to population, roads, buildings, industries, agriculture, etc.). The whole dataset is implemented in a GIS environment (Fig. 2).

Fig. 1 – An example of historical newspaper.

As there is an overlapping period of 33 years between old AVI database and new dataset obtained by newspapers, a detailed discussion of the statistical effect of this dataset improving is realized. In fact through the database it is possible to make some statistical elaborations about the spatial distribution of the events on the territory, the temporal frequency of the events in particular DHEs-prone areas, and the density of the events in specific boundaries.

This discussion is finalized to assess the effect of studying in depth historical archives on results of historical analysis of DHEs. This result offers a validation of widespread used AVI database.

Soil gas Radon concentrations in three study areas of Calabria (Southern Italy)

C. BRUNO (1), G. BUTTAFUOCO (2), G. FALCONE (3), R. GRECO (1), I. GUAGLIARDI (2), G.G.R. IOVINE (1), A. TALLARICO (3)

Key words: *soil-gas concentration, Radon, Calabria.*

INTRODUCTION

Radon is a naturally occurring radioactive gas, colorless, odorless, practically chemically inert; it is present in only trace concentrations in the atmosphere. It is one of the products of the natural decay of uranium, which is ubiquitous in rocks and soils, though variable in concentration according to the specific mineralogy (TANNER, 1964; CLAMP & PRITCHARD, 1998, SEGOVIA *et al.*, 2007; SINGH *et al.*, 2011).

The World Health Organization (WHO), through the International Agency for Research on Cancer (IARC), has classified, since 1988, radon in Group 1 (which lists 95 substances classified as carcinogenic to humans). Radon would be the second most important cause of lung cancer after cigarette smoking. Therefore, knowledge of the levels of radon in the soil gas and underground water or in the dwelling's atmosphere is necessary to protect populations from the consequences of excessive exposure to radiation (NERO, 1990).

Radon tends to migrate from its source mainly upwards. Its rate of migration and soil-gas concentration are controlled by a large number of factors, such as: the distribution of uranium in the soil and bedrock, soil porosity, permeability and humidity, degree of fracturing of rocks, micro-cracks of the bedrock, granulation, rainfall, air temperature, barometric pressure, surface winds, and so on (NISHIMURA & KATSURA, 1990; AL-TAMIMI & ABUMURAD, 2001; PLANINIĆ *et al.*, 2001). As a result, the ease with which Radon moves in pore spaces or fractures affects how much radon reaches the Earth's surface at any given location. Anomalously high concentrations are often found in soils above highly fractured rocks, such as those associated with geologic faults, active volcanoes and geothermal sources.

Radon spatial information is commonly obtained at specific sampling points. Geostatistical methods (MATHERON, 1971; BADR *et al.*, 1993) provide a valuable tool to study the spatial structure of radon concentrations. The interpolation technique of the variable at unsampled locations, known as kriging, provides the "best", unbiased, linear estimate of a regionalized variable in an unsampled location - where "best" is defined in a least-square sense (CHILÈS & DELFINER, 1999).

This study is aimed at defining the relationships between geological features, seismicity and soil-gas Radon concentrations in three study areas of Calabria (Crati Graben, northern border of the Sila massif, and "Stretta di Catanzaro" – cf. Fig. 1).

^{222}RN: SOURCES AND DISTRIBUTION

Radon has 86 protons and may have a variable number of neutrons in its atomic nucleus, depending on the parent radionuclide of the decay series. The three primary sources for natural Radon are the parent isotopes of the two uranium series (^{238}U and ^{235}U) and of the thorium series (^{232}Th) (MUDD, 2008). Approximately, Radon has a 3.2 days half-life. Although there are 33 radon isotopes known with 110–142 neutrons (EKSTRÖM & FIRESTONE, 2008), only Radon (^{222}Rn), Actinon (^{219}Rn) and Thoron (^{220}Rn) are relevant in natural or industrial contexts.

The concentration of radon in air and in soil is expressed in Becquerel per cubic meter (Bq m^{-3}) in SI. As for the geographical distribution of Radon levels in the world, useful data can be found in AL-TAJ *et al.* (2004), FONT *et al.* (2008), KEMSKI *et al.* (2009), NERI *et al.* (2011), PEREIRA *et al.* (2010).

ENVIRONMENTAL SETTING

The study areas (Fig. 1) are located in the Central-Northern sector of the Calabrian Arc (CA), an arc-shaped structure of the circum-Mediterranean orogenic belt, representing an accretionary wedge of crustal terranes originated by the Africa-Europe collision (TORTORICI, 1982).

The CA consists of a series of ophiolite-bearing tectonic units and of overlying basement nappes, which are considered to be a remnant of the Cretaceous–Paleogene Europe-verging Eo-Alpine Chain, involved in the construction of the Apennine orogenic belt during Oligocene-Early. Since Middle Miocene, overthrusting - combined with the progressive eastward migration of the CA - was associated with the opening of the Tyrrhenian basin (DE CANDIA *et al.*, 1998). The migration occurred along a NW-SE trending regional strike-slip fault system, which dissected the thrust assemblage of the Arc.

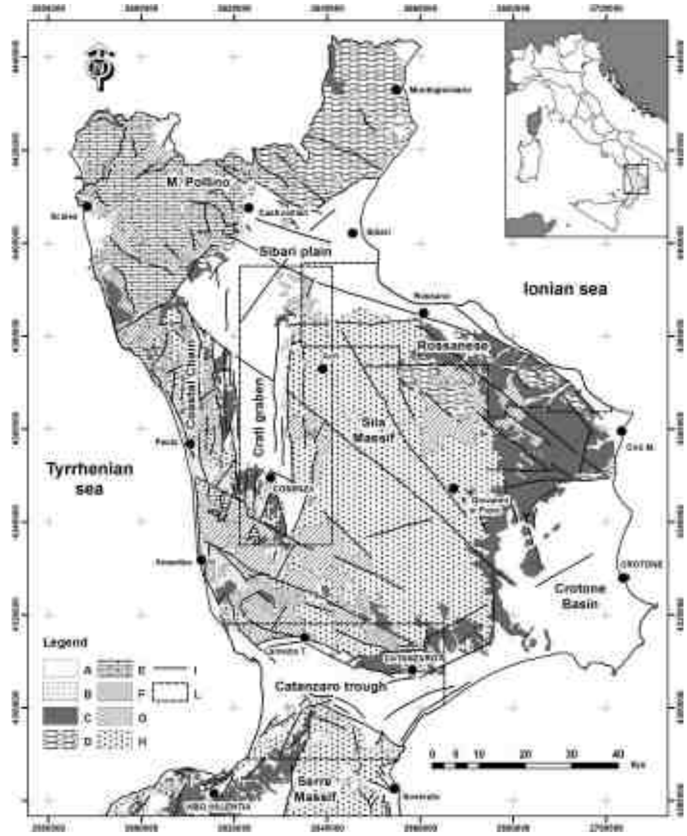

Fig. 1 – Geological sketch of Central-Northern Calabria (after SORRISO-VALVO & TANSI, 1996, mod.), and location of the study areas. Key: A) loose deposits; B) detrital coherent deposits; C) detrital argillaceous deposits ; D) flysch; E) limestone and dolostone; F) middle-high grade ophiolitic metamorphic rocks; G) low grade metamorphic rocks; H) middle-high grade metamorphic rocks and plutonites; I) main fault; L) study areas.

During Middle Miocene-Middle Pleistocene, the NW-SE system affected the northern portion of the CA, assuming the characters of a crustal oblique transpressional shear zone (mainly dipping toward NE), characterised by left-reverse movements (VAN DIJK *et al.*, 2000).

METHOD

In the study area, the survey of Radon soil-gas concentrations has been carried out through a portable monitor, (AB-5 PYLON), a trace environmental level gas detector (which detects radon levels as low as 11 Bq m^{-3}), and a data acquisition unit (instantaneous measurements).

The soil gas has been pulled off at opened holes of 75 cm depth, through a vacuum soil probe by a vacuum hand pump - as shown in Fig. 2.

Measured soil gas radon data were modelled as an intrinsic stationary process (CHILÈS & DELFINER, 1999) and interpolated using a geostatistical approach called multi-Gaussian ordinary kriging. It is based on a multi-Gaussian model and requires a prior Gaussian transformation of the initial attribute into a Gaussian-shaped variable with zero mean and unit variance.

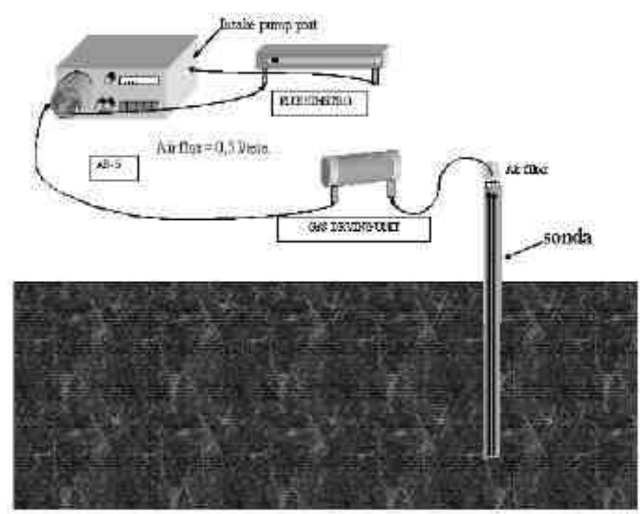

Fig. 2 – Sampling method of soil gas radon.

Shallow landslides induced by heavy rainfall on terraced slopes: the case study of the October, 25, 2011 event in the Vernazza catchment (Cinque Terre, NW Italy)

ANDREA CEVASCO (*), GIACOMO PEPE (*) & PIERLUIGI BRANDOLINI (*)

Key words: *Cinque Terre, debris flows, heavy rainfall, Italy, man-made terraces, small coastal catchment, soil slips.*

On October, 25, 2011 heavy rainfall affected Cinque Terre and Val di Vara (Eastern Liguria, Italy). A cumulative daily rainfall of 539 mm was recorded by the Brugnato rain gauge, with intensity up to 153 mm/h and 328 mm/3h (A.R.P.A.L.). This event triggered several slope movements and floods, causing 13 casualties, severe structural and economic damages.

This study investigates the shallow landslides occurring within the Vernazza catchment, which was the most affected, in the Tyrrhenian basins. Because of its great environmental value, due to the presence of an emblematic agricultural terraced landscape, this area was included in the Cinque Terre National Park and recognized since 1997 as a world heritage by UNESCO (TERRANOVA, 1984; 1989; BRANDOLINI & TERRANOVA, 1995; BRANDOLINI *et alii*, 2005).

The Vernazza catchment shows the typical geomorphological features of many Ligurian coastal basins: small areas (about 5,7 km^2), very steep slopes, short linear streams often controlled by tectonics (CEVASCO, 2007).

The bedrock is mainly composed by a sandstone-claystone flysch (Macigno Fm., Tuscan Nappe), and a pelitic complex (Argille e Calcari di Canetolo Fm., Canetolo Unit), involved in a wide overturned antiform fold (ABBATE, 1969; GIAMMARINO & GIGLIA, 1990; SERVIZIO GEOLOGICO D'ITALIA, 2003).

Geological and geomorphologic complex settings and recent land-use modifications played a key role in determining slope instabilities triggered by the rainfall. In fact, shallow landslides affected steep slopes covered by colluvial and anthropically reworked deposits overlying a heterogeneous and structurally complex bedrock.

(*) DISTAV - Dipartimento di Scienze della Terra, dell'Ambiente e della Vita. Università degli Studi di Genova.

Fig. 1 – Location of the study area.

The lack of maintenance of the dry stone walls retaining the terraces, which have represented over the centuries a basic factor of erosion and landslides prevention and control, has been a further factor favouring slope instabilities.

On basin scale, the heavy rainfall occurring on the 25th of October, led to erosional phenomena, both concentrated and diffused, and also triggered hundreds of shallow landslides, mostly soil slips (KESSELI, 1943; CAMPBELL, 1974) and debris flows (VARNES, 1978; HUTCHINSON, 1988; HUNGR *et alii*, 2001). Debris flows increased sediment transport and the erosive energy of streams along steep channels, leading to the destruction of buildings and carrying large boulders and cars towards the sea.

Flooding phenomena was caused by unsuitable hydraulic works in relation to rainfall able to mobilize large volumes of debris. In particular, the filling of the final tract of the Vernazza stream (formerly diverted from its natural path and covered for a total length of about 150 m), caused the flooding of Vernazza's centre with mud and debris deposits reaching heights up to 6 m.

The effects of flooding have been disastrous both in terms of structural and economical damages in the centre of Vernazza, where three casualties occurred.

Besides a basic mapping of shallow landslides within the Vernazza catchment and a preliminary analysis of their distribution as respect to geological, geomorphologic and land-use management, the study presents the results of laboratory and in situ tests aimed at the geotechnical characterisation of slope deposits.

Fig. 2 – Soil slips and debris flows affecting terraced slopes surrounding Vernazza.

In detail, disturbed soil samples were collected at different sites. Grain size analysis, by sieving and sedimentation, and Atterberg limits determination have been performed on these samples. Hydraulic conductivity and shear strength of soils have been obtained respectively by permeability tests with field instruments and dynamic penetration tests.

Based on the results obtained from the previous investigations, stratigraphical and engineering-geological representative models are proposed.

Fig. 3 – A complex shallow landslide affecting a terraced slope in the middle sector of the Vernazza catchment.

Integrating geological, geomorphological and GIS analysis to evaluate the spatial distribution of landslides in the Cino stream catchment (Calabria, south Italy)

CONFORTI M. (*), FILOMENA L. (°), MUTO F. (°)

Key words: *Geomorphology, landslide, GIS, Calabria, South Italy.*

INTRODUCTION

Landslides play an important role in the evolution of landforms and represent a serious hazard in many areas of the World. Landslides are the common natural hazard in Calabria (Southern Italy) and are causes of widespread damage. Geologic, geomorphologic and climatic characteristics prone this region to landslides.

The presence, size, type and abundance of landslides in an area depend on the characteristics of the causal factors and on the trigger factors. The links between the landslides, and the geo-environmental features are complex and inter-related with each other. Geo-environmental conditions that control the location, abundance and type of landslides include the lithological, structural and morphological setting, the type and depth of the soil, the type of the land use/cover, and the mechanical and hydrological properties of the rocks and soils (TURNER & SCHUSTER, 1996). Also, the role of the causal factors on controlling landslide is important to determine landslide susceptibility and hazard (CARRARA *et alii*, 1999; GUZZETTI *et alii*, 1999).

Combining field investigation and air-photo interpretation, this work provides a first analysis of the relationships between lithological, structural setting, morphometric features, distribution and characteristics of landslides in the Cino stream catchment (Calabria, south Italy). The morphometric parameters were obtained by digital elevation model (DTM) with pixel size of 10 meters. The DTM has been produced from digitization of contour lines and points of the topographical map of Calabria Region at 1:5000 scale.

Data collected were geo-referenced and digitized using a Geographic Information System (GIS), in order to carry out a spatial analysis of landform distributions. For each mapped landform, a database containing attributes of the main features observed has been developed.

GEOLOGICAL AND GEOMORPHOLOGICAL SETTING

The Cino stream catchment is located in the northeastern sector of Calabria (South Italy) (Fig. 1). The stream basin originates on the eastern flank of the Sila Massif, the northernmost portion of the Calabrian-Peloritan Arc (CRITELLI, 1999) and drains into the Ionian Sea. The overall area of the basin is about 48 km^2, with altitude ranging from 0 to 1.305 m a.s.l. The average slope gradient is about 19° but more than 45% of the study area falls in the areas with slope gradient above 25°. The Cino stream represents a basin of the 5^{th} order with a drainage density equal to 5.72 km^{-1}, which indicates a rather dense drainage network in a strongly dissected area. The drainage network in general has a sub-dendritic pattern which often is structurally controlled (Fig. 1).

From a geological point of view, the bedrock of the study area consists of a Hercynian crystalline basement (Sila Unit) overlain by a Mesozoic and Cenozoic sedimentary succession (CRITELLI, 1999). Sedimentation occurred from late Serravallian to middle Pleistocene, and was controlled by strike-slip and extensional tectonics (VAN DIJK *et alii*, 2000). The stratigraphic succession consists of the continental consisting in conglomerates, passing upward to marls, siltstones with interbedded graded calcarenites, turbiditic sandstones and silty marls (BONARDI et *alii*, 2005). The Calcare di Base Formation and the overlaying Argille Marnose Salifere Formation, both heteropic with the Molassa di Castiglione Formation, were deposited during the Messinian salinity crisis (RODA, 1967). The Gessi Formation and the Argille Scagliose Formation cap the Miocene succession, onto which upper Pliocene and Pleistocene deltaic and marine deposits lie unconformably. These deposits are truncated by a fluvial erosion surface.

In the study area, the crystalline basement consists, mainly, in plutonic rocks and secondly in phyllites and schists (Fig. 1). This rocks are characterized by an extensive net of faults, fractures and are intense weathered, also, in many places covered by a thick regolith and or colluvial deposits. The Miocene–Pleistocene sedimentary rocks consist mainly of conglomerate and clay; Holocene alluvial deposits are present along valley floors.

The geomorphology setting reflects the complex relationship between geological and structural conditions of the

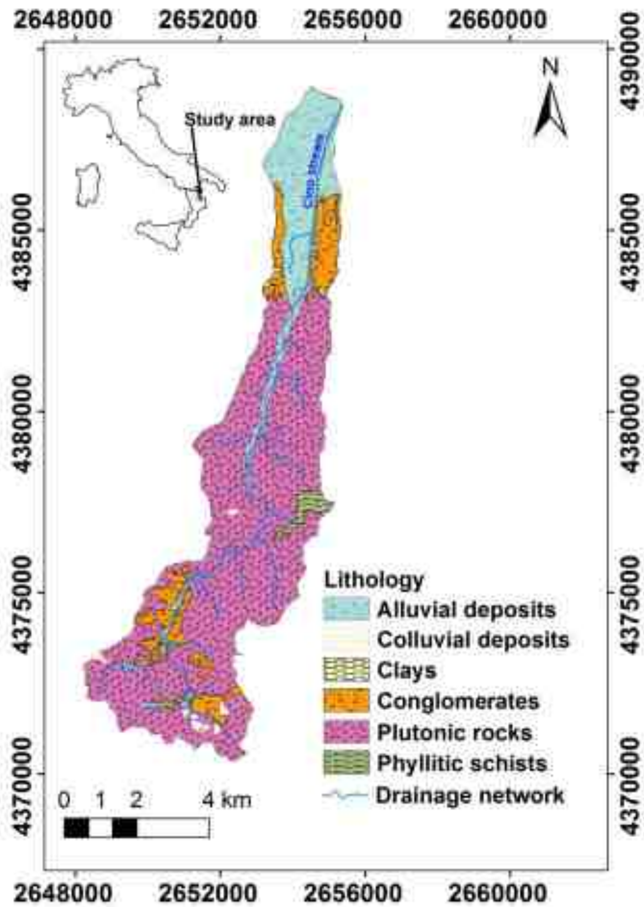

Fig. 1 – Location and lithologic map of the Cino stream catchment.

study area. The southern sector is dominated by a mountainous landscape with deep, V-shaped river valleys and summit remnants of an ancient flat or gently undulated landscape, that slopes to the north. The middle sector is characterized by steep slopes, more than 30° in average, and a high local relief due to the uplift of the Quaternary tectonics activity. Northern sector is characterized by more erodible lithologies, low-angle slopes, and slightly incised valleys. In the lower sector of the Cino basin alluvial terraces occurs, due to a combination of large-scale uplift and eustatic sea level changes (ROBUSTELLI *et alii*, 2009). Also, recent alluvial fans are observed along the main river valleys.

In the study area, the main denudation processes are related to landslides and running water processes (diffuse and/or linear) that essentially control the present-day landscape evolution.

SPATIAL DISTRIBUTION OF LANDSLIDES

The work was achieved through geological and geomorphological analysis carried out by means field survey and mapping supported by air-photo interpretation. The aerial photographs used are to different scales (1:10000 and 1:33000) and were taken at different dates (2000 and 1990 respectively). As a topographic basis were used the 1:10,000 and 1:5,000 sheets of the Carta Tecnica Regionale (edited by the Cassa del Mezzogiorno and by Calabria Region, respectively).

Landforms created by mass movement are widespread in the study area (Fig. 2); different movement types (CRUDEN & VARNES, 1996), their size and evolution depend upon the litho-structural setting and slope angle. A total of 129 landslides were recognized and they occupy a surface of 2.7 km^2, corresponding to more than 5% of the whole study area. The minimum, mean and the maximum landslide areas are 0.2, 2 and 34 ha, respectively. Landslides widely occurred in the central part of the Cino stream catchment, where plutonic rocks, extensively crop out; this sector of the stream basin was considered landslide prone due to a high degree of fracturing and weathering of the rocks, to high local relief, produced by tectonic activity, and to river down-cutting, forming V-shaped river valley and steep slopes. Analysis of landslide density revealed that landslides are particularly abundant between 20° and 35° in slope. The field survey, has highlighted that most of the detected landslides occur on slopes bordered down-slope by streams displaying clear field evidence of ongoing down-cutting processes. Based on the type of movement, the mapped landslides were classified into rotational or translational slides (53 bodies, 41%), flows (39 bodies, 30%), complex landslides (37 bodies, 29%).

Most of the observed slope movements were found to be dormant; as for the evolutionary trend of slope movements in the area, retrogressive evolution generally prevails. Depth of the landslides varies from shallow landslide (<2 m) and deep (>10 m). In many case, shallow landslides represented a partial reactivation of pre-existing quiescent deep landslides. Debris flows commonly develop where thick weathering mantles develop on the Paleozoic bedrock. Rock falls are present in the study area but were not shown in the inventory map, because are very small. Also, small rock/earth falls and earth slump occur along the outer edge of fluvial valleys, particularly during heavy rainstorms.

During field survey was observed that many man-made infrastructures are periodically damaged and/or destroyed by landslides activity.

The triggering landslide factors are manly represented by heavy rainfall, less frequently by earthquakes and, in many case by human-induced activity.

In many places, the hillslopes are often deeply gullied as a result of erosion caused by ephemeral streams, this areas were mapped as slope wash processes (Fig. 2). The severe water erosion is particularly act in areas without vegetation cover and/or in cultivated fields on steep slopes. Finally, alluvial fans are often accumulated at the mouth of various order drainage channels.

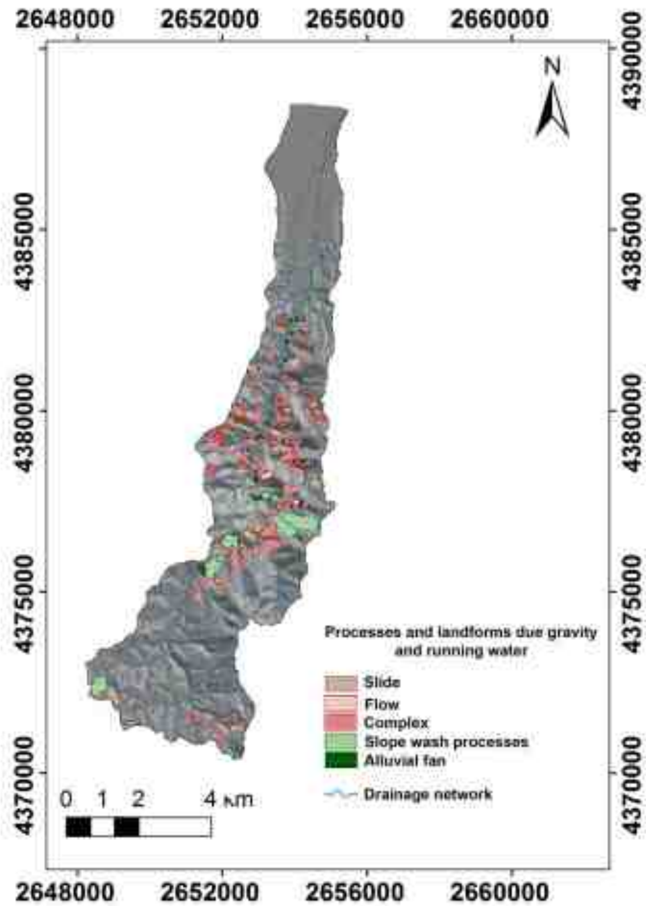

Fig. 2 – Denudation processes and landforms map of the Cino stream catchment.

CONCLUSIONS

In the Cino stream catchment, availability of local topographic, lithological, tectonic and landslide information has allowed to investigating the relationships between the mainly landslide predisposing factors and the known distribution of slope instability. The analysis revealed that geological conditions control the abundance of landslides in the catchment. Landslides are most abundant where plutonic rocks, intensely weathered, crop out, and where tectonic setting is chaotic or disorganized.

Finally, the database obtained in GIS environment, may provide the basis for the assessment of landslide hazard and risk.

Neural Network model for predicting landslide susceptibility: a case study from Crotone Province (Calabria, South Italy)

MASSIMO CONFORTI (*), STEFANIA PASCALE (**), FRANCESCO MUTO (***), GAETANO ROBUSTELLI (***) & FRANCESCO SDAO (°)

Key words: *Neural Network, GIS, landslide susceptibility, Crotone Province, South Italy.*

INTRODUCTION

Landsliding is a natural geologic and geomorphic process that plays a key role in denudation, landform development, in hilly-mountainous terrain. Besides, landslides are one of the most natural hazard that cause damage to both property and life all over the world. During the last decades, the landslide hazard assessment has become a subject of major interest because it plays a major role in land use planning. Owing to its particular geological and geomorphologic setting, Italy is a country widely affected by landslides. In Calabria, landslides are very frequent all over the regional territory. This paper addresses the issue of spatial prediction known as landslide susceptibility expressed as the spatial correlation between factors leading to the initiation of the slope failures and the distribution of landslides in the territory. There are a number of methods to obtain landslide susceptibility maps of which the evaluation of the susceptibility demands correct identification and quantitative assessment of the conditioning factors. All the methods are based on the criterion that ‘‘slope-failure in the future will be more likely to occur under those conditions which led to past and present instability’’ (CARRARA *et alii*, 1995). Accordingly, the susceptibility assessment can be used to predict the spatial location of future failures in territories with similar geo-environmental conditions. In particular, in this work the artificial neural network (ANN) technique was tested for the evaluation and mapping the landslide susceptibility in Crotone Province (Calabria, South Italy).

STUDY AREA AND DATA USED

The study area is located on the eastern sector of northern Calabria (south Italy) and covers the whole extent of the Crotone Province, about 1720 km^2 (Fig. 1). The climate is typically Mediterranean, with hot summers, mild winters. The average annual precipitation (1176 mm) ranges from 600 mm to more than 2000 mm moving from the coastline to the mountainous areas. The bedrock of the study area consists of the Sila Massif basement, a sector of the Alpine orogenic belt of western Europe made of Paleozoic granitoids and metamorphic rocks (gneiss, amphibolite, schist and phyllite), locally covered by Mesozoic sediments. Miocene to Pleistocene sedimentary deposits, belonging to the Crotone forearc basin, unconformably rest on the Palaeozoic- Mesozoic substratum. The basin is bounded by two NW-SE trending left-lateral fault zones responsible for its opening, during the Serravallian-Tortonian age (VAN DIJK *et alii*, 2000 and reference therein). The geomorphological setting of the study area is strongly controlled by geological and structural conditions. The western part of the area, where Paleozoic and Mesozoic rocks outcrop, is dominated by a mountainous landscape with steep slopes and narrow V-shaped valleys. The middle sector, where rock erodibility is higher, is characterized by a hilly morphology with low-gradient slopes and karstic landforms (LUCÀ *et alii*, 2011). Also, in many places this sector is characterized by homoclinal ridges as hogback and cuesta landforms (CONFORTI *et alii*, 2012). The coastal area is characterized by the presence of marine terraces developed in response to regional uplift and related sea level changes. In the study area, the main denudational processes are related to mass movements, running water processes (diffuse and/or linear) and karst processes (IOVINE *et alii*. 2010; LUCÀ *et alii*, 2011). In particular, mass movements essentially control the present-day landscape evolution (CONFORTI *et alii*, 2012).

GIS database was developed using ArcGIS 9.3 software and include a series of relevant landslide predisposing factors and the landslide inventory map. The construction of cartographic database, comprising several maps, was based on three different tasks: digitizing and editing of previous cartographic information, air-photo interpretation, and field survey. All the data layers were transformed in raster format with pixel size of 40x40 meters for evaluate the landslide susceptibility using the artificial neural network method.

Landslides were detected through air-photo interpretation and field surveys and a total of 379 landslides have been recognized and they occupy a surface of 121 km^2, corresponding to more than 7% of the whole study area (Fig. 1). The spatial distribution, size and typology of landslides are

(°) Dipartimento di Strutture, Geotecnica, Geologia Applicata, Università della Basilicata, Potenza, Italy

largely controlled by the geological and geomorphological context, including structural factors, tectonic setting, local relief and fluvial downcutting. By simplifying the VARNES (1978) classification, the landslides were mapped on the basis of the type of movement as follows: falls, slides, flows and complex landslides. The landslide predisposing factors were selected on the basis among the most widely used in literature and by from field investigations. In order, eight predisposing factors were considered, namely lithology, soil texture, land use, and a series of topographic factors: elevation, slope, aspect, plan curvature and topographic wetness index. The

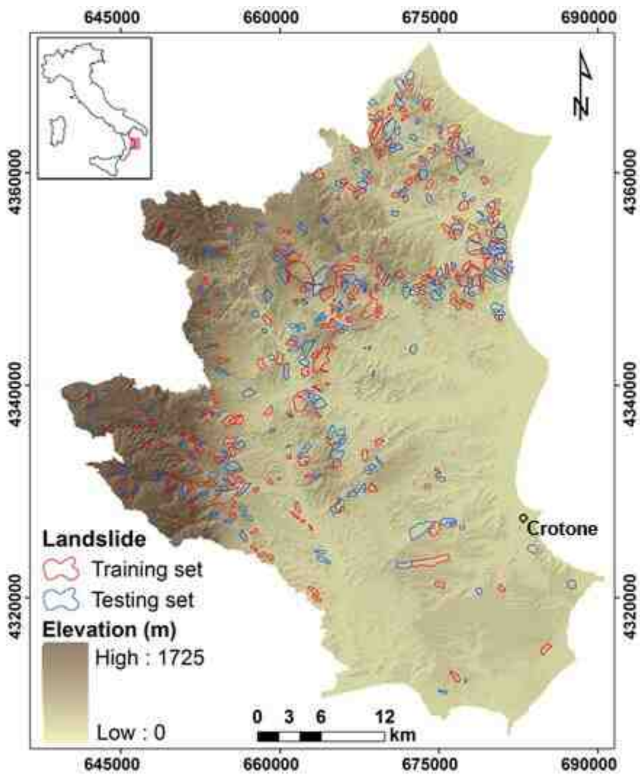

Fig. 1 – Location of the study area and spatial distribution of the landslide on the DTM of the Crotone Province.

topographic parameters were directly extracted from a digital elevation model, with a resolution of 40×40 m pixel size.

LANDSLIDE SUSCEPTIBILITY ASSESSMENT

To evaluate the landslide susceptibility in the Crotone Province was applied the ANN model that can be considered as a quantitative method and as a black-box model (ALEOTTI & CHOWDHURY, 1999). An important advantage of the ANN method is that it is independent from the statistical distribution of the data and there is no need for specific statistical variables (LEE *et alii*, 2004). The theory behind ANN is based on an attempt to imitate human learning processes through the creation of ANNs. An ANN comprises of a number of neurons that work in parallel to transform input data into output classes. The network used in this study consisted of three layers namely input, hidden and output. The module Multi-Layer Perceptron (MLP) in Idrisi Taiga software (EASTMAN, 2009) was used for application the ANN and the back-propagation algorithm was then applied to calculate the weights between the input and the hidden layers, and between the hidden and the output layers (ERCANOGLU, 2005). The numbers of hidden layers and the number of nodes in a hidden layer required for a particular classification problem are not easy to deduce. In this study, a 8×17×1 structure was selected for the networks, with the input data (predisposing factors) normalized in the range 0 – 1. Before running and train the neural network, the training sites were selected, to do this, the landslide dataset, that corresponding a 77595 pixels, were subdivided, using a random partition, into two mutually equal subsets (each containing 50% of the landslide area): training and testing sets (Fig. 1). Moreover, an equal number of non-landslide cells, both for the training and testing sets, were randomly selected from the study area, and merged to the two subsets, respectively (SANTACANA *et alii*, 2003). The training set was used for building landslide susceptibility model by means ANN method, whereas the testing set was used to evaluate the prediction performance of the susceptibility model.

The ANN analysis is made up by adjusting many parameters including: the number of hidden nodes, the number of pixels of the training set, the learning rate, the momentum factor coefficient, the number of training epochs (iterations) and the Root Mean Square Error (RMSE). The learning rate is a constant controlling the adjustment of the weights associated with the connections, for this analysis was set to 0.01. The momentum factor prevents problems of divergence during research for minimum errors, and was used to accelerate convergence. It was chosen 0.5. The number of epochs was set to 10000, and the RMSE value used for the interrupt the training phase was set to 0.1. The best result of the learning process for the built ANN model, showed a RMSE of 0.281 and produced a training overall accuracy of 87.7%, which reflects the sign of good correlation between the landslide and predisposing factors used. After completion of the training phase, the data obtained were fed into the network in order to estimate the spatial pattern of the landslide susceptibility for the whole study area. The susceptibility values for each cell, were converted to raster format file in a GIS, and the final landslide susceptibility map was produced (Fig. 2). The pixel values were classified into five susceptibility classes: very low, low, moderate, high, and very high. A comparison between the susceptibility map (Fig. 2) and the landslide inventory map (Fig. 1), show more than of 79% of the landslide were correctly classified, falling in high and very high susceptibility classes.

In order, to validate the susceptibility model the landslide of the testing set (not used during the fitting and the building modeling process) was used. In particular to quantify the performance of the ANN model and evaluate its efficacy of predictions, the receiver operating characteristic (ROC) curve was defined (FAWCETT, 2006). The ROC curve can be summarized quantitatively with the help of the area under curve (AUC). The AUC value is between 0 and 1; a higher

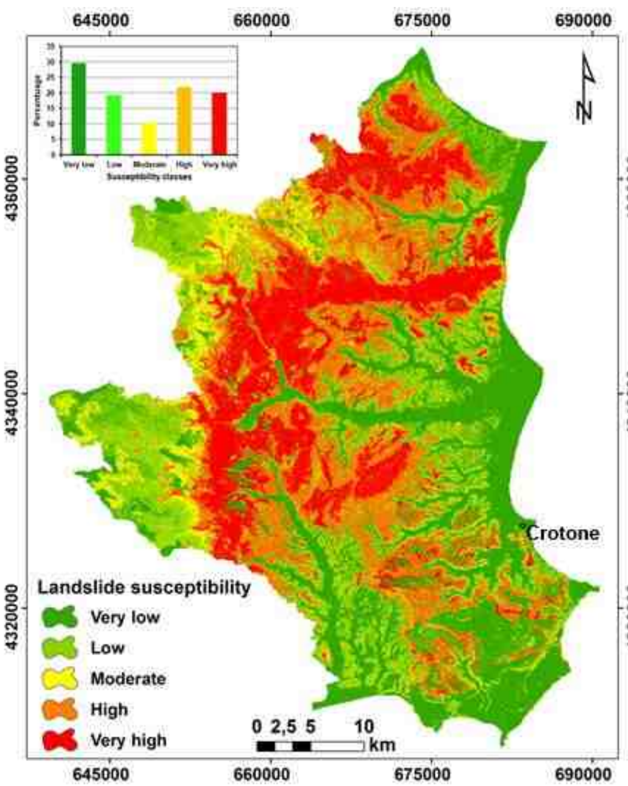

Fig. 2 – Landslide susceptibility map of the Crotone Province.

value indicates a higher prediction rate, whereas a value near 0.5 means the prediction is no better than a random guess.

The ROC curve (not show) for the ANN model showed the area under the ROC curve is 0.90, equivalent to an accuracy of 90%, which exhibit the robustness and the good reliability of the landslide susceptibility map.

CONCLUSIONS

The present study demonstrates that ANN model can be successfully applied for landslide susceptibility mapping in the Crotone Province. It highlights the influence of geo-environmental factors towards slope instability in the study area. The results of such studies can be used for mitigating the hazard associated with landslides through judicious and planned developmental activities in areas of high landslide susceptibility within the study area.

Using meteorological information and orography to characterize maximum rainfall in South Italy

SALVATORE GABRIELE (*) & FRANCESCO CHIARAVALLOTI (**)

Key words: *Maximum rainfall, regional analysis, homogeneous regions, atmospheric field*.

INTRODUCTION

Extreme precipitation and floods are among environmental events with the most disastrous consequences for human society. Estimation of their return periods and design values are of great importance in hydrological modeling, engineering practice, design of urban drainage system, planning for weather related emergencies, etc. In this paper, we analyze, at mesoscala, the effect of orography and of the spatial distribution of some atmospheric indexes strongly related with maximum rainfall. In this study, maximum annual rainfall values for rain gauge stations located in South Italy are retrieved from the System for Italian Flood Evaluation (SIVAPI) database (GABRIELE, 2000). To select "extreme" rainfall events, a criterion of intensity based on the number of rain gauge stations that simultaneously recorded their annual maximum of daily rainfall was considered.

For extreme events identified in this manner, meteorological characterization was carried out using the 40-Year Re-analysis Archive (ERA40) of the European Centre for Medium-Range Weather Forecast (ECMWF) (UPPALA, 2001), containing atmospheric thermodynamic fields, reanalyzed using a 6-hourly three-dimensional variational version (3DVAR) of the ECMWF data assimilation system (UPPALA, 2005).

The spatial and temporal resolution of the reanalysis fields used in this study is, respectively, of 0.5°x0.5° in latitude and longitude on 23 pressure levels (from 1000 hPa to 1 hPa), and of 6 hours.

EXTREME EVENTS IN SOUTH ITALY

To characterize the atmospheric conditions for extreme events selected as above, the Vertically Integrated Atmospheric Moisture Flux (J), and the Convective Available Potential Energy (CAPE), was calculated using the ERA-40 reanalysis fields: temperature, geopotential, specific humidity and wind. In more detail, the flux J is defined as:

$$J = -\frac{1}{g}\int_{p_s}^{p_t} q\mathbf{V}\,dp$$

(**V** is the wind, q is the atmospheric specific humidity, g is the gravitational acceleration and p_s and p_t are the pressures at the surface and top of the atmosphere, respectively), and it is a fundamental parameter in the hydrological balance (MARIOTTI et al., 2002), useful to typify large-scale patterns in moisture transport that lead to extreme precipitation (RUDARI et al., 2005).

The index CAPE represents the level of buoyant energy that is available to develop atmospheric convection, and it is defined as:

$$CAPE = g\int_{LFC}^{EL} \frac{T_p - T_e}{T_e}\,dz$$

where T_p and T_e are the virtual temperatures (Doswell et al., 1994) of lifting parcel and environment, respectively, and z is the height; the integral is from the Level of Free Convection (LFC) to the Equilibrium Level (EL). High values of CAPE correspond to strong thermodynamic instability, and they are typically associated with extreme convective events. In this

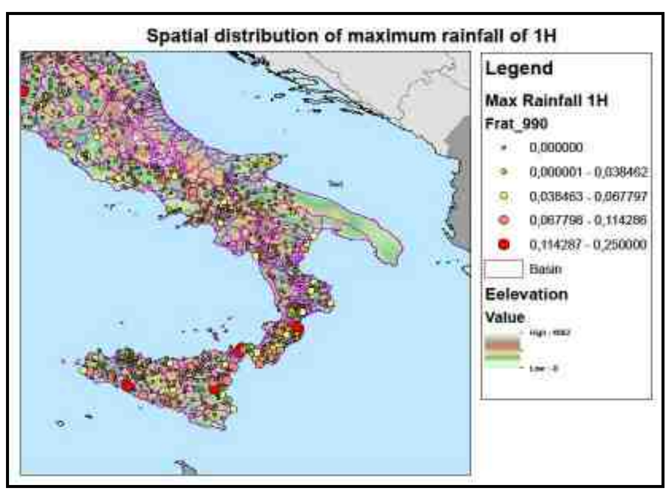

Fig. 1 – Spatial distribution of maximum annual rainfall of 1H.

(**) Università della Calabria, Dipartimento di Fisica, Arcavacata (CS), Italy

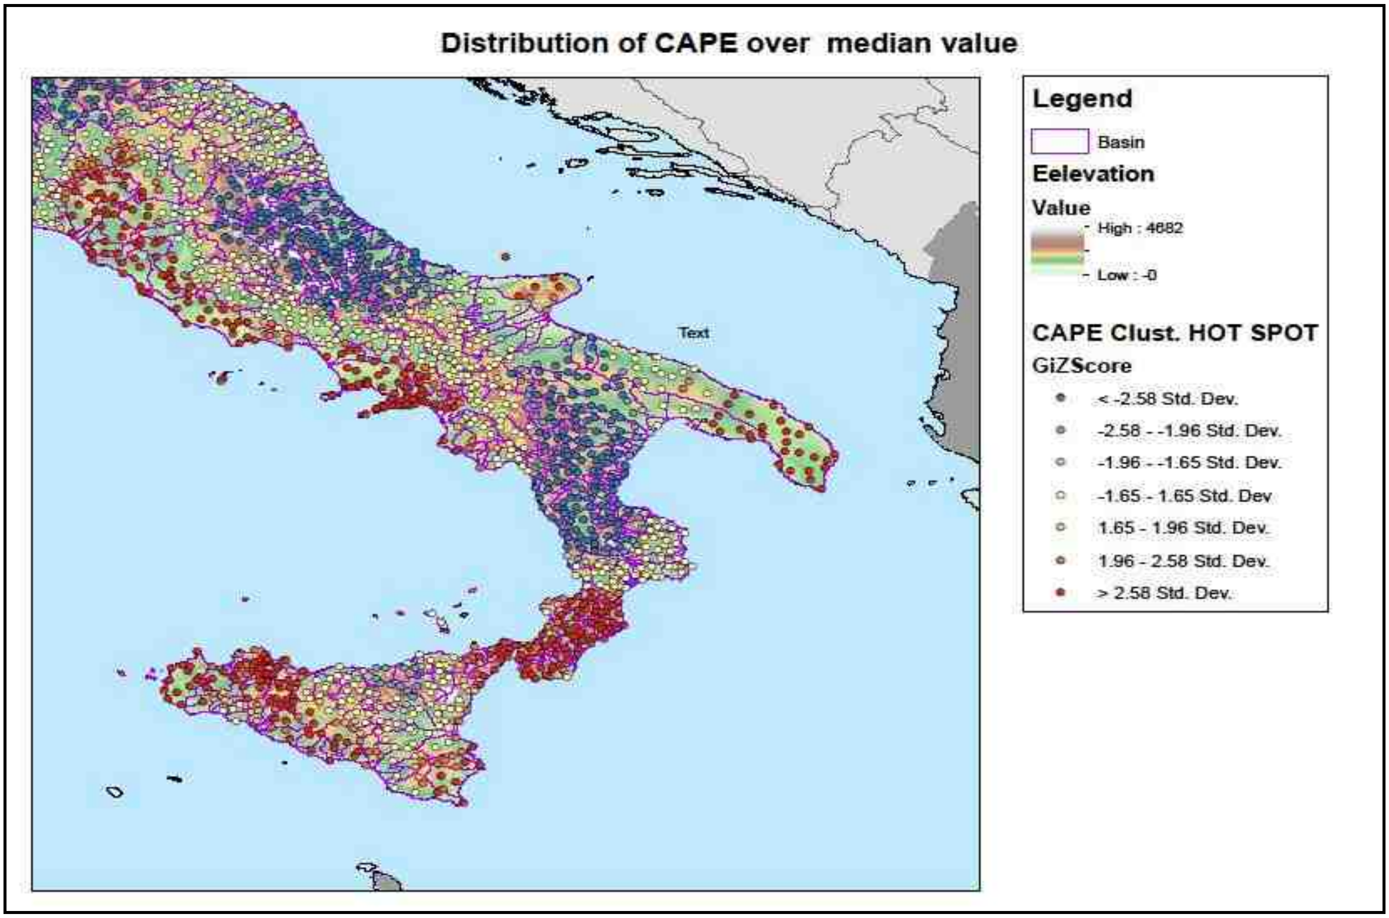

Fig. 2 – Distribution of CAPE over the median value evaluated all over Italian Territory. Red and yellow circles represent areas prone to convective rainfalls.

work, CAPE was computed using the *Lifted Parcel Theory* (MANZATO & MORGAN, 2003).

South Italy experienced several catastrophic flash floods in the last decades. Examination of the most disruptive events (Crotone1996, Sarno 1998, Soverato 2000, Bari 2005, Vibo 2006, Messina 2009, Atrani 2010), shows that flash floods occur in well-defined hydro-climatic regions of the South Italy, which appear to be characterized by high flash flood potential. Flash floods increase systematically when moving from east to west regions, while seasonality shifts accordingly from summer to autumn months with few exceptions.

Figure 1 shows spatial distribution of the maximum annual rainfall in South Italy. Legend describes the frequency of maximum annual rainfall of 1H over the median values of all Italian data. Maximum frequency values (red circles) are located according to the site experienced in flash flood in the last two decade: the Amalfi peninsula, the east Puglia, the south Ionian side of Calabria, the Sicily oriental side.

As shown in fig. 2, the maps of CAPE include all the previously described sites, so far, distribution of CAPE may be considered a robust meteorological index to locate regions prone to flash flood. GABRIELE & CHIARAVALLOTI (2012) showed that CAPE may be used to delimitate homogeneous region for regional rainfall analysis.

The second index considered, is the Vertical Integrated Moisture Flux. Fig. 3 shows intensity and direction of this index. The effect of the orography over this index is clear and of great appeal. The Apennine Mountains split south Italy in two well defined climatic regions: Tyrrhenian and Adriatic. In the first one the flux is quite homogeneous in intensity and direction (South West – North East) and is is confined by the Apennine Mountains. The Adriatic region is characterized by a less intense flux coming from North – North West. Salento, South Calabria and Sicily, show a minor organization and a more complex direction and intensity for the Vertical Integrated Moist Flux.

GABRIELE & CHIARAVALLOTI (2012) showed that the Vertical Integral Moist Flux may be considered for searching homogeneous sub-regions wherein coefficient of variation and skewness of historical rainfall series may be considered constant. In conclusion, combined use of some meteorological index and orography strongly characterizes the distribution

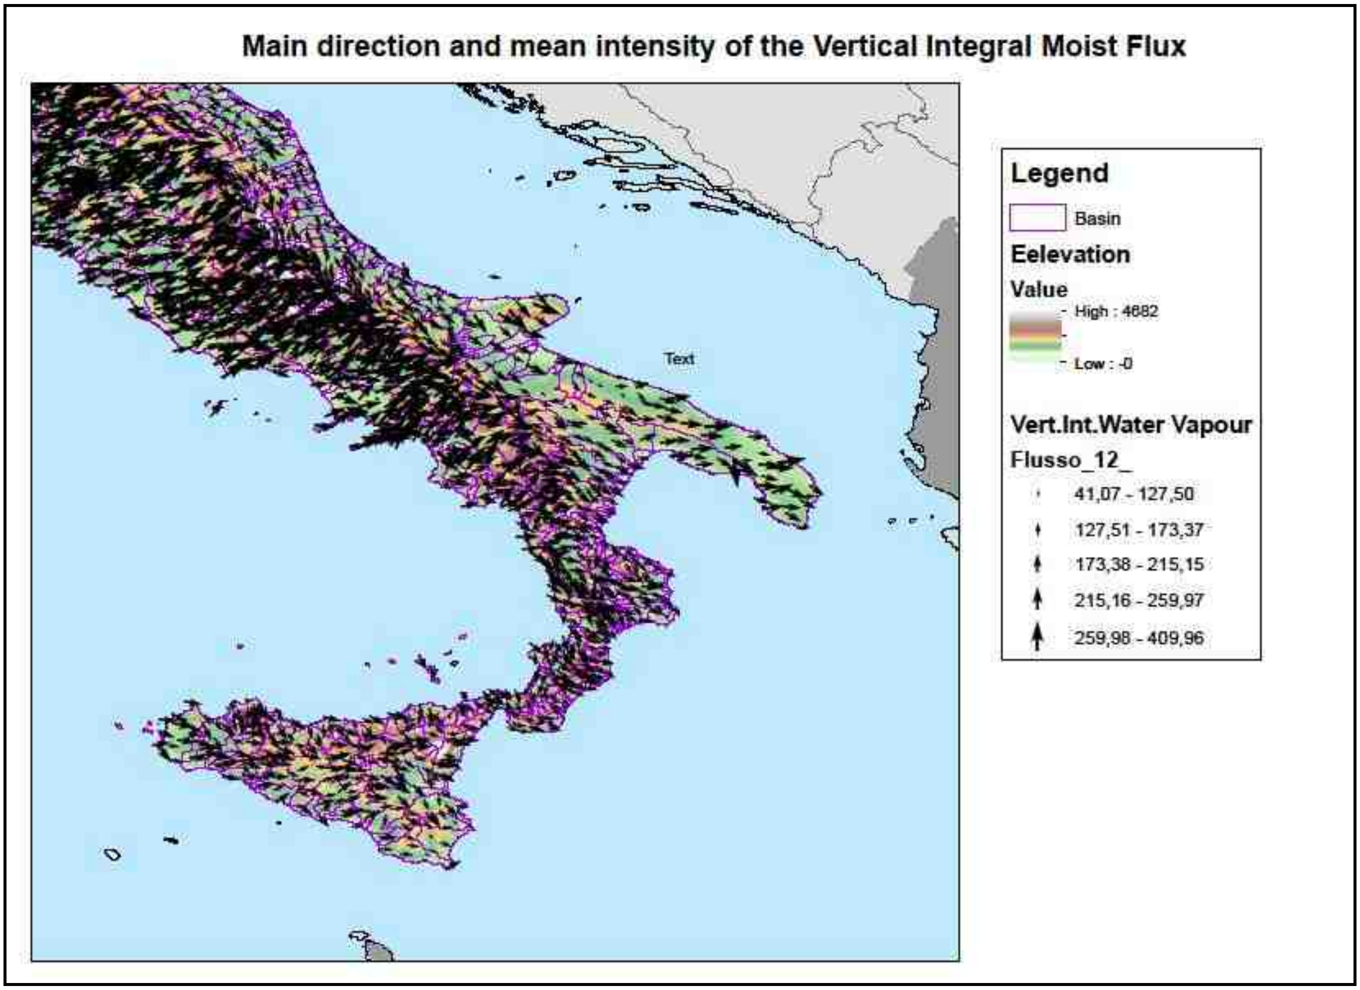

Fig. 3 – Main direction and mean intensity of the Vertical Integral Moist Flux

pattern of extreme rainfall in South Italy. Such information is relevant in the regionalization of extreme rainfalls.

Populating a catalogue of rainfall events that triggered shallow landslides in Italy

S.L. GARIANO (1), G.G.R. IOVINE (1), M.T. BRUNETTI (2,3), S. PERUCCACCI (2), S. LUCIANI (2,3), D. BARTOLINI (4), M.R. PALLADINO (5), G. VESSIA (6,7), A. VIERO (8), C. VENNARI (3), L. ANTRONICO (1), A.M. DEGANUTTI (8), F. LUINO (5), M. PARISE (6), O.G. TERRANOVA (1), F. GUZZETTI (2)

Key words: *early warning, rainfall thresholds, shallow landslides.*

INTRODUCTION

In Italy, rainfall induced landslides - including soil slips and debris flows - occur every year, claiming lives and causing severe economic damages. In the 61-year period 1950-2010, such phenomena have caused more than 6400 casualties (SALVATI *et alii*, 2010). During 2011, 25 people have been either killed or wounded by landslides. As a result, the prediction of slope failures triggered by rainfall is of primary importance for decision makers and civil protection authorities.

The predictive ability for rainfall induced landslides is still limited due to the complexity of the problem, to the number of the involved variables, and to the methodological approaches that are not always rigorous.

As regards shallow landslides, a team of researchers working at CNR-IRPI (Italian National Research Council, Institute of Research for Geo-Hydrologic Protection) is carrying out a research project funded by the Italian national Department for Civil Protection (DPCN), aimed at defining regional and sub-regional rainfall thresholds.

METHOD

A hydrological approach has been adopted to evaluate the dependence of landslide occurrence on rainfall values. The method is based on a statistical-probabilistic analysis of rainfall series and dates of occurrence of landslides (see, among the others: CAMPBELL, 1975; CAINE, 1980; WILSON & WIECZOREK, 1995; SIRANGELO & VERSACE, 1996; ALEOTTI, 2004; GUZZETTI *et alii*, 2007; 2008).

Empirical thresholds may define the rainfall conditions (e.g. cumulated event rainfall, mean rainfall intensity vs. rainfall duration, cumulated event rainfall vs. rainfall duration) that, when reached or exceeded, are likely to trigger landslides (REICHENBACH *et alii*, 1998). Landslide rainfall thresholds can be defined through the statistical analysis of past rainfall events that resulted in slope failures. They can be classified based on the geographical extent of the study area for which they are determined (i.e., global, national, regional, or local), and on the type of rainfall information used (GUZZETTI *et alii*, 2007, 2008).

Reliable regional and local rainfall thresholds require the collecting of large amount of information on geographical and temporal location of the slope failures, and on rainfall amounts responsible of the mass movements. For this purpose, the team is compiling a catalogue containing information about rainfall events that have resulted in landslides in Italy in the 10 year period 2002-2011.

The catalogue contains 2318 rainfall events that triggered single or multiple landslides in Italy. Figure 1 portrays the abundance of rainfall events that triggered landslides in the 20 Italian regions. The collected events are distributed almost equally between Northern, Central and Southern Italy (Fig. 2).

Information on rainfall events that resulted in landslides in Italy has been searched on (*i*) newspapers, in particular those available on line (actually the main source of information), (*ii*) blogs, (*iii*) historical databases, (*iv*) event reports and information provided by DPCN, and (*v*) recent publications and other technical reports. In particular, among technical reports, an important source of information is given by the reports of landslide events compiled by local fire brigades. Currently, fruitful collaborations exist with fire departments in Basilicata, Calabria, Campania, Marche, Sicilia, and Umbria.

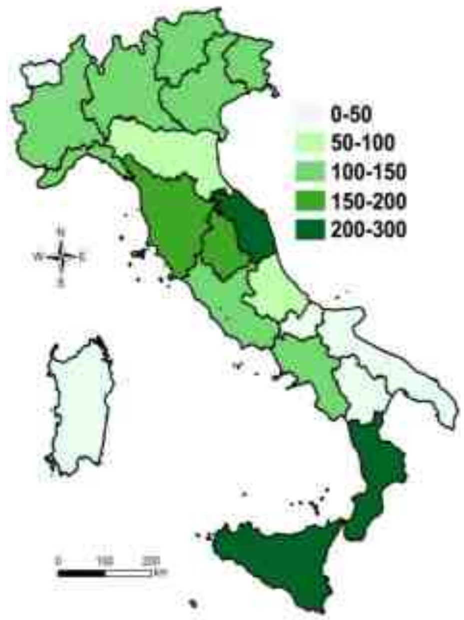

Fig. 1 – Classes of the number (*N*) of rainfall events that triggered landslides in the Italian regions.

In the catalogue, for each rainfall event that triggered one or more landslides, the information includes:

a) event identification (ID number, reference source);
b) landslide localization (place, municipality, province, region, geographical precision);
c) landslide classification;
d) temporal information (day, month, year, time, date, temporal precision);
e) rainfall information (representative rain gauge, rainfall duration, *D*, mean intensity, *I*, cumulated event rainfall, *E*).

The geographic coordinates of the documented slope failures have been obtained using Google Earth®. Different levels of uncertainty can characterize landslide locations, so four classes of geographic precision have been adopted.

In order to reconstruct the rainfall conditions responsible of the mass movements, the precise occurrence date must be known. Time of the failure can be also affected by some uncertainty, thus three classes of temporal precision have been adopted.

Once location and (known or inferred) time of initiation of the failure(s) are established, related rainfall information from the DPCN national network of 1950 rain gauges are analysed (Fig. 3). Additional data from regional rain gauge networks have also been used.

The selection of the "representative" rain gauge used to reconstruct the rainfall event (rainfall duration, *D*, rainfall mean intensity, *I*, and cumulated event rainfall, *E*), responsible of the individual failure, is based on *(i)* the geographical distance between the rain gauge and the landslide, *(ii)* the comparison between the elevation of the rain gauge and of the landslide, and *(iii)* other local topographical and morphological settings.

The rainfall duration *D* is determined as the time elapsed

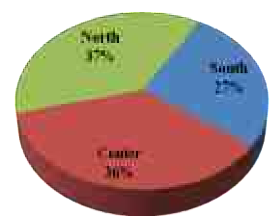

Fig. 2 – Percentages of rainfall events that have resulted in landslides identified in Northern, Central and Southern Italy.

between the rainfall starting time, and the time (known or inferred) of landslide initiation. The definition of the rainfall starting time is not trivial. Two rainfall events are considered separated when a minimum period without rain exists. A four-day period without rainfall is selected for the late autumn and winter (October to April), and a two-day period without rainfall was selected for other seasons (May to September). Furthermore, "frontal" from "convective" type of rainfall events should also be distinguished. Recently, a stationary criterion to identify the effective rainfall responsible of shallow landslides has been proposed by VESSIA & PARISE (2012). Finally, once the rainfall event is identified, the rainfall duration *D* [h], the corresponding cumulated event rainfall *E* [mm], and the mean rainfall intensity *I* [mm h^{-1}] can be calculated.

The catalogue represents the single largest collection of information on rainfall induced landslides in Italy (Fig. 4), and will be exploited to determine empirical rainfall thresholds for the possible initiation of shallow slope failures. To define objective rainfall thresholds and associated uncertainties, two consolidated statistical methods, including a *Bayesian* inference method and a *Frequentist* probabilistic approach, can be adopted

(BRUNETTI *et alii*., 2010, PERUCCACCI *et alii*, 2012).

The final aim of the research project is the definition of reliable rainfall thresholds for each of the 20 Italian regions, for the 129 alert zones (established by DPCN), and for homogeneous contexts (i.e. lithological, pedological, climatic) (PERUCCACCI *et alii*). The obtained thresholds could be implemented in a landslide warning system to forecast the possible occurrence of rainfall-induced shallow landslides in Italy.

Investigation of land subsidence in Southern Mahyar Plain in Isfahan province, Iran

M. GHAFOORI (*), R. SALEHI (*), G.R. LASHKARIPOUR (*) M.DEHGHANI (**)

Key words: *Environmental hazards, land subsidence, Iran*.

ABSTRACT

Land subsidence is one of the environmental hazards in which various mechanisms take part in its formation and development. One of the most important factors of subsidence is the drop of groundwater level that caused subsidence in many plains inside Iran in the recent decades. Excessive extraction of groundwater has caused severe land subsidence and earth fissures in the Southern Mahyar Plain located in Isfahan province in the peripheral part of Iran's central desert. In the last decades, fast agricultural expansion coupled with rapid population growth has tremendously increased pressure on the ground water resources. This paper deals with the relation between declining of ground water level, land subsidence and earth-fissure based on the available data in Southern Mahyar Plain. Based on field data, the temporal and spatial distribution of land subsidence is investigated and the causes for earth fissures are analyzed. Collected data using peizometric wells on the plain surface shows that the mean drop of water level in the period of 12 water years was 6m. Moreover, investigation of groundwater level fluctuations and compiling iso-depth maps in the district of the plain confirmed sharp drop of groundwater level. The areal distribution of the land subsidence is closely related to the cones of depression in the main exploited aquifers. In addition, field surveys in the study area indicated that fissures and cracks due to subsidence occur in the peripheral part of plain that inflicted severe losses to the agricultural lands.

Interferometric SAR technique (InSAR) is the most modern technology for the subsidence surveys.

In this study, Interferometric SAR technique with the aid of radar image of the satellite ENVISAT was used for the determination of the area affected by subsidence and investigation of surface undulation in short-term and long-term periods. Also by analysis of maximum time series, the mean rate of subsidence in the period of 2003-2006 was calculated to be 8.2 cm yr^{-1}.

INTRODUCTION

Land subsidence is a gradual settling or sudden sinking of the earth surface associated with negligible horizontal displacements (BATES & JACKSON, 1980). Subsidence due to the drop of groundwater level is a universal hazard that caught attention throughout the world. There are a variety of methods available to monitor land subsidence. They include vertical extensometers, baseline and repeated surveys of benchmarks using Global Positioning System (GPS) or conventional survey methods, and Interferometric Synthetic Aperture Radar (InSAR). Also, new methods and techniques such as advanced geographic positioning and radar have been applied in some plains of the Iran including the Neyshbour plains in the Khorasan-e-Razavi province (DEHGHANI *et alii*, 2009) and the Mashhad plains (DEHGHANI *et alii*, 2009b; MOTAGH *et alii*, 2007).

This paper focuses on the study area Southern Mahyar Plain SE of Isfahan, which bounded on the north by the southern part of the Kolah Ghazi Mountains, with trending NW-SE (Fig. 1). It is a broad sedimentary basin composed primarily of Quaternary-Neogene alluvial deposits (ZAHEDI, 1976). Annual rainfall in the area is estimated to range from 100 to 150 mm yr^{-1}, occurring mainly during spring and winter seasons. This study has been done with the aim of investigation the fluctuations of groundwater level across the Southern Mahyar Plain.

Investigation of groundwater level undulation takes an

Fig. 3 - Example of surface fissures in Southern Mahyar Plain

important rules in this study regarding to the causes of land subsidence. Therefore data from groundwater level changes during 1997 to 2009 from the piezometers located in the Southern Mahyar plain have been used. According to the unit hydrograph, despite seasonal fluctuations, groundwater level of the plain show descending trend and mean drop of the plain's groundwater level in the 12 years period was found to be 50 cm. Maximum drop of groundwater level belongs to 1990s which shows drops more than 3 m.

Results of the time series analysis reveal the subsidence short term and long term changes pattern in the period of 2003 to 2006. Final mean rate of the subsidence resulted from the time series analysis for the entire region is shown in (Fig .2) and according to this map, maximum subsidence in the region was found to be 8.2 cm yr^{-1}.

The natural features of land subsidence is the formation of fissures and cracks in the land and structures (Fig 3). In fact, these features are representation of subsidence phenomenon in the region.

Shallow-landslide susceptibility evaluation by means of Logistic Regression. The Costa Viola case study (Southern Calabria, Italia)

R. GRECO (1), O.G. TERRANOVA (1), A.D. PELLEGRINO (2), S.L. GARIANO (1), P. IAQUINTA (1), G. MANDAGLIO (3), A. LA TORRE (4), G. IOVINE (1)

Key words: *Shallow-landslide, Susceptibility, Logistic Regression.*

INTRODUCTION

Shallow landslides are among the most destructive and dangerous types of slope movements for people and infrastructures. The "Costa Viola" study area (Southern Calabria), especially in the sector between Bagnara Calabra and Scilla, has repeatedly been affected by slope instability events in the past, mainly related to shallow landslides (debris slides and debris flows) (PELLEGRINO and BORRELLI, 2007).

Evaluation of landslide susceptibility, the first step in regional hazard management, can be achieved by means of multivariate statistical analyses (GUZZETTI *et alii*, 1999). Logistic Regression (LR) is a type of multivariate analysis widely utilized (cf. among the most recent studies: GRECO *et alii*, 2007; SORRISO-VALVO *et alii*, 2009; ROSSI *et alii*, 2010); it allows estimating the presence/absence of a phenomenon, represented by the dependent variable *y*, in terms of probability P(y), on the basis of linear statistical relationships with a set of independent variables. The adopted LR procedure consists of four steps: i) variable parameterization, ii) sampling, iii) fitting, and iv) application.

An attempt of improving preliminary results, recently presented at the Second World Landslide Forum (IOVINE *et alii*, 2011), has been performed by considering other territorial variables, the use of different variable parameterization, and by processing data through a specific statistical package.

STUDY AREA

The study area (82.2 km^2) is located in the "Costa Viola" mountain ridge, between Bagnara Calabra and Scilla (Fig. 1). It is characterized by Palaeozoic metamorphic and crystalline bedrocks, covered by Upper Miocene to Holocene sedimentary deposits. At the base of the mountain ridge, a NE-SW trending fault marks the transition between the basement and the sedimentary terrains of the coastal plain.

Morphologically, the area is characterized by steep slopes, cut by deep canyons (the longest thereof are T. Favazzina and T. Sfalassà); a set of marine terraces can be recognized between 100 and 600 m a.s.l. The study area is crossed by relevant infrastructures (railway, highway A3, State road SS.18) (cf. Fig. 1); the narrow coastal plain is densely urbanized.

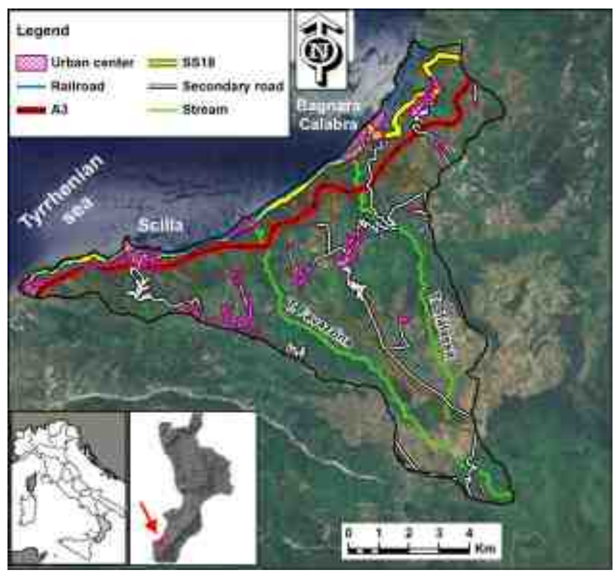

Fig. 1 – Location and main infrastructures of the study area

METHOD

In LR, the presence/absence of a landslide can be expressed in terms of a dichotomic dependent variable, whose probability of being true is determined on the basis of statistical relationships with a set of independent territorial variables. The probability of occurrence of the dependent variable, P_y, can be calculated as follows:

$$P_y = 1 - \left[1 + exp\left(-\sum a_i X_i\right)\right] \qquad [1]$$

(1) CNR-IRPI - U.O.S. di Cosenza, via Cavour, 6 – 87036 Rende (CS) Italia – e-mail: g.iovine@irpi.cnr.it

(2) ABR Calabria, Catanzaro (CZ), Italia.

(3) Università degli Studi Mediterranea di Reggio Calabria, Italia.

(4) Provincia di Reggio Calabria, Italia.

in which a_i and X_i are the regression coefficients (i.e., the variables weights), and the independent variables, respectively.

The adopted LR procedure, first proposed by GRECO *et alii* (2007), consists of four steps: i) variable parameterisation, performed by considering landslide incidence in given portions of the study area, named the "sampling zones"; ii) sampling, in which a fitting data set is extracted from buffer sampling zones, obtained by generating a buffer around each landslide source; iii) model fitting, iteratively performed by testing all the possible values for the weights of the independent variables, until the quadratic mean residuals are minimized; iv) model application, in which the logistic function is applied to the whole study area. A grid of values, ranging between 0 and 1, is obtained as output. The forecast capability can be evaluated by means of the ROC analysis (Receiver Operating Characteristics Analysis, Hosmer and Lemeshow, 1989).

The territorial distribution of shallow landslides (i.e. the dependent variable) has been obtained by interpreting a set of aerial photographs (1954-1955). In Fig. 2, the 181 landslides employed as training set during the phase of calibration are shown.

Independent variable maps have been obtained through field survey, from available published maps, and by processing other variables (derived from the DEM).

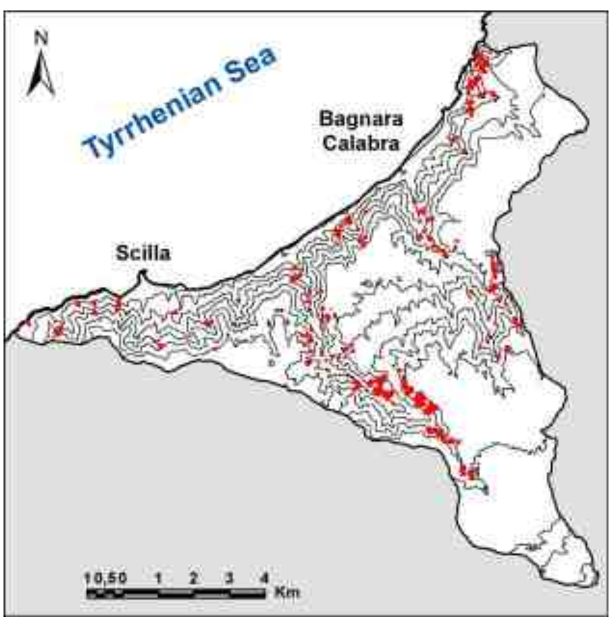

Fig. 2 – Landslide inventory maps of the study area.

The data set of independent variables includes the nine causal factors (Fig. 3a-h): lithology (LU), land use (LUS), soil type (ST), elevation (ELEV), slope angle (SLO), aspect (ASP), curvatures set along the direction of maximum slope (ACUR), curvatures set orthogonally to the direction of maximum slope (DCUR), topographic wetness index (TWI).

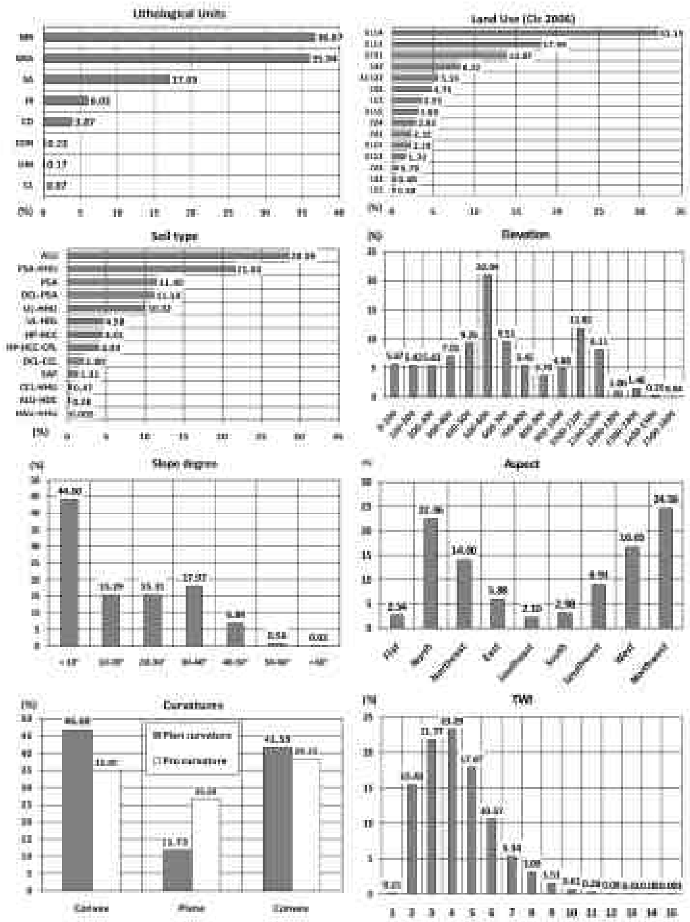

Fig. 3 – Distribution of independent territorial variables for the study area: Keys: a) Lithological Units: CL = Clay; LIM = Limestone; CON = Conglomerate; CD = Colluviums and debris; IR = Igneous Rock; SA = Sand; GRA = Gravel; MR = Metamorphic Rock; b) Land Use Categories: 112 = Discontinuous urban fabric; 2111 = Intensive cultivations; 222 = Fruit trees and berries plantations; 223 = Olive groves; 241 = Annual crops associated with permanent crops; 242 = Complex cultivation patterns; 243 = Land principally occupied by agriculture, with significant areas of natural vegetation; 3114 = Chestnut forest; 3115 = Beech forest; 3121 = Coniferous forest; 31322 = Mixed forest; 3212 = Discontinuous grassland; 3231 = High "Macchia"; 324 = Transitional woodland-shub; 333 = Sparsely vegetated areas; c) Soil type: ALU = Artenic-Leptic Ubrisol; CCL = Cutanic Chromic Luvisols; CPL = Chromi Profondic Luvisols; DCL = Dystri-Cutanic Luvisol; HAU = Humi-Arenic Umbrisols; HCC = Haspli-Calcaric Cambisols; HDC = Hapli-Dystic Cambisols; HDL = Hapli-Dystric Leptosols; HHU = Hapli-Humic Umbrisols; HP = Haplic Phaeozems; PSA = Pachi-Silic Andosols; SAF = Skeletic-Arenic Fluvisols; UL = Umbrihumic Leptosols.

PRELIMINARY RESULTS AND IMPROVEMENTS

In Table 1, regression weights of each independent variable, RMSE and Chi-square values obtained in the model fitting are shown. Through the logistic function [1], the probability of existence has been evaluated for the whole study area. Finally, the probability has been re-classified into 5 classes: Null ($P(y) \leq 5\%$); Low ($5\% < P(y) \leq 25\%$); Medium ($25\% < P(y) \leq 55\%$); High ($50\% < P(y) \leq 75\%$); Very high ($P(y) > 75\%$) (Fig. 4).

coefficient	variable	value
a_0	Intercept	-11.552
a_1	LU	0.028
a_2	LUS	0.013
a_3	ST	0.000
a_4	ELEV	0.018
a_5	SLO	0.025
a_6	ASP	0.032
a_7	ACUR	0.027
a_8	DCUR	0.043
a_9	TWI	0.037
RMSE		0.485
Chi-square		475.990

Tab. 1 – Regression weights, RMSE and Chi-square values.

As shown in Figure 4, the sectors most threatened by shallow-landslides are located by the Tyrrhenian coast, and along the steep flanks of the Sfalassà and Favazzina torrents. Obtained weights (Tab. 1) suggest that down-slope curvature, topographic wetness index, aspect and lithology play a primary role in favouring slope instability.

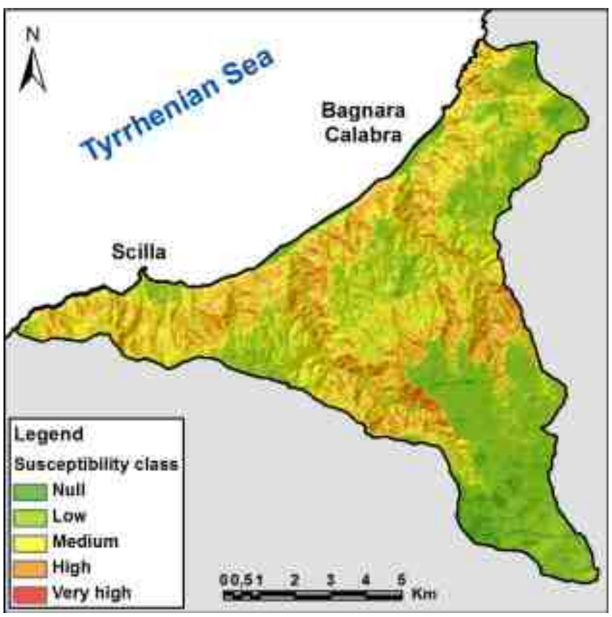

Fig. 4 – Susceptibility map of Costa Viola study area.

In order to check the performance of the LR models, a ROC analysis has been performed. The obtained ROC-curve (Fig. 5) indicates a percentage of 85.6% of correctly classified cells, confirming the goodness of classification for the “Costa Viola” study area, where the LR sampling procedure satisfactorily described the probability of presence of mass movements.

The next step of the study, still in progress, is an attempt of improving the cited preliminary results, through: i) introducing other territorial variables (like the distance to fault, the soil thickness, the weathering grade); ii) using different variable parameterization (dummy approach); iii) processing data through a specific statistical software (like IBM SPSS Statistics 19).

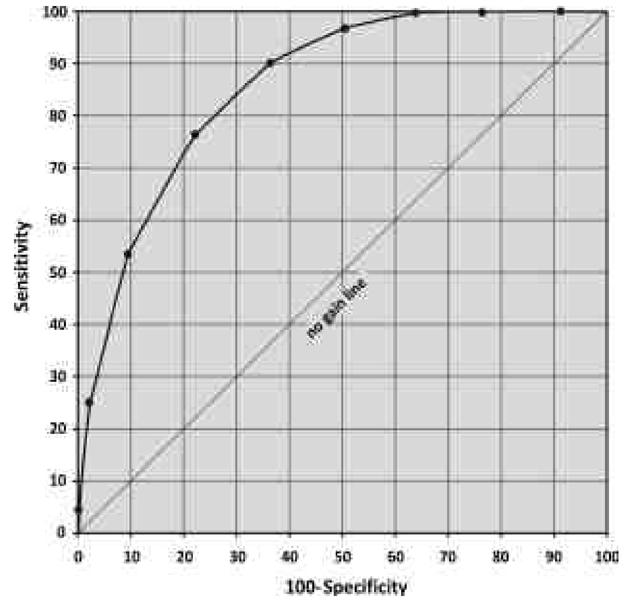

Fig. 5 – Obtained ROC curve.

A.M.A.Mi.R: an expert system for sensor network management and landslides monitoring over a wide area with enhanced features for the uncertainty assessment in the measurement samples

N. GULLO (*), G. MARTINI (**), C. TANSI (**) & V. AZZARO (°)

Key words: *monitoring, landslides, risk management, sensor network, expert system, uncertainty measurement.*

INTRODUCTION

The term "monitoring" is used to describe functions or, better, control processes, even complex, of a given phenomenon.

Monitoring is an indispensable tool to make analysis on phenomena that may cause adverse or catastrophic effects on the social context.

Designing, installing and managing of monitoring systems placed to control of landslides arise from the need to provide a reference tool for those working in the area for purpose of prevention, control and arrangement of slopes.

The monitoring of landslides is a complex and dynamic process that requires continuous technological improvements in order to obtain more detailed information on natural phenomena that affect the area and especially their evolution.

More fundamental is the management phase of such systems that grows through a series of actions necessary to grab really significant informations.

A.M.A.Mi.R. (Advanced Monitoring Actions to Mitigate the geo-hydrological Risk), is a landslide-sensing network management system for data collection and their qualitative assessment.

In metrology, measurements are intrinsic features of a particular phenomenon. So, a correct analysis can not ignore the qualitative assessment of the data collected.

According to ISO (2004), the uncertainty (of measurement) is a "parameter that characterizes the dispersion of the quantity values that are being attributed to a measurand, based on the information used".

Operatively, in the monitoring systems, the uncertainty of measurement can arise from several causes: technical issues (under-sampling in the measurement frequency, low voltage and interference issues, a faulty sensor, etc) and environmental conditions of the observed region (weather, vegetation, wildlife, vandalism, etc) may alter the sensing capabilities.

These factors, not always obvious and predictable, may lead to underestimate or ignore "potential" alarms (fig. 1), especially in the simultaneous monitoring of multiple landslides on large (regional scale), which involves the management of a significant number of sensors.

The present work aims to highlight the benefits of an expert system for the measurements collection and their qualitative

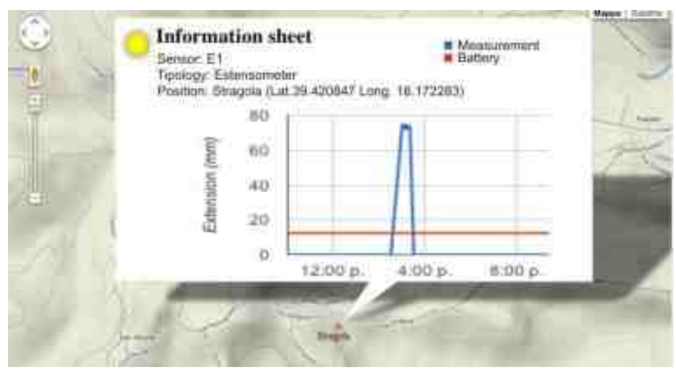

Fig 1 - The last 8h information sheet in the potential alarm state - recognized as a false alarm from the A.M.A.Mi.R. system - of a rotative extensometer monitoring the landslide of Stragola.

assessment, taken from sources, heterogeneous and distributed on a large scale in the monitoring of landslides (WALLEY P., 1996).

(**) CNR-IRPI – UOS of Cosenza, via Cavour, 6 Rende (CS), Italy.

(°) Indipendent professional geologist, via Mercurio 60 Mirto Crosia (CS), Italy.

The system was tested on a sample area, located in Montalto Uffugo (Cosenza, Southern Italy), where a 24/7 monitoring system operates, in real-time, and it is involved in the measurement of a large-scale landslide that seriously threatens the buildings in the Stragola locality, where there are nearly 100 people (fig. 2). In particular, the monitoring system consists of rotative extensometers and wall inclinometers.

Fig. 2 – The landslide of Stragola (Montalto Uffugo) was being monitored by the A.M.A.Mi.R. system. Note the main scarp of the landslide and the buildings at risk.

The rotative extensometers detect the change of the distance between two points "riding" the fractures of the ground produced by active landslides (fig. 3); fixed inclinometers are placed on the walls of buildings threatened by the failure and susceptible to sliding.

The A.M.A.Mi.R expert system, here exposed, provides a web gis overview on the entire observed area, where many colored icons stand for different types of sensing units and for their state (eg quiet, potential alarm, strumental alert). Selecting an icon from these, the expert open a detailed view of the sensing unit, where he will see all the features of the units and the last 24h trend of the measurements. Also, he will can access a feature for comparing data from different units and more and more.

Periodically, the system collects and qualitatively assess the measurement samples, refreshing the state of the sensing units. In detecting issues, it alerts by SMS the expert for a careful resolution.

This approach agrees with the EAL Task Force (1999) specifications for the "type B uncertainty estimation" method, which takes advantage from the human expert's scientific knowledge togheter with the more simple data statistical analysis.

In the present paper we will discuss an introduction to the risk management of measurement uncertainty, the architecture of the expert system, the choice of the qualitative assessment method and the results of the testing.

Fig. 3 – Monitoring through a rotative extensometer of a ground fracture produced by the landslide of Stragola. The opening of the fracture close to the buildings causes the stretching of the kevlar thread detected by the sensor that send a real time SMS alert.

Hydrological modelling to predict the timing of landslide activations. Calibration, validation and sensitivity analysis of ^{GA}*SAKe*

P. IAQUINTA, O.G. TERRANOVA, S.L. GARIANO, R. GRECO, G. IOVINE

Key words: *landslide, hydrological model, genetic algorithm, calibration, validation, sensitivity analysis.*

INTRODUCTION

In Italy, a recent nationwide investigation has identified more than 1.6 landslides per km^2 (GUZZETTI *et al*., 2008). Most of the landslides that affect the Country are usually triggered by rainfalls. Forecasting the timing of rainfall-induced landslides is then a fundamental step for Civil Protection purposes. This goal can be obtained by means of either empirical "hydrological" or physically-based, "complete" models.

The hydrological approach (adopted in the present study) tries to identify the mathematical relationship that links the rainfall series to the dates of landslide activation. With respect to shallow landslides, the dynamics of deep-seated slope movements generally shows a more complex relationship with rainfall: activations commonly require greater rainfall amounts, spanned over longer periods (from ca. 30 days to more than a single rainy season).

MODELING APPROACH

SAKe (*Self Adaptive Kernel*) is a hydrological model that can be employed to predict the occurrence of one of the most pernicious effects of rainfall on slope stability: slope movements. The model can be useful for real-time warning purposes. It is self-adaptive and based on the assumption of a linear and steady response, in terms of stability, of the slope to rainfall.

SAKe is based on an empirical approach – "black-box" type (Fig. 1) – inspired from *FLaIR* (SIRANGELO & VERSACE, 1996). By properly tuning the model parameters, a mobility function and a threshold value can be identified that allow to reconstruct the series of known landslide activations of the past by minimizing the occurrence of false alarms. The ranges of parameters depend on: (i) the specific hydrological conditions that characterize the triggering events, (ii) the characteristics of the slope and, (iii) the landslide type.

According to classic hydrologic assumptions, usually made in rainfall-runoff modelling, the model output is represented by a "mobility function", *Z(t)*, defined in terms of convolution between the rains and a "filter function" (the *kernel*).

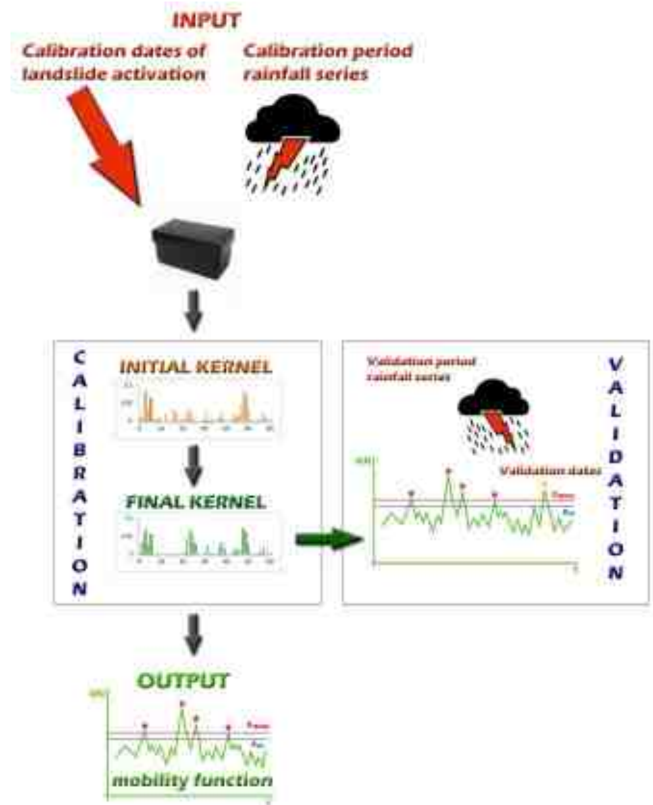

Fig. 1 – Scheme of the model *SAKe*.

The following input data are needed for a given case study:

i) the series of rains;

ii) the set of known dates of landslide activation. More specifically, either the mobilizations of a single phenomenon, or those of a homogeneous set of landslides occurred in a given area can be analyzed.

For calibration purposes, only a subset of available historical dates of activation can be employed; model validation can then be performed against the remaining subset.

CNR-IRPI – U.O.S. di Cosenza, via Cavour 6 – 87036 Rende (CS) Italia - e-mail: g.iovine@irpi.cnr.it

As regards model calibration, different automated tools can be utilized, based on either iterative cluster modification – ^{CM}*SAKe* – or Genetic Algorithms (HOLLAND, 1975) – ^{GA}*SAKe* – as recently done for debris flows modelling by IOVINE *et al.* (2005). As a result, a family of optimal, discretised kernels can be obtained from initial standard analytical functions, whose values represent the probability of landslide activation given that a critical threshold is overcome.

The family of optimal kernels – that maximize the adopted fitness function – is selected by means of a calibration technique based on elitist Genetic Algorithms. In this way, the values of model parameters are iteratively changed, aiming at improving the fitness of the tested solutions. A suitable fitness function must first be defined, able to minimise the number of false alarms. In the present study, fitness is defined as follows:

a) the N available dates of landslide activation are sorted, in chronological order, in the vector $S = \{S_1, \ldots, S_i, \ldots, S_N\}$;
b) the vector of the relative maxima of the mobility function Z = $\{z_1, \ldots, z_k, \ldots, z_M\}$, where M is the number and k is the rank of the relative maxima, is sorted in decreasing order;
c) the vector of the partial fitness values is defined as $\varphi = \{\varphi_1, \ldots, \varphi_i, \ldots \varphi_N\}$.

The following cases can occur:

i) $\varphi_i = 1$ if the date of the *i-th* activation, S_i, matches, within a pre-fixed tolerance (Δ), the date of a *k-th* relative maximum of the mobility function, z_k, with $k \leq N$;
ii) $\varphi_i = (k-N+1)^{-1}$ - i.e. it is inversely proportional to the rank of z_k in Z – if the date of the *i-th* activation, S_i, matches, within a pre-fixed tolerance, the date of a *k-th* relative maximum of the mobility function, z_k, with $k > N$;
iii) $\varphi_i = 0$ if the date of the *i-th* activation, S_i, does not match any date of the relative maxima in Z.

Accordingly, the fitness of a generic kernel is:

$$\Phi = \frac{1}{N} \sum_{i=1}^{N} \varphi_i \ .$$

^{GA}*SAKe* is based on two levels of optimization. The first optimization process allows to search for the mobility function that gives the maximum fitness function f_n. The second optimization process looks for the maximum difference between the critical threshold, Z_{cr}, and the smallest value of the relative maxima of the mobility function, Z_s. Note that the operational levels can modify the filter function, producing an integral that differs from the unity. Thus, a normalization process is also necessary.

The genetic algorithm is an iterative process based on the following operators (Fig. 2):

- *Selection* of the elements to be copied in the "mating pool" for reproduction purposes (in this study, it is of elitist type);
- *Crossover* of pairs of elements (based on probability, p_c);
- *Mutation* of elements (based on probability, p_m).

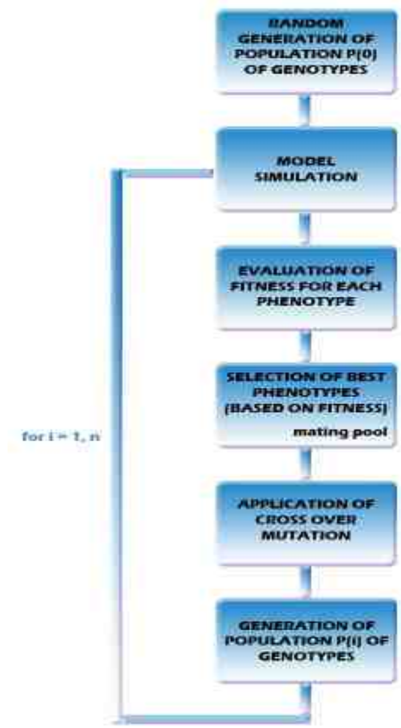

Fig. 2 – Steps of the Genetic Algorithm for model calibration.

The mating pool contains N elements of the population; these elements eventually originate N new mobility functions. Minimum, average and maximum values of the fitness functions for each iteration are evaluated and plotted. New generations are obtained by repeating the steps above.

An example of model optimization is presented, with reference to the Uncino rock slide (maximum width = 200 m, length > 650 m) (Fig. 3**)**, developed in clay and conglomerate (Late Miocene) overlaying gneiss and biotitic schist (Palaeozoic). The landslide repeatedly threatened the northern rim of the San Fili village, in Northern Calabria. For this case study, N=7 historical dates of mobilization are available. On such occasions, the railroad connecting Cosenza to the Tyrrhenian coast was damaged or even interrupted. Preliminary results of model calibration, carried out using all the dates of activation, are shown in Fig. 4. Aiming at temporal validation purposes, only a subset of the dates of landslide activation has been used; sensitivity analysis results are discussed.

Interventi di mitigazione del rischio da colata rapida, nell'area di Favazzina (RC, ITALY)

SAVERIO INFANTINO (*) ADRIANA LA TORRE (**) GIUSEPPE MANDAGLIO (***) & ANNA MARIA PELLEGRINO (****)

Key words: *rapid landslide hazard, strategies, risk mitigation*.

ABSTRACT

During the last ten years the coastal area between Bagnara Calabra and Scilla villages (RC) has been affected by numerous shallow landslides (rock fall and mud or debris flow events), that involved some structures and infrastructures such as the Favazzina village, the Salerno-Reggio Calabria highway and the coastal national road SS18. The mud or debris flow events were produced by translational landslides involving the superficial and weathered part of the metamorphic substratum; they occurred upslope to the channels, concomitant with very intense rainfalls. The landslide masses were channelled and fluitized by stream waters (ABR 2001, 2005; 2006 BONAVINA *et alii*, 2006).

In this paper the results of a wide research performed for the design of works on the "mitigation of landslide risk in the slope upstream of the Favazzina village" characterized by rapid flows, are shown.

The study is based on a holistic approach considering the different levels of hazard recorded along the cliff between Scilla and Bagnara Calabra due to the specific morphogenetic processes, the high susceptibility to shallow landslides (ABR 2006; GARIANO *et alii*, 2011), and the high index of landsliding (CHIODO *et alii*, 2008). Moreover the study aims to draw guidelines for the definition of the structural and not structural risk mitigation works, that can be extended at the adjacent portions of territory characterized by similar morphdynamical structures.

QUADRO GEOLOGICO E GEOMORFOLOGICO

Il settore studiato rientra nell'horst di Campo Piale, compreso tra il graben longitudinale del Mesima ed il graben trasversale dello Stretto di Messina (GHISETTI, 1981). Lo stesso è caratterizzato dalla presenza di alti morfologici con sommità sub-pianeggianti, delimitati da ripidi versanti, talora terrazzati, con pendenza media del 60%, che localmente supera il 100%. Lungo il transetto Gambarie – Scilla (MIYAUCHI *et alii*, 1994), sono stati individuati almeno dodici ordini di terrazzi marini, il primo dei quali si ritrova attualmente a 1350 m s.l.m., in corrispondenza dei Piani di Aspromonte.

Nel settore affiora il basamento cristallino-metamorfico, costituito dalle porzioni di crosta continentale più profonda dell'Unità Aspromonte-Peloritani, di età Ercinica. Il basamento è rappresentato da un complesso migmatitico, intruso da corpi granitoidi, in cui si alternano:

a) paragneiss biotitici, spesso con chiare evidenze di fusione parziale;

b) gneiss migmatitici leucocratici ("Gneiss chiari" Auct.), a tratti con forti concentrazioni biotitiche.

Tale complesso presenta, in proporzioni non cartografabili , livelli di gneiss occhiadini, anfibolitici e micascistosi (micascisti a granati). Le metamorfiti sono intruse da plutoni leuco granodioritici tardo-Ercinici, da cui si diramano diversi sistemi di filoni pegmatoidi/aplitoidi, di spessore da centimetrico fino a decimetrico.

La successione sedimentaria al di sopra del basamento metamorfico è rappresentata essenzialmente da sabbie ed arenarie pleistoceniche e da depositi ghiaioso-sabbiosi continentali, distribuiti a diverse quote su più ordini di terrazzi marini. La successione presenta numerose lacune deposizionali a testimonianza dell'evoluzione tettonica recente della zona, caratterizzata da un intenso sollevamento polifasico (GHISETTI, 1981).

Fonti storiche e testimonianze di recenti eventi (ABR, 2001; 2005; 2006; CHIODO *et alii*, 2008) hanno messo in luce che nell'area, oltre alle frane per crollo e scorrimento, si verificano spesso le condizioni per la mobilitazione di colate rapide. L'analisi dei meccanismi di innesco e propagazione delle colate porta a ritenere che la loro origine si debba a scorrimenti traslazionali nelle coltri alle testate dei valloni, innescati da intense precipitazioni, concentrate in poche ore; i detriti, incanalandosi nei valloni, aumentano il contenuto in solido ed acqua, dando origine inizialmente a colate di fango che evolvono in colate di detrito. Le colate rapide,

Fig. 2 - Versante a monte dell'abitato di Favazzina con eventi 2001-2005, tratto da "Tratto di costone compreso tra Bagnara Calabra e Scilla (RC)-Studio speditivo dei fenomeni di dissesto Idrogeologico per l'individuazione dei primi interventi di mitigazione del rischio. 1° Rapporto (da ABR 2006).

accompagnate a volte da fenomeni di tipo idraulico (flussi iperconcentrati o debris torrent), rappresentano l'evoluzione più evidente del versante a monte di Favazzina, come testimoniano gli eventi del maggio 2001 nel vallone Favagreco e del marzo 2005 nel vallone adiacente l'abitato (BONAVINA *et alii*, 2006; PELLEGRINO *et alii*, 2012), con magnitudo rispettivamente di circa 9000 m^3 e di 2000 m^3. Oggi la frequenza di questi fenomeni appare aumentata rispetto al passato, probabilmente anche perché ai fattori di innesco "naturali" si aggiungono fattori determinati da trasformazioni antropiche del territorio che alterano il già precario equilibrio esistente.

SINTESI APPROCCIO METODOLOGICO

Per la definizione e la predisposizione del piano degli interventi, sul versante a monte dell'abitato di Favazzina, sono stati avviati appositi rilievi, indagini e studi di dettaglio a carattere geologico, litostratigrafico, geomorfologico, idrogeologico, geotecnico, idrologico, idraulico ed ambientale.

In particolare, sono emersi diversi elementi di predisposizione nel possibile sviluppo di fenomeni superficiali e veloci, che oltre all'elevata pendenza sono rappresentati in particolare dalla presenza di coperture alteritiche/residuali e colluviali e/o detritico-colluviali, nonché di un substrato cristallino-metamorfico variamente alterato e degradato. Pertanto, è stato eseguito un rilievo, mirato alla caratterizzazione degli orizzonti e dei peculiari profili di alterazione dei litotipi affioranti (GSE-GWPR, 1995; PELLEGRINO *et alii*, 2008), nonché alla definizione della loro distribuzione spaziale. Nell'area di interesse sono state riconosciute quattro Classi di alterazione a comportamento omogeneo (ABR 2001; PELLEGRINO *et alii*, 2012):-roccia litoide in classe III (roccia moderatamente alterata) e roccia tenera in classe IV (roccia altamente alterata); -roccia sciolta) classe V (roccia completamente alterata o "saprolite") e classe VI (terreni residuali, colluviali e detritico-colluviali).

Nello specifico, le frane superficiali rapide, tipologicamente ascrivibili a fenomeni di scorrimento traslazionali che evolvono in colata rapida, interessano, prevalentemente, le coltri di terreni residuali e colluviali (classe VI) e, secondariamente, la facies poco consistente del substrato metamorfico completamente alterato o saprolite (classe V).

Inoltre, specifiche indagini geognostiche sono state eseguite in differenti periodi dal 2001 ad oggi. Le finalità essenziali delle suddette indagini sono state:

i) determinare il trend degli spessori sia dello strato costituito da terreno eluvio-colluviale, sia delle differenti Classi di alterazione del substrato roccioso;
ii)avere un quadro delle porzioni di versante, con associato grado di alterazione, in condizioni di incipiente collasso e potenzialmente mobilizzabili nelle zone di sorgente (slide) dei fenomeni rapidi;
iii)verificare, sulla base della distribuzione spaziale delle Classi di alterazione, l'erodibilità o meno per "effetto valanga" lungo i canali di deflusso delle colate e/o flussi iperconcentrati;
iv)poter verificare, conseguentemente ad una stima degli spessori delle differenti Classi di alterazione e relativa consistenza, anche la "pericolosità residua" connessa al volume di materiale direttamente coinvolto nella zona di sorgente oppure che può essere eroso per "effetto valanga", a seguito di differenti e ripetuti eventi di colata rapida e/ fenomeni idraulici;
v) definire un quadro geologico-tecnico (sia areale che spaziale) per la progettazione di opere di mitigazione del rischio compatibili con le problematiche definite.

DISCUSSIONE

Dalla complessità delle indagini condotte, è emerso che per la mitigazione del rischio occorre agire su tre fronti:
i)abbassare il livello di pericolosità attraverso opere di protezione idraulica e opere di sistemazione idrogeologica dei versanti;
ii)diminuire la vulnerabilità dei beni esposti;
iii) prevedere azioni aggiuntive predisponendo un "Piano di presidio e manutenzione" .

In particolare, tenuto conto delal descritta situazione di pericolosità da colate rapide, sono stati individuati:
- interventi sui principali meccanismi innescanti, nella fattispecie connessi ai punti di criticità idraulica lungo la strada di servizio e le piste poste a monte dell'abitato di Favazzina, le quali tra l'altro controllano a luoghi l'evoluzione dei fenomeni rapidi ed idraulici;
- interventi strutturali di regimazione dei punti di sorgente delle colate, in modo da mitigare il rischio dell'improvviso apporto di materiale lungo gli impluvi;
-il ricorso ad opere a basso impatto ambientale adottando, ove possibile, interventi di ingegneria naturalistica;
-l'inserimento lungo il percorso/canali di opere aventi la funzione di dissipare in modo significativo il potere distruttivo delle colate rapide.

Alla luce delle situazioni rilevate e della rapidità con la quale esse si modificano, il suddetto "Piano di presidio e manutenzione" deve prevedere un'attività di vigilanza dei bacini con costante monitoraggio, a manutenzione programmata, ordinaria e straordinaria, dei torrenti e dei fossi e di tutte le opere di sistemazione e di raccolta e convogliamento delle acque (canali di raccolta, caditoie e tombini).

Meteo-hydrological analysis of intense flash-flood events over Southern Italy

S. LAVIOLA (*), S. GABRIELE (**), M.M. MIGLIETTA (*), E. CATTANI (*) & V. LEVIZZANI (*)

Key words: *Mediterranean flash-flood, numerical model forecast, rain gauges, satellite retrieval*

INTRODUCTION

The intense rainfall systems typically forming on the Mediterranean basin are often characterized by trajectories which are directed to the Southern part of the Italian Peninsula. With exception of the so called Tropical Like-Cyclone (TLC), that is a well-organized system rotating around a central eye with a strong surface wind, the majority of the flash-flood events are generated by deep convective rainfall characterized by a small scale domain and a very short life time. As demonstrated by CHARAVALLOTI & GABRIELE (2009) these systems can be extremely localized up to the basin scale and the intense precipitation associated to them are responsible for strong runoffs. For this reason, these systems are very difficult to model and appear substantially unpredictable. Furthermore, the observations with meteorological satellites are often not representative of the system characteristics and the use of rain gauges is generally inadequate to fully reconstruct the ground rainfall field. Therefore the goal of this work is a multidisciplinary approach based on the integration of satellite, numerical model, synoptic maps and ground-based hydrological information. The satellite investigation has been mainly based on the geostationary satellite MSG and on the NOAA polar orbiting satellites. The Meteosat Second Generation (MSG) and the NOAA passive microwave (PMW) rain rate products (LAVIOLA & LEVIZZANI, 2009, 2011a,b; Cattani et al., 2009) will be employed to describe precipitating events discerning intense convection cells from other rainy clusters. The main strength of this activity is to combine the capabilities of the optical geostationary satellite wavelengths with those of the polar PMW sensors. The investigation will evolve following two main streams: an initial stage will be mainly dedicated to develop an operational procedure to characterize rainy scenes by identifying severe storm cores on the basis of the MSG Spinning Enhanced Visible and Infrared Imager (SEVIRI) data. In the second step a method to combine PMW rainfall products with SEVIRI thermal infrared images will be engaged. Following an advanced propagation scheme based on the concept of advection vectors derived from MSG channel at 10.8 μm, the CMORPH scheme will be applied to describe the scena at high temporal and spatial resolution. The characterization of convection from satellite is supported by the Weather Research and Forecasting (WRF) model runs. The output of the WRF model contributes to a better understanding of the status of the atmosphere, to evaluate the variation of the key parameters of the convection dynamics and to possibly quantify the forecasting errors, which mainly affect the accuracy of the prediction. The analysis is completed by ground-based rain gauge measurements.

CASE STUDY: VIBO VALENTIA FLASH-FLOOD

In this section is briefly described an example of our approach applied to the case flash-flood of 3 July 2006 where a deep localized convective cluster with a life time of 3 hr affected the city of Vibo Valentia. In figure 1 is reported the distribution of rain gauge stations over Calabria region and the data of the rain gauge station of Vibo Valentia. As we can see, the precipitation started around 0900 UT have reached the maximum value on 1020 UT. The MSG-RGB image detects the triggering of the convection while the NOAA satellite overpass of the 1018 UT identifies the mature stage of the system. The application of the 183-WSL method allows to retrieve the precipitation amount and classify the type of precipitation in terms of convective and stratiform contribution. As it can be noted only the rain pixels placed on the borders of the main system are flagged as stratiform but the core are "purely" convective. To corroborate this conclusions, in figure 2 the WRF simulations in terms of rain rates, wind convergence and cloud vertical development have been reported. Although, the model well reconstructs the wind field and the mixing ratio on the target area the forecast of the precipitation rates is underestimated and misplaced. We have evaluated a shift of about 2 hours in advance (compare red circle indicating the WRF forecast with red square which indicates the rain gauge measurement) with respect to the ground measurement of waterfall. The spatial shifting of the

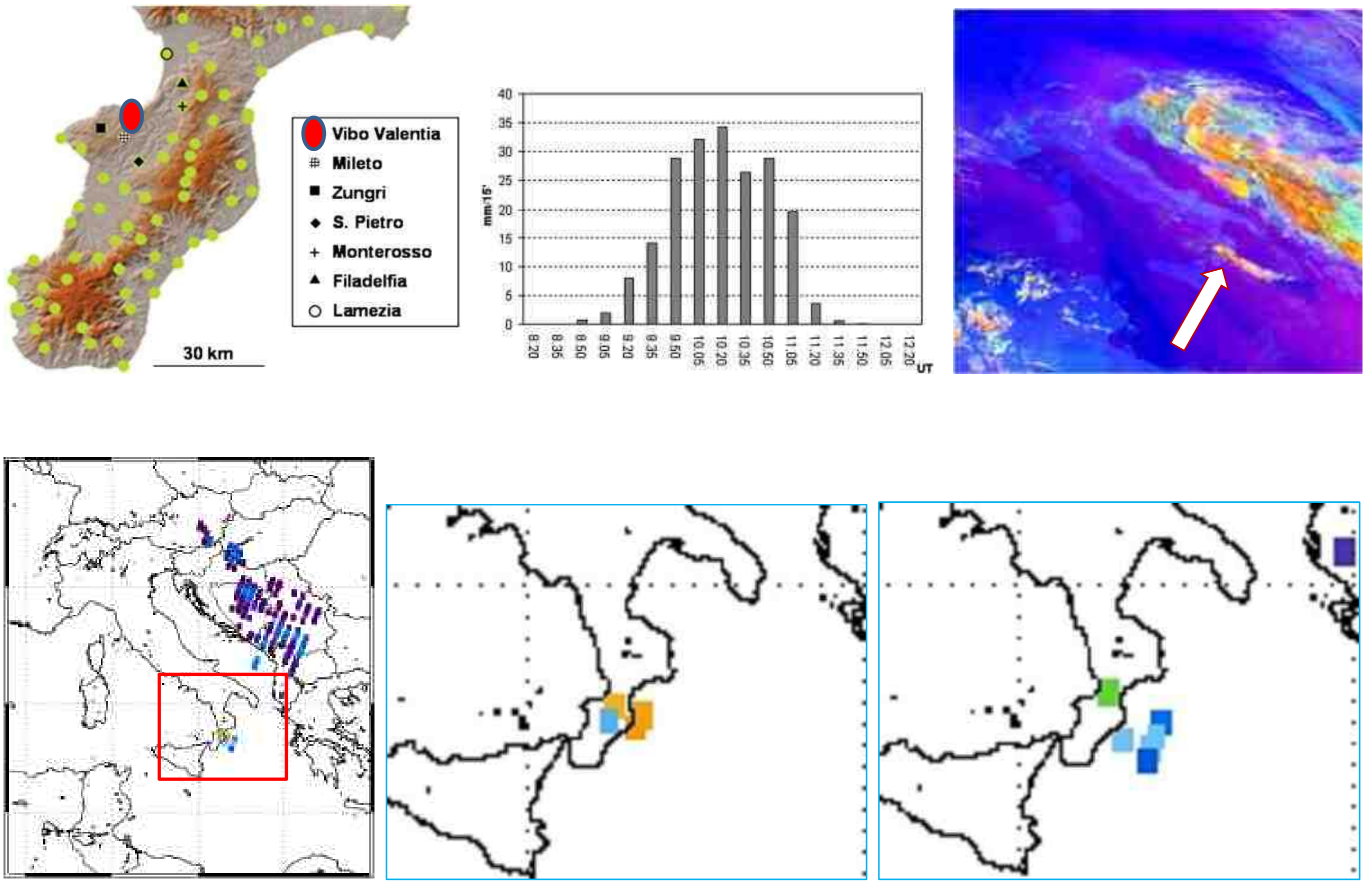

Fig. 1 – Vibo Valentia flash-flood on 03 July 2006 (CHIARAVALLOTI & GABRIELE, 2009). On top panel from left to right are reported the rain gauge network of the National Civil Protection over Calabria region, the rain gauge data of the Vibo Valentia station (mm/15′, 3 July '06), and the RGB composition for the MSG slot at 8:45 UT, where the red arrow indicate the vigorous convection localized over Vibo Valentia. Bottom panel, from left to right shows the retrieval of the 183-WSL method (LAVIOLA & LEVIZZANI, 2011b) and the zoomed images only for the convective and stratiform precipitation, respectively, as retrieved by the 183-WSLC and 183-WSLS modules.

convective clusters is more evident by observing the images on bottom panel of the same figure 2 where the analysis is centred on the Vibo Valentia geographical coordinates. The model prediction indicates the formation of a well-identified convective cluster corresponding of one of the maximum values of relative humidity but it is positioned on top of mountain. In this case the effect of orography associated to the high resolution of the spatial grid used to identify the small scale processes could be on the basis of the erroneous position of the convective core. The future studies are pointed to analyse other cases over Mediterranean area with the task to refine the proposed approach and create an integrated robust tool for hydrological applications.

Investigation results for the improvement design of the foundation rocks of the Amendolea Castle (Condofuri, Reggio Calabria, Italy)

MARIA CLORINDA MANDAGLIO (*), GIUSEPPE MANDAGLIO (**) & SAVERIO INFANTINO (**)

Key words: *improvement design, metamorphic rock, RMR index.*

The Amendolea Castle is in extreme degradation conditions set up to slip and to lateral spreading due to different factors such as the intense fracturing of crystalline metamorphic bedrock, the lack of interlocking foundations, the degradation of the walls, the imperfect forming of walls portions. The paper focuses on the results of the geomechanical survey and in situ investigations (geophysical prospecting and GPR, etc.) that allowed to classify the rock mass of the Amendolea Castle foundation as a class III rock mass according to the Bieniawski classification (Rock Mass Rating RMR, 1989). On the base of the obtained investigations results, the designing of the support systems of foundation rocks of the castle has been performed. The design involved works to bound the danger coming from narrow detachments and falls, such as steel nets with 5 m deep nails, and works to prevent the sliding along the inner rock mass, such as 12 m anchors.

The regional Catalog of Latium sinkholes and susceptibility map construction using geospatial analysis

FABIO MELONI (*), STEFANIA NISIO (**), GIANCARLO CIOTOLI (°),LORENZO LIPERI (*),MARIA GRAZIA FINOIA (**) & PIETRO ZIZZARI (*)

Key words: *geospatial analysis, Latium region, regional catalog, sinkholes, susceptibility.*

INTRODUCTION

Lazio is a land particularly affected by catastrophic collapses. It shows some areas where the sinkholes appear to be sporadic and, on the contrary, other areas that are particularly affected by sinkholes (St. Victorinus and the Pontine Plain).

The event can cause considerable damage when it occurs in a urban areas or in areas with infrastructural networks. In Lazio, the last event of considerable size occurred in 2001, near the town of Marcellina in agricultural area, without causing damage to nearby infrastructure (high-voltage electricity grid and pipeline).

For years, the Lazio Region conducted studies on Sinkholes in order to define and govern the risk areas. The first example of rules in Latium region were those imposed for St. Victorinus plain (Ri) and for a small land in the Pontine Plain (Lt).

It was subsequently produced the first catalog and the first regional regulation to determine the studies that they have to conduct in risk areas when propose it for the edification (2002). Then it was followed by a new study for a better identification and classification of risk areas (2009, in progress). This studies involved the use of cartographic sources, historical documentation, as well as field trips, and allowed to reach a significant increase in the number of sinkholes.

In order to obtain a more complete mapping of the phenomenon both as number of events either as completeness of the information we made the unification of the catalog of Latium Region and the National ISPRA catalog. In particular ISPRA, which is forefront in the study of the phenomenon, has carried out a consistent catalog for Latium region, based on detailed studies, on historical sources and on old maps (Fig. 1).

The effort has been to eliminate some sinkhole duplication and to equip them with more historical information in order to characterize the moment of genesis, or at least a range of time as close as possible to the date of the event (eg with historical evidence of the presence of the sinkhole to a given time or with

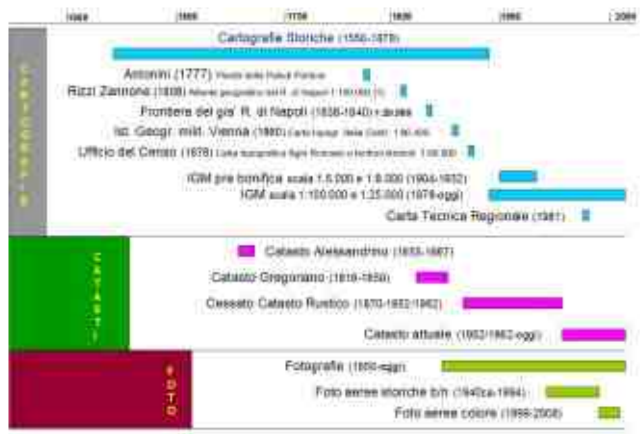

Fig. 1 – Fonti cartografiche, catastali e fotografiche consultate.

more maps in a range of time). As well, to characterize the geological and hydrogeological environment, the water type, the surrounding vegetation and degree of urbanization. Correlations were also performed with the tectonic and structural trends.

THE LATIUM SINKHOLES CATALOG

The new catalog (Fig. 2) was composed of 393 sinkholes with a significant increase compared to the first catalog of 2002, which included only 96 events. The municipalities involved rose from 22 to 68 with the involvement of the province of Viterbo, before without events reported. In order to prepare appropriate legislation to address regional land use planning in these areas, is necessary to arrive at a zoning of the territory, through the creation of maps of susceptibilityis.

THE SUSCEPTIBILITY MAP

The susceptibility map is the subdivision of land in different hazard levels that are discretized the likelihood of the

Fig. 2 – The unified regional catalog of Latium Sinkhole (green points) plotted on geological vectorial map (2012).

observed phenomenon. The methods of analysis are different:

• geomorphological methods: qualitative synthesis of information about the status of the area (geology, structural setting, etc..);

• Heuristic methods: identification of predisposing factors that are weighed and classified subjectively on the basis of their influence on the phenomenon;

• Statistical methods: correlation between factors predisposing the event and the spatial distribution of phenomena.

The latter come developed through an analysis of Logistic Regression (LR) which is a special case of linear regression analysis when the dependent variable is not quantitative, but dichotomous.

In the LR model the results are expressed in terms of probability that the phenomenon manifests itself in the space (considering an infinite time) and allows the calculation of regression coefficients which define the weight of each variable in the model.

The exponential transformation of the coefficients used to determine the weight in terms of probability that each variable has in the occurrence of the event.

FUTURE DEVELOPMENTS

The GIS has allowed the management and processing of large amounts of data and the logistic model by analyzing the statistical relationships between the presence of the phenomenon (eg, sinkholes) and a series of conditioning factors (independent variables) allowed the calculation of weights of objective for the variables included in the model.

Another technique of spatial regression is the Geographically Weighted Regression (GWR), which allows to evaluate non-stationary phenomena, ie when the measure of the relationship between a number of variables differs from place to place. Like the classical multivariate regression, the GWR produces an equation that summarizes the relationship between a dependent variable and a set of explanatory variables (independent). The benefits of the GWR are due to the fact that it is possible to represent the variability of the regression coefficients expressing the relationship between the variables and you can only use ArcGIS.

Aquaresi valley - Problems of geological instability of underground voids and safeguard of roads

MUREDDU A. (*), A. S. CORDA (**) G. VIRDIS (***)

Key words: *acquaresi, collapse, geological instability, lowering of underground water, mining subsidences, safeguard of road.*

The Mine of Acquaresi, (SW Sardinia), is located in a valley within the territory of Iglesias between the mining towns of Masua and Buggerru. Following the persistence of the mining subsidences, in the last twenty years there are gradually aggravated the problems concerning the stability of the geological structure of the area, in relation to the sustainability and the safety in underground mining operations, that were conducted for the exploitation of metalliferous deposits. At the same time, there was the problem of maintaining the stability and security of the Provincial Road 83, originally located on the eastern side of the valley.

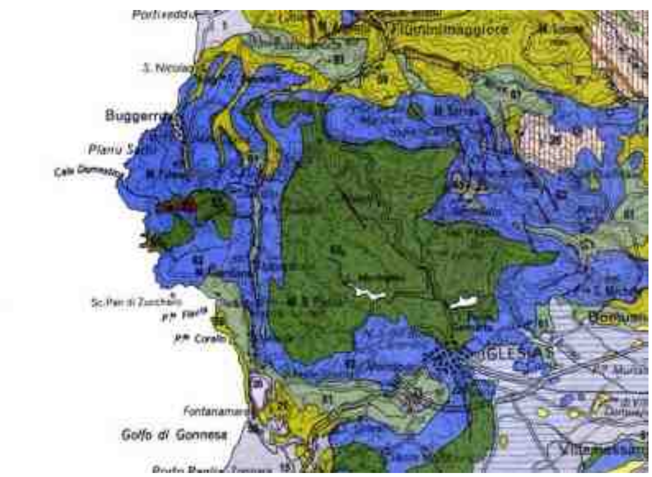

Fig.1 – - Geological Classification - From the Geological Map of Sardinia - National Geological Survey

Following a sharp worsening of the overall security of the area, were suspended the deep mining works and, in a very short time, the provincial administration has built a new road, with a variation of the original route in order to maintain the same services levels and at the same time to preserve public safety.

The mining area (mining lease "Acquaresi - Enna Murta") is set to lithologies of Paleozoic age: in the middle of the valley emerge soils of the younger formation of Iglesiente's Cambrian, formed by metamorphosed shales of the Formation of Cabitza that follow, symmetrically with respect to the axis of the valley, the oldest limestone lithologies, which is to say, limestones and dolomites of the Formations of Gonnesa and Nebida (Fig. 1). Within the Cambrian limestones, are found the metalliferous deposits (Pb, Zn, Ag), with elongation in the direction north-south, with sub-vertical arrangement, limited westward by tectonic contact with the shales of Cambrian of the Formation of Cabitza.

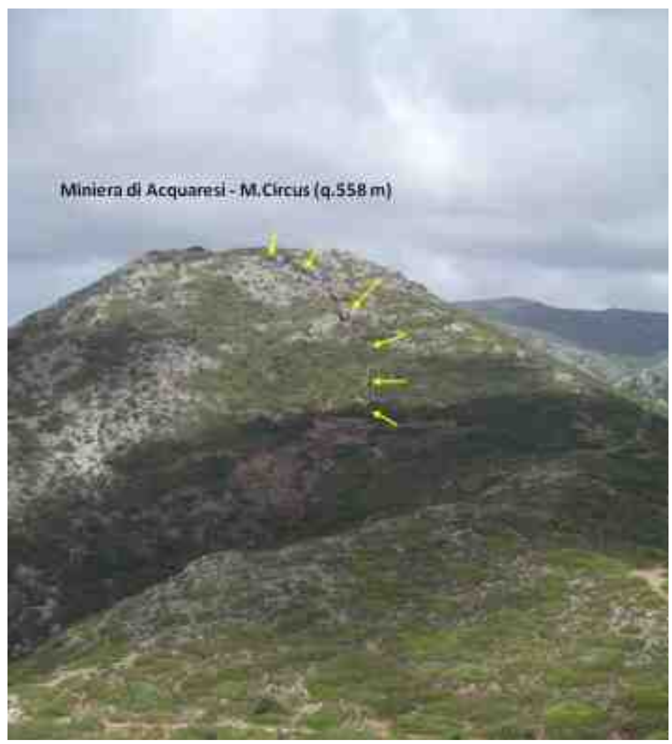

Fig.2 – Acquaresi valley - Extended fracture appeared in 1977 in a limestone hill M.Circus (alt. 558 m asl)

The mining's works are set primarily on the richest deposits, named Marx, through tunnels arranged in multiple layers, and were pushed with a lowering of underground water, over 400 meters deep (318 to -90 m), generating mining voids than 4.5 million cubic meters.

Evaluated the compactness of the deposit and the quality of

(***) Regione Autonoma della Sardegna – Assessorato dell'Industria – Servizio attività Estrattive.

rock masses, the extraction was carried out with the cultivation technique to empty without support (sub-level-stopping), whose stability, however, in the long run, certainly was not proved safe. As we proceeded with the extraction, were left in place, in poor stability, large mining voids, separated by slab thickness of 20 m, at the contact sub-vertical between the limestone and the shale. The exploitation had however already reached upwards shares near the surface, with cover thikness between 40 and 80 meters.

The first manifestations of instability have occurred in the underground area in the late '70s, in the limestone hills of Mt Circus (alt. 558 m), where, following a series of underground mining collapses, were manifested signs of geostructural instability, with visible effects on the surface, with the appearance of an extensive and deep fracture (Fig. 2).

With the closure of the mine, the phenomena of instability were intensified, with the occurrence of collapsed rock surfaces, that covered the underground voids. These phenomenologies were facilitated by rising the height of water + 90 meters from sea level, with a profound change in hydrogeological balance of the valley.

Currently, the bucklings of the subsurface are monitored by the current license holder, "IGEA SpA", in-house company of the Autonomous Region of Sardinia, in order to verify the safety conditions of the mine, and the monitoring and prevention of possible interactions with the Provincial Road No. 83.

Since 1977, following the collapse of the underground mining, there were manifested six sinkholes, four of which are perfectly aligned and near at the slopes of Mt St. George, also aligned with the North/South direction of the mineral deposit. The effects of subsidence are visible in the surrounding land, affecting a large area estimated at around 1.9 sq km.

In the mining area, a first type of phenomena, characterized by detachment and sliding of calcareous blocks left in place from the excavation's works, has occurred in the years 1978 and 1998, (first, collapse of the vault of the upper chamber of the yard called "Marx North", then, final collapse of all the cover slab).

A second type of instability has instead occurred in 1991 and 2003 with landslides of the walls of the voids of cultivation, at points where they were exposed lithologies belonging to the "Formation of Cabitza", connoted locally for the conditions particularly unfavorable in the geostructural equilibrium, (with the schistosity parallel to slope, the proximity of the landslide to the fault plane, the presence of clay material). Particularly, in September of 1991 a vacuum of cultivation has experienced a sudden collapse that has moved a significant quantity of material, causing a massive landslide caused by a structural failure within the shale formations.

During the mining work, the exploitation of the panel's deepest reservoir, (-90 m asl), in February 1998 led to a new landslide estimated about 230,000 cubic meters of material moved, perched on a thick slab of rock about 20 meters .

Given the instability of the Marx deposit, was necessitated the abandonment of the mining and, to this end, in line with the provisions from the relevant Mining District, has been prepared by the grantee a monitoring instrument of the internal structures, existing in deep.

In July 2003, just 10 meters from the main road n ° 83, in the field Marx, was manifested a phenomenon of collapse, fortunately happened on Sunday, so in the absence of workers. This collapse (Fig. 3), which affected the schists near the contact with the limestones, has generated a landslide with area of about 7000 square meters and a volume of 46,000 cubic meters. The first immediate evidence produced by the

Fig.3 – Surface gravitational movements induced by underground collapses

materials handling, was the formation of a true "river of mud and debris" that has been poured out on the beach Masua, at a distance of about 4 km as the crow air from where was triggered the gravitational movement.

In the immediate vicinity of the crash, it is suddenly revealed the presence of severe lesions along the road axis, resulting in the decision to close to traffic the only existing road along the west coast, which connects the towns of Masua to Buggerru. The ban on access to the only road, (in full summer season), in an area where tourism is highly economy developed and is the driving force for the whole region, have given rise to various problems of managerial and public policy.

Given the encountered uncertainty , the provincial administration has implemented a series of archive researchs and verification of cases of similar problems, and so, in a short time, carried out the planning and design of the works necessary to mitigate the existing risk and lower the levels of hazard.

In the preliminary design stages, there have been significant information with appropriate archival research and verification of data with the relevant authorities, who have ruled out the presence of cavities immediately beneath the road, but also to investigate the consistence of the formation of shale.

Fig.4 – Deep fractures in carbonate rocks

Particular importance was given to the possible dynamics evolution of fessurative geometries and deep chasms, formed parallel to the valley, with movement between the surfaces of the shear zones that had taken metric sizes (Fig. 4).

Following more detailed studies about the geological structure model and its possible evolutionary dynamics, have been highlighted in particular the geometry of the substrate that marked fessurative families of fracture lines in lateral extent than the road pavement, progredenti to the parameters of the valley. Ultimately has been highlighted as the major displacements of materials interessassero an area much greater than any hypothesis of movements of confined spaces.

Were appropriately assessed also the mass movements of 2003, reactivated later in 2005, 2007 and 2009, with gradual and sudden expansion eastward (near the contact shale - limestone) and northward.

Given the context of the geological structure and subsidence hazard existing in areas adjacent to the new road layout, the works of the project were based on the choice of materials and flexible structures (reinforced soil, gabionades,

Fig.5 – Strutture flessibili del nuovo tracciato stradale

Fig.6 – Hydroseeding of reinforced soil

etc. - Fig 5) for building the new road , minimal use of rigid structures, and only for the works of art.

The search for the best technical solutions and design, with the best cost/benefit has thus led to the choice of the shift of the road on the opposite side of the Valley of Acquaresi, compared to the original position, in order to remove as much possible the risk of danger of subsidence and collapse.

In addition, through the use of bioengineering techniques and reinforcements with plant (Fig. 6) it was finally contribuited to the overall stabilization of areas.

Effects of Landslides and floods on people: a classification of damage scenarios obtained from the analysis of past events

OLGA PETRUCCI (*), A. AURORA PASQUA (*)

Key words: *floods, landslides, people vulnerability*.

ABSTRACT

The whole of all the phenomena triggered by bad weather periods have been defined as Damaging Hydro Geological Events (DHE). In numerous countries, bad weather periods are a source of multiple hazards, because they can cause damaging phenomena which may cause different kinds of impacts on quite a lot of natural and manmade elements in a wide range of circumstances.

The kinds of phenomena which occur during DHEs can be sorted in some main groups: landslides, floods, erosion processes and sea storms. Each type of phenomenon is characterized by a proper dynamic and, according to the social and economic framework in which it develops, can cause different impacts.

During bad weather periods all these phenomena occur at the same time (or in a short while), often strongly amplifying damage and hinting emergency management actions. Nevertheless, the studies available in literature tend to analyse each type of phenomenon (and its impact) separately, thus supplying a fragmentary framework of the effects.

In the present work, basing on a dataset concerning effects of DHEs in Calabria (southern Italy), a classification of the effects on people affected by the different types of triggered phenomena is attempted. The result is a collection of main circumstances during which the different types of phenomenon triggered can hit people.

This kind of result can be useful in education programs for people living in risk prone areas, in order both promote more conscious people behaviors and avoid unnecessary risk-taking actions.

Pianificazione ordinaria e governo del territorio: nuove strategie di prevenzione e mitigazione dei rischi idrogeologici

ANTONIO PIZZONIA (*)

ABSTRACT

Le leggi urbanistiche emanate da molte regioni italiane, a partire dalla seconda metà degli anni novanta del secolo scorso, denominate leggi per il governo del territorio, delineano una pianificazione per lo sviluppo sostenibile, che è chiamata, tra l'altro, a rivolgere particolare attenzione alle pericolosità e rischi connessi a fenomeni geologici quali frane, dissesti, erosione costiera, subsidenze, esondazioni, terremoti, e, in rapporto ad essi, a fornire significativi contributi non solo per la prevenzione ma anche per la mitigazione.

Positivamente, inoltre, una siffatta pianificazione, contempla ora percorsi di verifica delle implicazioni ambientali delle trasformazioni, secondo i canoni più moderni della *Valutazione Ambientale Strategica* (VAS).

In questo contesto, che chiama in causa in maniera nuova l'Urbanistica e la Geologia, il presente lavoro tratteggia un profilo metodologico del processo integrato di pianificazione urbanistica territoriale e valutazione, in cui la verifica diventa elemento costruttivo, valutativo, gestionale e di monitoraggio, particolarmente idoneo a promuovere strategie nuove ed efficaci per la prevenzione e mitigazione del rischio idrogeologico.

Tali nuove prospettive sono esaminate considerando i tre livelli (regionale, provinciale, comunale) in cui si articola la pianificazione ordinaria, la loro diversa attribuzione dei carichi conoscitivi, vincolistici e mitigatori, i rapporti di reciprocità tra i piani di diverso livello, e i rapporti con i piani e programmi settoriali e specialistici.

Role of engineers in prediction, prevention and Mitigation of natural disaster

H. K. RAMARAJU (*)

INTRODUCTION

As we have just embarked upon a new century and millennium, natural hazard prevention is set to play a prominent role in global efforts to reduce human suffering and damage to natural and built environments. Prediction, prevention and mitigation of natural disaster are both possible and feasible if the sciences and technologies related to natural hazards are properly applied. The extent to which society puts this knowledge to effective use depends firstly upon the political will of its leaders at all levels. Coping with hazards - whether natural or attributable to human activity - is one of the greatest challenges of the applications of science and technology in the 21st Century.

While we cannot prevent an earthquake or a hurricane from occurring, or a volcano from erupting, we can apply the scientific knowledge and technical know-how that we already have to increase the earthquake-and-wind resistance of houses and bridges, to issue early warnings on volcanoes and cyclones and organize proper community response to such warnings. Although prevention of natural disasters is not possible, reduction in the undesirable effects of disasters can be the only way to cope with them. Natural disasters point to the mistakes made in the process of development of civil engineering structures in that particular locality, and teach important lessons for the future. If the learning from such undesirable events is utilized, hazardous effects can be reduced in the coming years. Engineers can play a major role in disaster mitigation by creating safe structures through the integrated efforts of all those involved in the construction process.

RECENT EARTHQUAKE AND TSUNAMI DISASTERS IN THE WORLD

During recent few years, the disastrous earthquakes and tsunamis have attacked the Asian countries. The 2004 Sumatra earthquake and consequent tsunami killed more than 2 hundred thousand people in the areas around the Indian Ocean. In the same year, a devastating earthquake caused serious damage to Niigata Prefecture, Japan due to extensive slope failures in mountainous areas. In 2005, about 70 thousand people were killed in Pakistan, and last year, a disastrous earthquake attacked the Java Island, Indonesia. Fig. 1 shows the number of earthquakes and tsunamis with more than one thousand casualties in each five years period during the last 60 years in the world. The number of events has drastically increased in the last two decades. The number of earthquakes with magnitudes more than 7.0 and more than 6.0 in the world during the last 60 years is shown in Fig. 2. On the contrary, the increase of the earthquake and tsunami disasters, the number of occurrences of earthquakes with magnitudes more than 6.0 and 7.0 have been decreasing during the last 60 years. The number of earthquakes with more than 6.0 slightly increased during the last decade, but was not consistent with the rapid increase of the number of earthquake and tsunami disasters. This suggests that the reason for the increase of the earthquake and tsunami disasters is the increase of the vulnerability of our human societies. The regional ratio of the number of earthquake and tsunami disasters and of the number of causalities during the last two decades is shown in Figure 3. 25 earthquake and tsunami disasters occurred in the world. Among them, 16 were in the Asian region. About five hundred thousand people were killed in the Asian region amounting to almost 90% of the total number of casualties in the world.

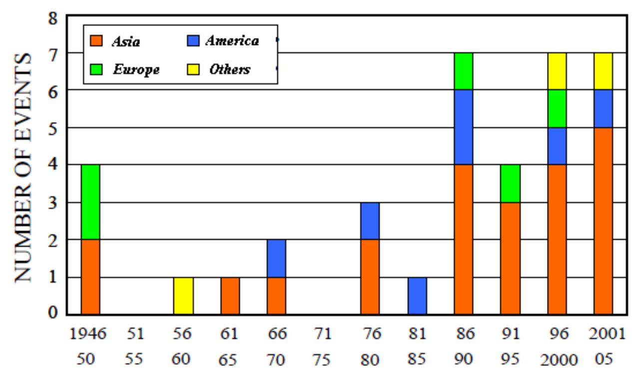

Fig. 1 - Damaging Earthquakes and Tsunamis in the World in the last 60 Years (Events with more than 1000 casualties) courtesy: Masanori HAMADA, Japan.

RECENT STORM AND FLOOD DISASTERS IN THE WORLD

Storm and flood disasters also have affected people in the world in recent years. During the last decade, one hundred

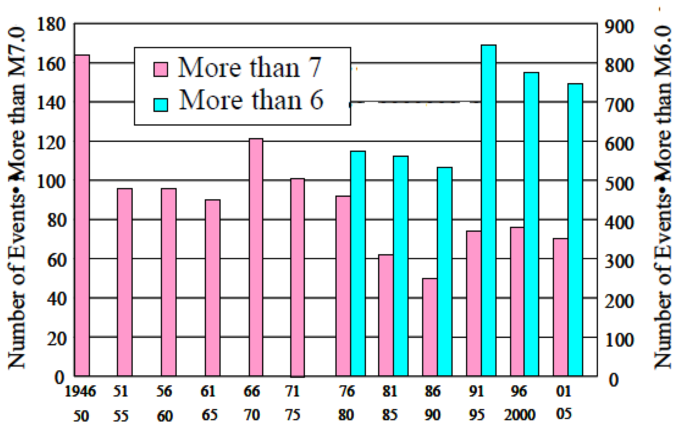

Fig. 2 - Number of Earthquakes with Magnitudes More than 7 and More than 6.

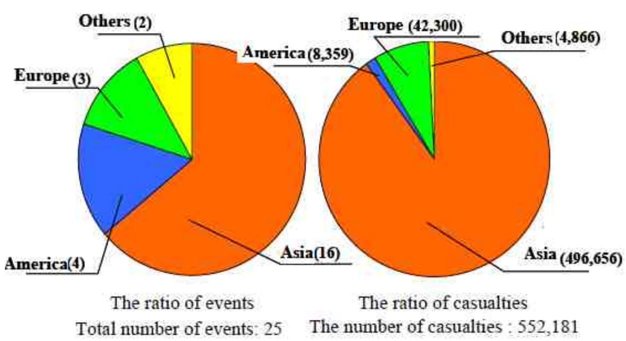

Fig. 3 - Regional Ratio of Earthquake Tsunami Events and Casualties (1986–2005: Events with More than 1000 Casualties)

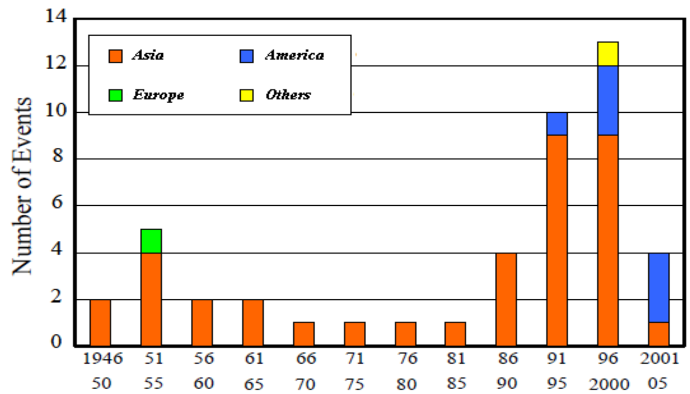

Fig. 4 - Damaging Storms and Floods in the World during the last 50 years (Events with more than 1000 casualties)

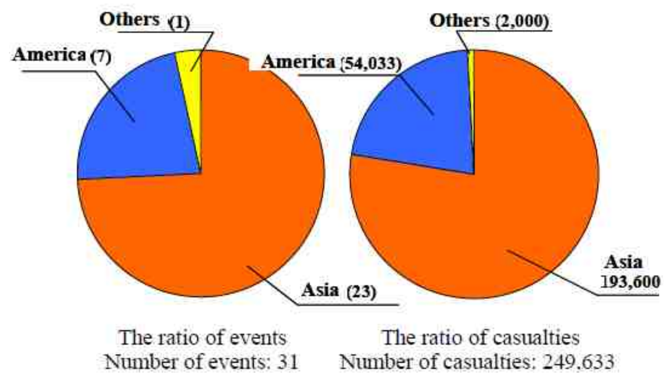

Fig.5 - Regional Ratio of Storm and Flood and Associated Casualties (1986–2005: Events with More than 1000 Casualties)

thousand people were killed by 21 disasters. Most of the storm and flood disasters were concentrated in the Asian region and the Central America. In 2005, Hurricane Katrina attacked Louisiana in the United States, and killed more than 5 thousand people. In 2004, the Asian countries such as Japan, Philippines, India and Bangladesh suffered from many typhoons and heavy rains, and about four thousand lives were lost. Fig. 4 shows the number of storm and flood disasters with more than one thousand casualties in each five years period during the last 60 years. The storm and flood disasters in the world have also increased during the last two decades. And, the disasters in Asia are dominant. The regional ratio of the number of storm and flood disasters and the number of causalities is shown in Fig. 5. 31 disasters occurred during the last two decades in the world, and 23 disasters, which were about three quarters of the total number, attacked the Asian region. About two hundred thousand lives were lost due to storm and flood disasters in the Asian region amounting to almost 80% of the total casualties. There may be two main reasons for the increase of the flood and storm disasters. Firstly, the increase of the vulnerability of the human societies against disasters, which is particularly remarkable in the Asian countries and secondly, the global climate change. The air temperature is raised to about 0.5 degree in centigrade and the sea water temperature to about 0.3 degree. The increase in the seawater temperature can be considered to be one of the causes of the occurrence of huge typhoons and hurricanes, and high tidal waves.

ROLE OF ENGINEERS

DEVELOPMENT OF MONITORING

Research on techniques for observing and monitoring natural disasters and for establishing disaster monitoring systems will emphasize the following areas:

- Research on equipment for earthquake observation;
- Research on systems for monitoring severe weather, climate and floods;
- Research on techniques for the dynamic monitoring of geological disasters such as rock falls, landslides, mud-rock flows, ground subsidence and ground

collapses;
- Research on real-time data collection systems for monitoring maritime disasters;
- Research on automatic data processing techniques for atmospheric monitoring.

DEVELOPMENT OF PREDICTION SYSTEM

Research on patterns of occurrence of natural disasters, on their prediction and on forecasting techniques for the main categories of natural disasters has suggested involving the following areas:
- Methods for forecasting severe weather and climatic conditions;
- New theories and new methods of predicting earthquakes;
- Prediction of maritime disasters and early warning systems;
- Dynamic simulation techniques and forecasting methods for outbreaks of crop and forest plant diseases and insect infestations;
- Prediction of future trends of geological disasters;
- Flood prediction models for rivers with wide and shallow shifting sandy channels.

DEVELOPMENT OF PREVENTION METHODS

Research on methodologies and techniques for disaster prevention, combating, relief and rescue will include research on the following:

Improving the combination of countermeasures for the prevention of disasters;

- Optimal schemes for mobilizing disaster protection systems during disasters;
- Optimal design of inhabitant refuge systems;
- Protection from disaster and emergency response measures for key urban services, such as communications, water, power and sewers;
- Technology for the modernization of equipment for rapid disaster relief response systems;
- Medical and health service techniques for emergency treatment of large numbers of the wounded and the sick persons, including the control of epidemics and the sanitary treatment of drinking water in disaster-stricken areas.

DEVELOPMENT OF INFORMATION PROCESSING SYSTEMS

- Improving communication systems;
- Further developing maritime disaster early warning systems to safeguard fishermen and those involved in other marine activities;
- Promoting the use of high technologies, such as remote sensing, in monitoring disasters and evaluating losses.

DEVELOPMENT OF DISASTER MITIGATION POLICIES

- Policy research on establishing a system of disaster insurance;
- Policy research on establishing a funding system for disaster mitigation;
- Policy research on compensation measures after the use of flood diversion and containment zones.

CONCLUSION

Professional discipline, sensitivity to the needs of society, an interdisciplinary approach, and integration of focused efforts towards the development of built environment will lead to a safer society in future. The role of engineers, whatever post they may hold in the field, is crucial in establishing a system for prediction, prevention and mitigation of disaster, which is compatible with the level of socio-economic development and which integrates engineering technology with legal, administrative, economic, managerial and educational means to provide a safeguard for social stability and the sustainable development of the economy. Developing a well-equipped mechanism to reduce losses, minimize the effects of disaster, avoid catastrophic consequences resulting from irrational development activities, protect fragile living conditions and increase the capacity of society as a whole to withstand natural disasters is undoubtedly the need of the hour.

The flood of October 2009 and the effect on the Messina area

MARIA SABATINO (*), ANTONIO BAMBINA (*) & SALVATORE MONTELEONE (*)

Key words: *debris flow, flood, Messina area.*

INTRODUCTION

On the afternoon of 1st October 2009 an area of approximately 50 km2 to the south of Messina has been affected by a very heavy rainfall: more than 220 mm of rain that, in few hours reached the valley floors feeding enormously the rivers.

The rains which infiltrated in the more altered area of the metamorphic substrate, allows for the complete saturation of the regolith (showing poorly physical and mechanical features), already heavily soaked due to the intense and prolonged rainfall of the last two decades of September.

This has enhanced the already instable conditions of the steep slopes of the whole area of the Peloritani Mountain range causing the triggering of several gravitational phenomena that concerned variable, but always modest, surface thicknesses.

The effects on the landscape and on population have been devastating and at the same time dramatic: the total budget was 31 dead and 6 missing, in addition to the enormous damage to buildings, infrastructure and, in general, to the socio-economic features of the whole area.

GEOLOGIC AND GEOMORPHOLOGIC FEATURES

In the East area of the Peloritani mountain range outcrops, from the bottom up, the Mandanici, Mela and Aspromonte units; the first two do not show meso-cenozoic sedimentary covers, while the last is covered in the transgression by neogenic-quaternary sedimentary sequences.

These formations consist mainly of metamorphic rocks of different various metamorphic aspect, and only in coastal and foothills areas, by post-orogenetic deposits (LENTINI *et alii*, 2000).

* Dipartimento di Scienze della Terra e del Mare – Università di Palermo

A spatial planning as the one described is certainly predisposing to the triggering of different geo-morphological instability forms, such as those due to gravity and those linked more directly to the flow of surface waters.

In particular, the main cause of triggering of landslides that characterized the flood described in this work can be ascribed to critical changes in the distribution of neutral pressures in coulters that cover the slopes, resulting in reductions of the shear strength and in the collapse of the materials.

In addition, these soils are characterized by a quick response of the interstitial pressures and therefore the landslide phenomena they set are determined precisely by short and intense rains (CAINE, 1980; CANCELLI & NOVA, 1985; BELLINI & MARTINI, 1997).

The flood has been characterized, on the other hand, for the high energy and destructive power due to the substantial transport in the water courses of solid materials after the instability and erosion phenomena that involved the slopes.

THE EFFECTS ON THE LANDCAPE

The rainfall of 1st October 2009 was characterized by a strong intensity and concentration. It is evident that in these extreme conditions, there will be a very strong erosive action along the thalweg with the development of gravitational forms which characterize soils with a physical state that look like a highly viscous fluid.

The effects induced by the rainfall that affected the east area of Messina have concerned both the slope sides and the bottom of the valley.

The slopes were involved in debris-flow forms that have totally removed the eluvial-colluvial cover, exposing to the rain action the substrate that was affected by linear erosion forms.

As far as concern the bottom valleys, there have been many episodes of overflow of the streams that, characterized by an exceptional solid transport, have invaded the surrounding areas with streams of muddy-detritus channeled, such as the one that struck at the center of the town of Scaletta Zanclea, that led to the destruction of many buildings and the irreparable loss of human lives.

The more disastrous damages to things and people are also attributable to rapid mudslides along the slopes mainly on metamorphic rocks; the mudslides that have concerned the Messina area are similar, in genesis and effects, to those that in

May 1998 devastated the area of Sarno in Campania (DE VITA, 2000; GULLÀ & ANTRONICO, 2003).

In fact, one of the more widespread and sometimes dramatic consequences of extreme hydrological events consists precisely in the activation of surface landslides that set in eluvial - colluvial deposits (DE LUCA *et alii,* 1996; JOHNSON & SITAR, 1990).

Fig. 1 – Damages in the Scaletta Zanclea area.

These forms of instability have resulted in the production of significant amounts of detritic materials, which were channeled along the hydrographical and then deposited under the less energy of the flow.

It is estimated that the slopes on the town of Giampilieri Superiore have fed mudflows with an overall volume estimated between 60 and 80 thousand cubic meters of material. It is estimated that during this flood were activated more than 500 landslides distributed on an area of approximately 50 sq Km.

In addition to the occurrence of gravitational phenomena the storm has caused intense and concentrated erosive actions predominantly linear, developed for all the thalwegs, both along the stream of a lower order that along the same slopes, reactivating practically disappeared outflow lines and determining the consequent expansion of the hydrographical pattern, up to that moment in an apparent period of stagnation of growth.

In this context, the erosive action exerted by the channelled water and the consequent reactivation of the strems of the first order has certainly contributed to the production of sediments and, therefore, to an overflow of the valley floor; these phenomena should not, however, to be confused with the gravitational ones even if they were intimately connected to these the early stages of the flood.

Fig. 2 – High erosion on the slope

DISCUSSION

Multiple and different were the consequences of violent storms that the 1ST October 2009 has affected the ionic area of Messina; it was mainly of the trigger almost simultaneous of numerous landslides that produced refluent along the hydrographic network. They have given rise to the very violent waves that, for their high content of debris, have produced enormous damage and loss of human lives.

The disruptions were those typical of intense and concentrated meteoric events, i. e. superficial landslides that have involved the eluvial-colluvial materials; they were triggered in geological and geo-morphological environments suitable for these kind of types of landslide, i.e. shallow cover materials with high values of permeability, that rest on not very permeable substrates or with low permeability, high slopes of the hills and of the adjacent watercourses.

The superficial landslides caused by the storms show dimensional and geo-morphological characteristics analogous to those already described in the literature for the Campania, the Alps and other regions of the world affected by this type of hydrological events.

Features of these landslides are the modest thicknesses involved, the limited areal extent and the high number per unit of surface, as well as their occurrence, almost simultaneously, in a very short time.

The intense erosion in both the mountains sides and along the hydrographic pattern has produced a considerable increase in the transport of solid in the water courses; this has led to the formation of large areas of deposit that have, in relation to the individual local conditions, interfered with the local structures and facilities.

The flood that has devastated the area of Scaletta Zanclea, for example, it has to be put in relation with the occur of many and nearly simultaneously gravitational phenomena along the slopes that, conveyed by the hydrographic network in the area at the bottom of the valley, have determined a muddy stream-detritus

Unfortunately natural events such as high rainfalls along the slopes can be turned into catastrophic events when they interfere with urbanized areas.

The flood in the Messina area points out, once again, the high environmental impact that extreme hydrological events can have on the territory, once they have passed the critical threshold.

Even if they involve small volumes of material for a single phenomenon, these forms of disorder occur very quickly and almost simultaneously, and along the hydrographic network, may give rise to a muddy streams-scree with a high destructive power.

It is clear, therefore, that the intensity and distribution in time of rainfalls as well as the capacity of infiltration of water in the topsoil, greater than the underlying substrate, were drive forces in creating very dangerous geo-morphological problems in these areas.

Effects of landcover changes on flood generation in a small Mediterranean catchment (T. Teiro, Italy)

CLAUDIA SCOPESI (*), IVANO RELLINI (*), MICHAEL MAERKER(**) & MARCO FIRPO (*)

Key words: *Flood generation, GIS, Runoff, Landuse scenarios, SCS-CN method, Terraced soils.*

INTRODUCTION

Most geomorphic processes are governed by temperature oscillations, rainfall intensity and human activities.

Mediterranean catchments are particularly sensitive to these changes, above all due to the progressive decrease of the rural activities and the abandonment of terraced cultivations. The resulting re-colonization of entire rural areas by shrubs and forests, increase significantly the risk of forest fires especially in the light of future climate change scenarios. All of these factors imply significant environmental problems in terms of soil erosion and control of the meteoric waters.

The main aim of this research is to assess the hydrological and geomorphological effects of four different land cover scenarios taking constant the climatic condition .

STUDY AREA

The studied area is the T. Arzocco catchment, a north-south oriented tributary of the Teiro River (Fig. 1), which basin extends for 28 square kilometers in the province of Savona, between the municipality of Stella and Varazze, and it is representative for many ligurian Mediterranean basins.

The altitude of the sub-catchment ranges between 385 and 4 m (all elevations are provided relative to sea level) and the middle area is 1,2 square km. The substratum is characterized by Voltri Group metaophyolite complex (VANNOSSI *et alii*, 1984; CHIESA *et alii*,1975), which is here mainly represented by serpentinites and metagabbro. Recent alluvial deposits are present in the lowest part of the basin.

Present land use is the result of recent actions that take place in the area. Once the lowest part of the basin was dominated by rural activities and cultivations on terraced soils, while in the upper part, mainly pine wood and shrubs established due to steep slopes and poor ophyolitic soils.

Industrialization and pressure from tourism activities led to important socioeconomic changes in rural areas, based on the abandonment of marginal terraced hillslopess. Because of the abandonment of the terraced sites, these anthropic hydrological infrastructures, which protected the soil and preserved the natural vegetation in the recent past, are progressively collapsing, mainly due to the rapid removal of the soil, causing important land degradation problems (DUNJÓ *et alii*, 2003).

Moreover, in the last 20 years, an high number of fires have been registered in the region (SITAR REGIONE LIGURIA, "Carta delle aree percorse dal fuoco" period 1996 to 2002 & 2002 to 2010, scale 1:10000). In particular in September 2001 a big forest fire destroyed the pine forest of the area.

Consequently the studied catchment is characterized by thinned pinewood and shrubs in the greater part of the basin and only in the lowest part we found rare cultivation and olive groves alternating with touristic country houses.

METHODS

To evaluate the hydrological and geomorphological consequences of different land cover under a static climate scenario, we applied a simple Soil Conservation Service Curve Number (SCS-CN) method (SCS, 1956) which was implemented in GIS.

The method is based on the following equation:

$$Q = (P-I_a)^2 / P-I_a+S \quad (eq.1)$$

Where Q is the direct runoff (*mm*), P is total rainfall (*mm*), I_a is the initial abstraction (*mm*) given by a second equation:

$$I_a = 0{,}2*S \quad (eq.2)$$

and S is the potential maximum retention (*mm*), which is derived from equation 3:

$$S = 25400/CN - 254 \quad (eq.3)$$

The value of CN is derived from the tables given in the National Engineering Handbook, Section-4 (NEH-4) (SCS, 1956) for the catchment characteristics, such as soil type, land use, hydrologic condition, and antecedent soil moisture condition (TYAGI *et alii*, 2008).

(*) Dipartimento Scienze Terra Ambiente e Vita, Università di Genova

(**) DIPSA Università di Firenze/ Heidelberger Academy of Sciences

Acknowledgements. We are grateful to the Ateneo 2011 Project of Genova University (Responsable PI: Dott. I. Rellini)

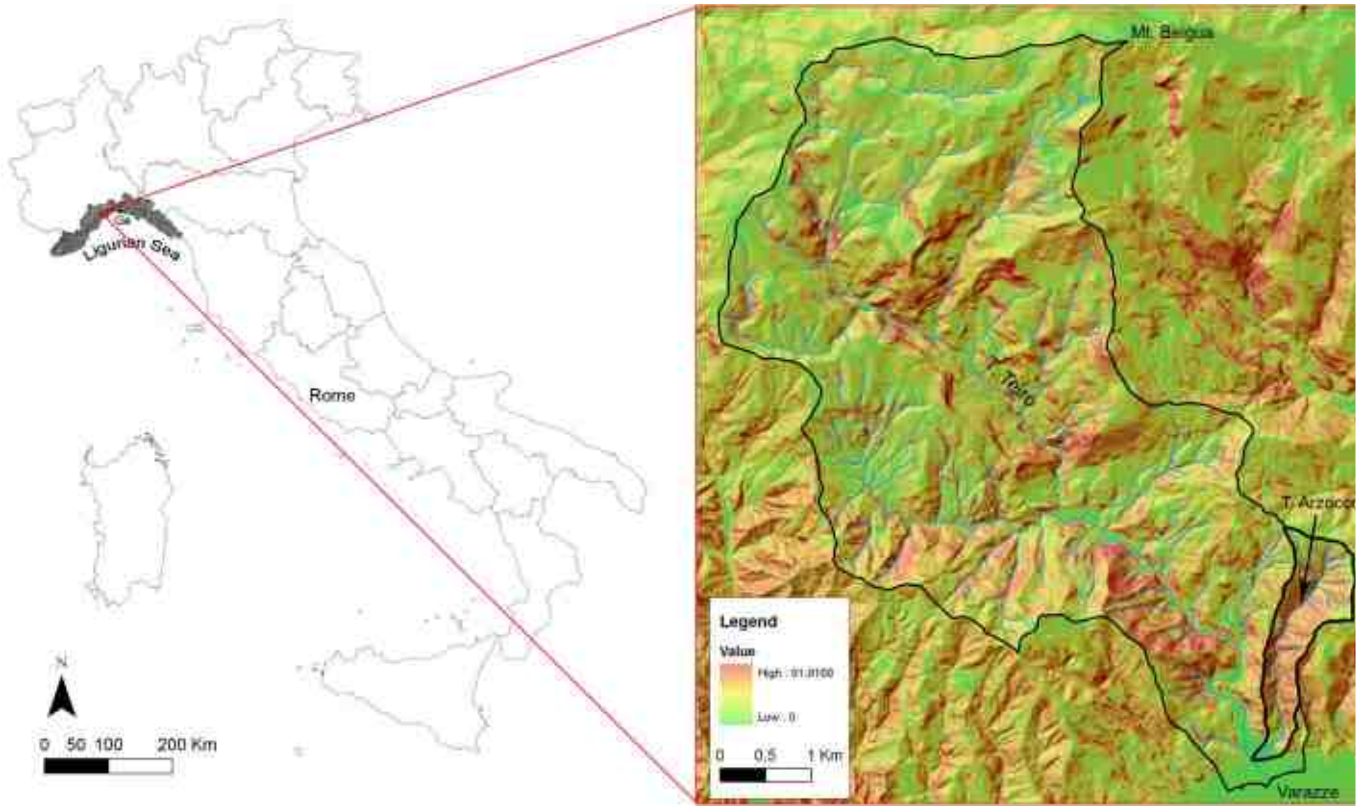

Fig. 1 – Geographical setting of study area. In the right picture, the slope in degree of the T.Teiro basin with the T. Arzocco sub-catchment is shown.

To collect input data for the SCS-CN model we subdivided the catchment in homogeneous units characterized by comparable erosional process "*ERU*" (*Erosion Response Units)* (FLÜGEL *et alii*, 2002; MÄRKER *et alii*, 2001).

For each ERU we collected soil data such as texture, thickness, organic carbon content etc.

For the hydrologic characteristics, we used a Compact Constant Head Permeameter (Amoozemeter) (AMOOZEGAR, 1989) to obtain the saturated hydraulic conductivity (*Ksat*) of the different type of soils and a Hood-Infiltrometer (SCHWARZEL *et alii*, 2007) to measure the surface infiltration.

For the land use characteristics we chose to run the SCS-CN model with four different type of land use, to simulate four different scenarios and therefore to observe the different hydrological response of the catchment under different land cover.

The different scenarios used were: (I) the catchment in "rural condition", with the lower part (one third) of the basin with terraced cultivation and the upper part with pinewood; (II) the catchment in "rural condition" after a pinewood fire; (III) the catchment in "abandoned condition" with abandoned terrace cultivations in the lowest part (one third) and the pinewood in the upper part; (IV) the catchment in "abandoned condition" after a pinewood fire.

The climatic condition chosen to analyze the given scenarios are corresponding to the recent flood event that occurred in Varazze on 4 October 2011.

Finally we used runoff values of the SCS-CN method *(eq.1)* in a weighted flow accumulation procedure implemented in a GIS environment to calculate total discharges of the subcatchment.

RESULTS AND CONCLUSION

The runoff and discharge volumes corresponding to the hydro-geomorphological settings of the different landcover scenarios are shown in Table 1.

The results show that higher runoff values are produced in scenario II. Consequently, in the study area forest fire events have stronger effects than the abandonment of terrace cultivations in terms of runoff production. Since the actual conditions in the Arzoco subcatchment correspond to scenario II conditions the discharge volume of the Arzocco torrent (discharge value in Tab.1) can be used to characterize flood events.

The results also underline that values of runoff production under scenario III are highly related to the proportional cover of the terrace cultivations. Hence, it is possible that in those catchments where the area covered by abandoned terrace cultivations is larger, the effect on runoff and on flood discharge production could be very significant.

In a further study we will focus especially on the latter phenomenon and will investigate more in detail the role of terrace-abandonment in catchment hydrology.

Sinkholes hazard. Case study: Palermo

ROSARIO SOTTILE (*), GIOACCHINO CUSIMANO (**)

Key words: *Palermo, sinkholes, subsidence, underground cavities*

The study of geological problems related to the presence of underground cavities, in an urbanized environment like the city of Palermo, is a theme that has had and still has strong implications for the development of the city.

Starting from the origins to the present day, the process of human land with urban development over the rivers Kemonia and Papireto of Palermo, supported by economic, technological and social progress, has contributed to the growth of the city, but has also altered the physical environment and a deterioration in the balance, causing him to cause those conditions of instability, which will be the subject of study.

The work has involved some type of underground cavities, such as bomb shelters, the culverts for hydraulic defense of the city and the anthropogenic cavities *l.s.* (underground mines, qnat, underground tombs, etc..). Through the pages of the newspaper "Giornale di Sicilia" survey was conducted a chronological historical survey on subsidence occurred on the beginning of last century until 2009, and we made use of the collaboration of the Prediction and Prevention task force of the Civil Protection Office and Building unsafe of the town of Palermo.

Were shown the geological characteristics of the areas affected by subsidence, that the analysis had a practical acknowledgment of the situation, we generated a database GIS regarding the phenomenology of the affected, and has produced a map of areas affected by the phenomena of sinkholes, in scale 1:10.000, which were limited to areas subject to this phenomenon and located the places where they occurred.

Sinkhole phenomena at San Basile, Northern Calabria

S. SURIANO (1), M. PARISE (2), T. CALOIERO (3), G. LANZA (4), G. IOVINE (5)

Key words: *sinkhole, origin, morho-evolution, Calabria.*

INTRODUCTION

Within the framework of a regional study, recently performed to implement a data base of the sinkholes in plain areas in Calabria (IOVINE & PARISE, 2008), n.5 cases have been recognised in the territory of San Basile (Northern Calabria) at "Piano dell'Acqua". The sinkholes are located in a hilly setting, in which the main landform is a slight valley draining toward the east (Fig.1). The area is characterized by Pliocene conglomerate and sand, likely dislocated by tectonic lines (CASMEZ, 1969; 1970).

The sinkholes show a variable freshness appearance (Fig.2). They are limited in size, with maximum diameter of 10 m, and maximum depth of 2.5 m; two of them are elongated, whilst the remaining three are circular (Tab.1).

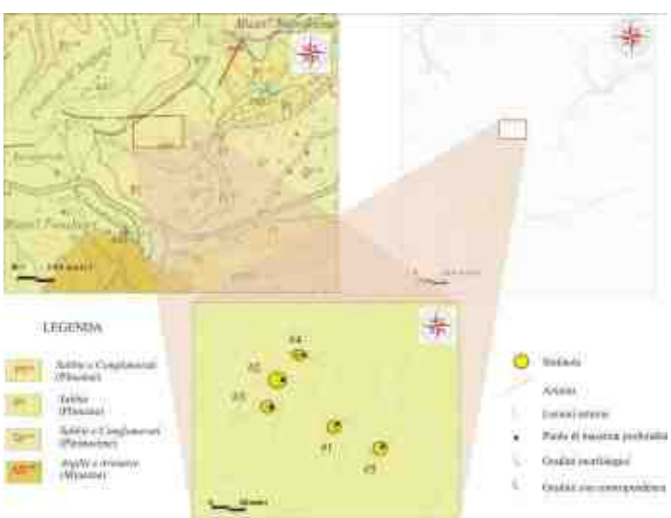

Fig. 1 – Litological-structural characteristics of Piano dell'Acqua.

#	*L*	*α*	*β*	*γ*	*W*	*A*	*D*

5	6.01	N60°E	10.5°	3.0°	6.00	28	**2.5**

Tab. 1 – Main characteristics of the Piano dell'Acqua sinkholes. For each sinkhole are given: id. (*#*); major axis length (*L*), azimuth (*α*) and inclination (*β*); minor axis length (*W*) and inclination (*γ*); area (*A*), depth (*D*) of the most depressed portion in relation to the most elevated part of the rim. For each column, maximum values are given in bold on a pink background; minimum values are in Italics on a grey background.

METHOD

The sinkholes were initially examined by means of multi-temporal aerial photos. The outcomes from this analysis were checked in the field through geological, structural and geomorphological surveys.

A historical analysis was also performed to collect and critically evaluate the existing information and testimonies about age of occurrence of the phenomena. At this aim, several interviews with local inhabitants were performed, and a number of archives scrutinized.

Geophysical investigations have also been carried out (cf. profiles in Fig.3) to investigate the geo-lithologic and hydraulic setting of the area. The resistivity of the terrain has been evaluated through bi-dimensional models (ERT, Electrical Resistivity Tomography – GRIFFITHS *et al.*, 1990; 1993).

By analysing historical, geomorphologic, hydrological and geophysical evidence, preliminary considerations of the origin and evolution of the sinkholes in the study area (Fig.4) are presented.

PRELIMINARY RESULTS

The study allowed to hypothesize that two sinkholes developed during the winter 2000-2001, with likely rapid formation. Two other cases probably originated during the 70's, as also suggested by the age of the vegetation hosted within the

sinkholes. The last sinkhole, eventually, opened sometime between February 2001 and November 2007. According to the collected testimonies, a further phase of sinkhole development might have occurred in the first half of the past Century, but no field evidence of this older phase has been found so far (IOVINE *et al.*, 2010a, b).

Furthermore, analysis of the seismic catalogues showed that no earthquake can be identified as possible trigger of any of the sinkholes at Piano dell'Acqua. Therefore, the origin of the studied phenomena should be related to sub-cutaneous erosion, within an area that is rich in groundwater (as also shown by the site name, meaning "Water Plain").

Fig. 2 – Geomorphologic evidence of the sinkholes #2 (top) and #4 (bottom).

Local changes in the water table, both related to climate and man-induced activities, may have triggered the development of the sinkholes. These can be classified – according to the first results of the tomography which suggest not cohesive deposits for the surface materials - as belonging to the "dropout" types (cf. classification suggested by WALTHAM *et al.*, 2005).

Fig. 3 – Traces of the tomography (Tomo-1 and Tomo-2) performed at Piano dell'Acqua. Locations of sinkholes (#1-5) are also shown.

In this study, the most recent results of the performed investigations, together with evidence of field surveys are discussed.

Reactivation of a dormant landslide due to cut of the foot

CARLO TANSI (*), GIULIA MARTINI (*) & VENANZIO R. GRECO (°)

Key words: *Engineering geology, Dormant landslides, Geological and geotechnical investigations, Retaining walls.*

INTRODUCTION

Dormant landslides are particularly insidious phenomena because, on the one hand, they are not always easy to identify and, on the other, the shear strength, available at the time of remobilization along the sliding surface, is almost always difficult to evaluate.

The slide, at the end of the slipping movement, tends to stop in a geometric configuration and spatial position which is characterized by a safety factor slightly greater than unity and a shear strength equal to that residual. The signs identifying the landslide body, initially highly evident, at least in the scarp of the landslide, and partly on the sides, are gradually obliterated over time, making an identification based on morphology sometimes difficult and uncertain, especially with respect to the depth of the sliding surface, so that, the displacements having ceased, can hardly be detected by instrumental investigation.

The shear strength, which during sliding could not be as low as the residual value measured in the laboratory in ring shear or direct shear tests, can have a partial recovery, as a function of the elapsed time, the effective stress state agent on the slip surface and the mineralogical features of soil and underground water. Such an increase in resistance can result in a stress-strain relationship of brittle type with consequent possible triggering of the phenomenon of progressive failure. However, since the recovery of strength is generally low and can be dissipated with small displacements, this phenomenon is almost always modest.

All this leads to a series of difficulties in the management of this category of instability, both as regards detection, and with the interaction with possible fabrications and colliding interventions.

Fig. 1 – Landslide on the slope of Scèuza, (Cetraro, CS).

This note relates to the reactivation of a dormant landslide on the slope of Scèuza, (Cetraro, CS), caused by a few minor earthworks at the foot of a slope to widen a plateau at the base and build a warehouse for commercial activity (fig.1). The retaining structures of the face, designed to support ordinary earth thrust wedges, could not counteract the reactivation of the landslide, which first severely damaged and then overwhelmed them.

CUT OF SCÈUZA SLOPE FOOT

The old town of Cetraro stands on a limestone cliff at a short distance from the Tyrrhenian Sea, in a position which for centuries ensured an effective defense against the marauding Saracens and Turks, but which today hampers urban development because of the narrowness of the usable spaces. At a short distance from the town, a small plateau had attracted interest for the construction of a warehouse for commercial activity, and, to obtain additional land for building, it was planned to cut the foot of the slope, adjacent to the plateau, with the construction of a complex system of retaining

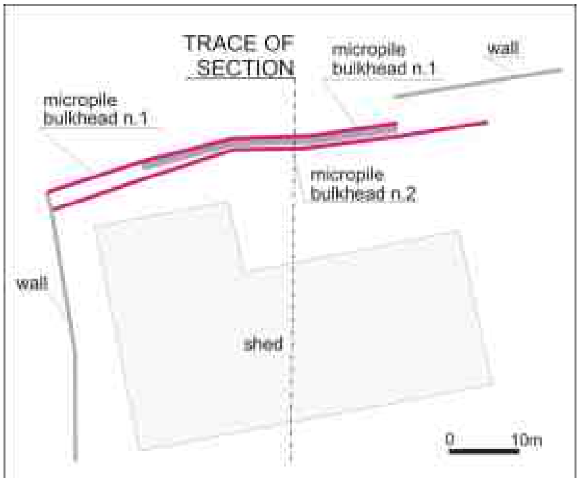

Fig. 2 – Plant of the shed of the retaining walls.

structures, represented schematically in figs 2 and 3. These structures, built on two levels, were in part founded on steel tubular micropiles (used temporarily as sheet piles during the construction) and equipped with active anchorages with tendons of prestressing steel.

There were no geological investigations of any kind carried out when planning the project. The geotechnical characterization was performed with an evaluation of the mechanical properties of the soil, whereas, according to the author of the geological report of the project, the survey showed that "the area is not affected by instability phenomena or liable to disruption". This occurred despite the geological report attached to the General Municipal Master Plan, affirming the propensity of the area to geological instability, and calling for special surveys to allow its use for construction (which, however, was excluded from the requirements imposed by the Civil Engineering Authority (Genio Civile). Indeed, as was later demonstrated, the slope, whose foot was affected by the excavation, was a dormant landslide, which was part of a complex of dormant landslides involving the entire slope (fig.4).

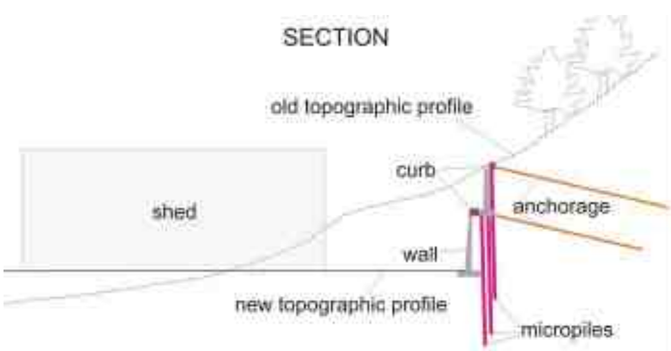

Fig. 3 - Section of the slope foot and retaining walls

The construction of the retaining structures was carried out between May and October 2006, and then some additional work between January and early March 2007.

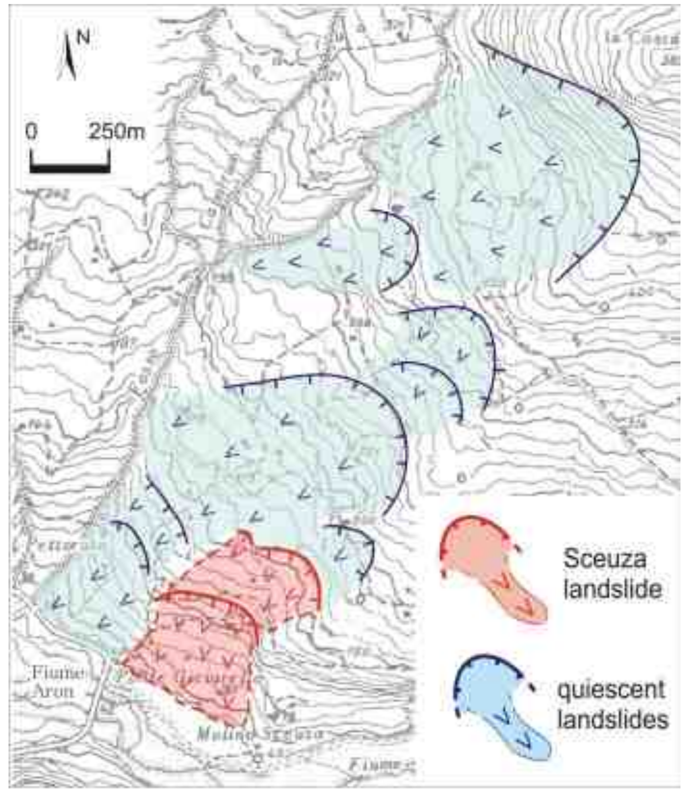

Fig. 4 - Dormant and remobilized slides of Sceuza slope

However, between March 20 and 22, 2007, heavy rains affected the Tyrrhenian coast, and in particular Cetraro, where there were landslides throughout the municipal area and severe damage to some houses on the Scèuza slope above the retaining structures. The walls were damaged due to a gradual process of slipping and overturning (fig.5) and this led to the complete collapse of the structures in February 2009 (fig. 6).

Fig. 5 - First displacements of the retaining walls

Fig. 6 - Collapse of the retaining walls

CHARACTERS OF THE SLIDE

From a geological point of view, the Scèuza slope consists of a blue-gray Paleozoic shale formation, covered by a blanket of debris in a silty matrix with a thickness of 6-10 m (fig. 7). The sliding surface developed at the contact between the covering layer and the schistose substrate, resulting from the reduction in resistance due to the increase in pore pressure and

Fig. 7 - The cut of the slope foot

the concomitant lack of thrust by the excavated soil (not compensated for by the action of the anchor ties).

This interpretation of the mechanism (landslide due to translational sliding along the surface of separation between two materials with different mechanical and hydraulic features) describes the kinematic collapse of the walls, which can be explained by the translation of the upper walls and

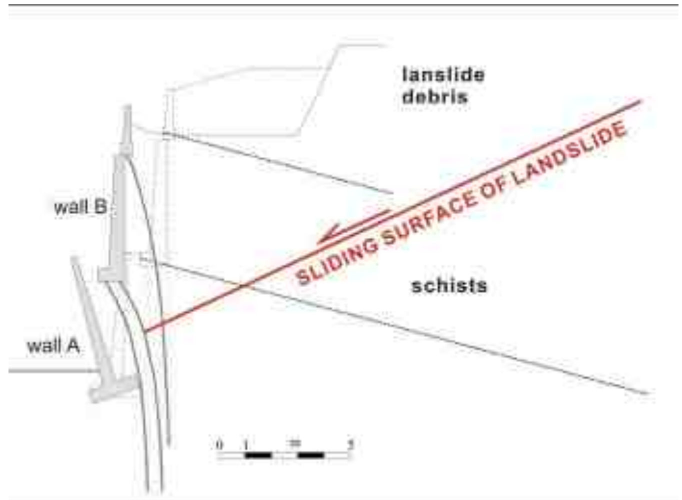

Fig. 8 - Interpretative model of the landslide

simultaneous rotation of those of the lower levels due to the ineffectiveness of the upper rods because of their insufficient length (fig.8). The cut at the slope foot was definitely the source of the of the landslide, which had previously reached a stable although precarious condition, as shown by the absence of injury and damage to an old building that stood at the foot of the slope and was partially built into it (fig. 9).

CONCLUSIONS

The story highlights the dangers which can result from the absence of geological and geotechnical investigations in the design of engineering works, on the one hand, and the need for the detection of dormant landslides with geomorphological analysis, on the other. The danger is amplified by the fact that along the old sliding surfaces of these landslides there is a reduction in shear strength, which is never fully compensated by the recovery of resistance due to ageing (however, difficult to evaluate), with consequent uncertainty in the assessment of the effective shear strength available in situ.

Identifying gullies in the Mediterranean environment by coupling a complex threshold model and a GIS

D. TORRI (1), L. BORSELLI (2), S.L. GARIANO (3), R. GRECO (3), P. IAQUINTA (3), G. IOVINE (3), J. POESEN (4), O.G. TERRANOVA (3)

Key words: *gully, threshold model, GIS*

INTRODUCTION

Soil erosion by water is an important physical process that leads to land degradation. In particular, gully erosion may contribute, in some cases, to 70% of the total soil loss. Water erosion occurs, forming a channel, when the erosive forces of overland flow exceed the strength of the soil particles to detachment and displacement. A relationship between local slope, *S*, and contributing area, *A*, is supposed to exists as runoff is proportional to the local catchment area. Therefore, an approach to interpret the physical process of gully initiation can be based on the concept of "geomorphologic threshold".

Already in the seventies, PATTON & SCHUMM (1975) and BEGIN & SCHUMM (1979) began modeling gully erosion as a threshold process. They suggested that an equation could be derived by considering that, to excavate a gully channel, the overland flow should produce shear stresses in excess of a critical value. This approach was further organized and systematized by MONTGOMERY & DIETRICH (1994). Similarly, a gully can be assumed to end when there is a reduction of slope, or the concentrated flow meets more resistant soil-vegetation complexes.

METHOD

This study aims to predict the location of the beginning of gullies, on the base of evaluation of *S* and *A*, by means of a mathematical model. To identify the areas prone to gully erosion, the model employs two empirical thresholds relevant to the head (T_{head}) and to the end (T_{end}) of the gullies (of the type $SA^b>T_{head}$, $SA^b<T_{end}$). Such thresholds represent the resistance of the environment to gully erosion, depending on: stoniness, vegetation cover, propensity to tunnelling erosion due to soil dispersibility in water, and the intrinsic characteristics of the eroded material and of the erosivity of the rainfall event.

Such thresholds must be weighed with the local steepness *S*, and applied to all the points of the spatial domain. The mathematical model works in steps as follows: (i) the territory is partitioned into elementary cells; (ii) a pre-processing allows for the identification and removal of sinks in the DTM; (iii) through analyses of hydraulic connectivity, the hierarchical relationships between the various cells are determined.

Literature data on the problem of topological threshold T_{head} was critically analysed. More in detail, data relevant to a) rangeland, b) renaturation situations (usually after abandonment), and c) databases for cropland have been merged. Selected data (see Tab. 1 in which "transitional" refers to abandoned land moving towards re-naturalization) have been examined and interpreted mathematically to assess a value to be taken as a constant for the exponent "*b*" of the above equation.

Tab. 1 – Literature data.

	rangeland		cropland		transitional	
	Coefficient (k)	Exponent (b)	Coefficient (k)	Exponent (b)	Coefficient (k)	Exponent (b)
average	0.56	0.27	0.07	0.26	0.19	0.21
st dev	0.35	0.14	0.07	0.16	0.17	0.11
median	0.31	0.26	0.06	0.30	0.14	0.20

Literature data on the problem of topological thresholds T_{end} are quite few. The basin area loses its relevance in the considered relationship between *A* and *S*; therefore, a constant value of *S* can be chosen as a threshold, as the trend with the basin area can present a very small exponent.

From Tab. 1: i) the explanatory paper by MONTGOMERY & DIETRICH (1994) seems to be falsified; ii) the exponent *b* may be a constant in the 3 situations; iii) the coefficient *k* shows a net change (i.e., it increases with increasing and more stable vegetation cover). This is in agreement with several erosion models, even if not specifically built to predict gullies (e.g. USLE, RUSLE, EUROSEM, KINEROS, WEPP). Regarding item i), it can be expected that the assumption of steady state is almost never verified. It is well known that runoff time-to-concentration increases with increasing size of the catchment, and that longer rainfall durations imply longer return periods. In other words, if the area of the catchment is used as

(1) CNR-IRPI - Perugia, Italia – e-mail: torri@cnr.it
(2) Instituto de Geologia / Fac. de Ingegneria, Universitad Autonoma de San Luis Potosì (UASLP) – MEXICO.

(4) GEO-INSTITUTE, Heverlee, Belgium.

"catchment area", areas larger than the real ones may be selected, and *A* may not be representative of the discharge anymore. A set of these types of data can artificially lower the exponent. Even trying to get the highest possible exponent out of the area-slope data, this caused a raising in the exponent which, in all cases, remained well below the 0.5-value proposed by MONTGOMERY & DIETRICH (1994) for laminar flow conditions, with a mean value of b=0.38±0.21, n=18 (5 of which from datasets by Montgomery and Dietrich; dataset derived from DTM and maps were ignored).

RESULTS

A threshold line for deposition to occur and for gullies to disappear was selected. This produced a line of "improbable gully observation" (i.e. sedimentation is certain if a gully is observed upslope) cutting through the line of gully Slope-Area threshold, as depicted in Fig. 1 (red line). The chosen trend for the lower end was taken from NACHTERGAELE *et al*. (2001). The composed threshold line (gully initiation and gully end) is also shown in Fig. 1, in which the blue line is still one possible threshold for gully head positioning - i.e. gully initiation (INI) - and the green line represents the effective threshold (ET).

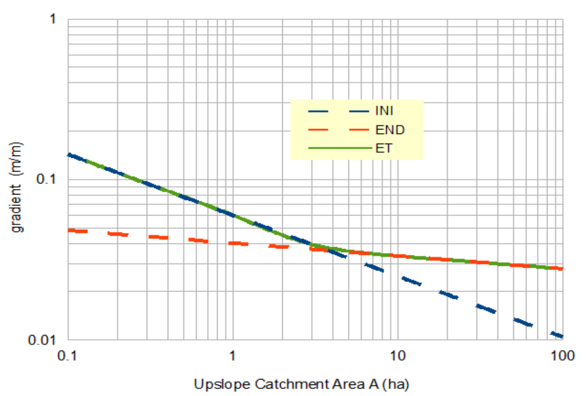

Fig. 1 – Composed threshold line. Blue line: possible threshold line for gully head positioning - i.e. initiation (INI); green line: effective threshold line (ET).

The model was applied to the "Esaro of Crotone" basin (Fig. 2), in Calabria, characterised by a Mediterranean climate. To calibrate the model, the following layers have been employed: (i) a 5-m DTM, (ii) a soil map at 1:25.000 scale, (iii) a land use map (CORINE-level IV).

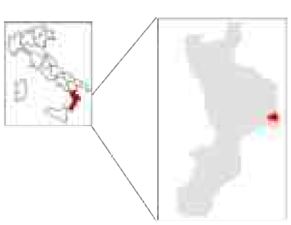

Fig. 2 – Localization of the "Esaro of Crotone" basin.

A sample check of the data has been conducted by means of direct surveys. Validation of the model and evaluation of its performances have been performed through photo-interpretation of low-altitude flights (Fig. 3).

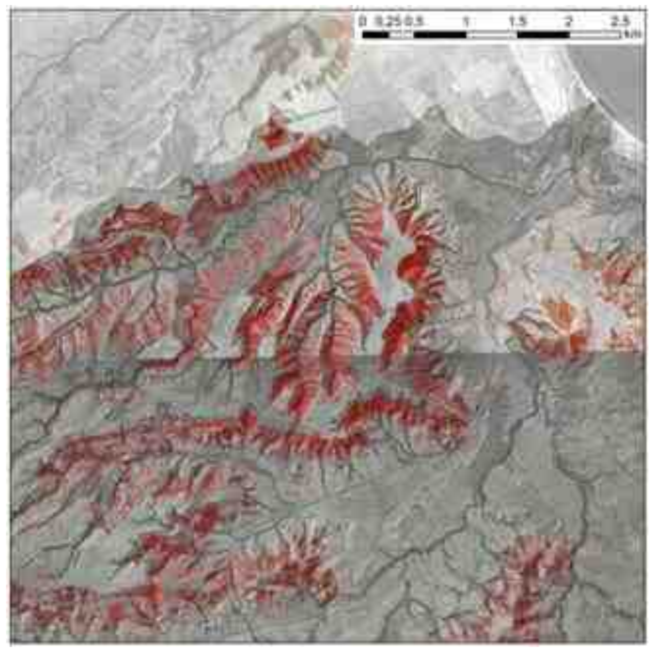

Fig. 3 – Gully-prone areas: sectors mapped through interpretation of air-photos are shown in pink; results of the model are in red.

As a result, a susceptibility map to gully erosion is presented (Fig. 4), related to the different combination among *A*, *S*, land use, and soil characteristics of the examined basin. Finally, an analysis is proposed (Fig. 5), based on the comparison between the current land use and a scenario characterized by insertion of sown grass strips for a number of land uses and for a set of slope classes.

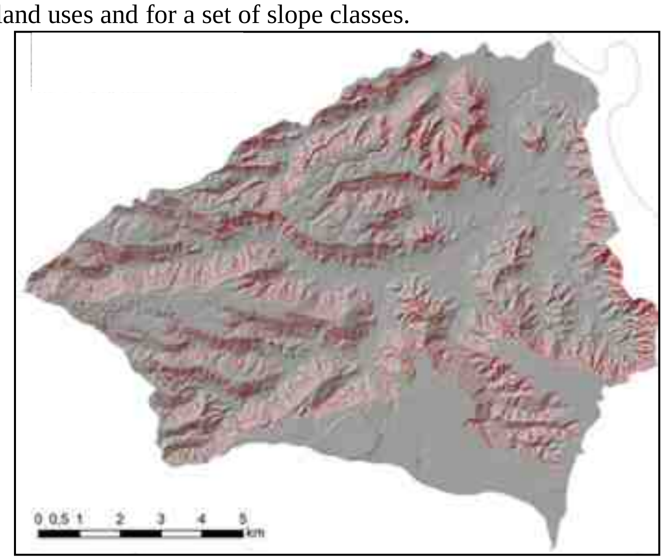

Fig. 4 – Susceptibility map to gully erosion. Actual combination among *A*, *S*, land use, and soil characteristics.

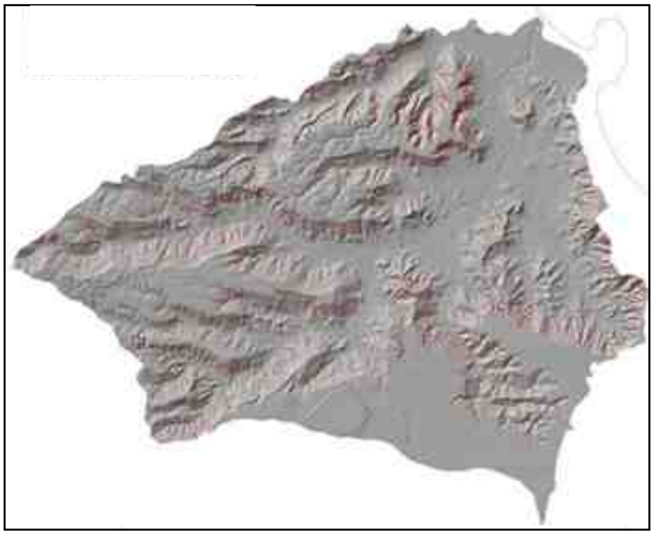

Fig. 5 – Susceptibility map to gully erosion relative to the insertion of sown grass strips for certain land uses and slope classes.

DISCUSSION

The model, as developed so far, is not definitive yet. The relationships have to be re-examined all together, to tune them and avoid over- or under-estimation of existing data. This phase, still in progress, is necessary before applications can be attempted, as – up to date – all the sub-factors have been determined by using only a subset of available data. Nevertheless, the methodological attempt of model application, described above, confirms that the adopted mathematical structure is able to properly capture real situations.

The review of published data on gully area-slope thresholds suggested a lower catchment area exponent with respect to the one proposed by Montgomery and Dietrich, which may be kept constant. In this case, differences in the position of the threshold curve in the Area-Slope diagram will be reflected entirely by the coefficient (slope of the line in the double log representation). This latter can be subdivided into a series of sub-factors, related to rock fragment content, vegetation, and dispersibility of the soil. The relationships here presented are only a first, rough approximation, and need further investigation. Their consistence with a real situation (i.e. the Esaro catchment) suggested that the adopted approach may allow for a better understanding of gully headcut locations and dynamics.

Preliminary rainfall thresholds for shallow landslides in Calabria

C. VENNARI (1,2), M.T. BRUNETTI (3), S. PERUCCACCI (3), S. LUCIANI (1,3), D. VALIGI (1), L. ANTRONICO (2), S.L. GARIANO (2), P. IAQUINTA (2), G. IOVINE (2), O.G. TERRANOVA (2), F. GUZZETTI (3)

Key words: *Calabria, rainfall thresholds, shallow landslide.*

INTRODUCTION

Italy is highly subject to geo-hydrological risk, and in particular to landslide risk. Even though slope movements may be caused by several causes, most of landslide events in Italy are triggered by rainfall. Determining the amount of precipitation needed to cause landslides is therefore a fundamental task (GUZZETTI *et al.*, 2008).

Landslides triggered by intense rainfall are generally shallow and develop in a short period of activity (from few minutes to few days - GUZZETTI *et al.*, 2007). For a given study area, the determination of empirical rainfall thresholds can be carried out through the analysis of rainfall events that induced landslides. Such thresholds can be defined in terms of duration (D, in *h*), intensity (I in *mm/h*) and cumulated rainfall (E, in *mm*). An empirical threshold can be defined as the amount of rainfall that, when reached or exceeded, is likely to trigger landslides. Thresholds can be identified both through process-based models or statistical analysis (COROMINAS, 2000; CROSTA & FRATTINI, 2001; ALEOTTI, 2004; WIECZOREK & GLADE, 2005).

METHOD

Aiming at determining cumulated event–duration (ED) rainfall thresholds for shallow landslides in Calabria, a statistical analysis of past rainfall events that resulted in shallow slope failures has been performed.

Information on rainfall-induced landslides occurred in the period 1996-2011 has been derived from newspapers (local, regional, national). For these landslide events, hourly rainfall data have been selected from the database provided by the Civil Protection Department and from the Regional Agency for the Environment Protection (ARPACAL). Rainfall measurements have been selected on the base of the distance, *d*, between the landslide and the rain gauge ($d < 10$ km), and by considering elevation and exposure of the slope.

In a first phase, landslides have been mapped as single points by using Google Earth®. A level of mapping accuracy (P), depending on landslide localisation precision, has been attributed to each case, by considering the following three classes: $P_1 \leq 1$ km^2; $1 < P_{10} \leq 10$ km^2; $10 < P_{100} \leq 100$ km^2. For each landslide event, the total amount of the triggering rainfall and its duration have been derived.

The definition of rainfall thresholds for Calabria has been performed by using two types of statistical analysis (BRUNETTI *et al.*, 2010): the first is based on the *Bayesian* method, and the second on the *Frequentist* approach. In particular, the *Frequentist* method allows to define ED rainfall thresholds for shallow landslides, characterized by different levels of probabilities (e.g. 1% and 5% exceedance probability levels).

In a second phase, investigations have been performed to:

i) increase the sample size of the landslide events, by extracting further data from the archives of the Fire Brigades, in order to enhance the reliability of the regional thresholds;
ii) include further informative layers (e.g. lithology, geomorphological contexts, soil texture, slope, exposure, climate), aiming at defining sub-regional thresholds.

At this latter purpose, depending on accuracy of location of the landslides, a given class of the informative layers (available in the WebGIS database of the Research Institute for Geo-Hydrological Protection, IRPI, Cosenza) could be associated to each slope movement. In case of statistically significant sample size, the correlation between landslide events, triggering rainfall and considered themes could be analysed to determine sub-regional thresholds.

RESULTS

In this study, the preliminary results of rainfall thresholds for shallow landslides in Calabria are discussed, with reference to national and foreign territories. Moreover, an attempt to define sub-regional thresholds has been performed, by considering sectors characterized by homogeneous environmental characteristics.

In particular, data collection allowed the reconstruction of

(2) CNR-IRPI - U.O.S. di Cosenza, via Cavour 6, 87036 Rende (CS), Italia

(3) CNR-IRPI, Sede di Perugia, via Madonna Alta 126, 06128 Perugia, Italia

232 rainfall events responsible for the triggering of 312 shallow landslides (Fig.1). In the map, Calabria is subdivided into sectors with similar geomorphologic characteristics.

Preliminary rainfall thresholds obtained for the whole Calabrian territory are shown in Fig.2. They have the following equations:

$E = 5.8 \cdot D^{0.61}$ (at 1% exceedance probability level),

$E = 8.6 \cdot D^{0.61}$ (at 5% exceedance probability level).

The above equations are quite similar to those recently obtained for the Italian territory (BRUNETTI *et al.*, 2010) and for other regions of Central Italy (e.g. Abruzzi, Umbria, and Marche – cf. PERUCCACCI *et al.*, 2012).

At present, the cited regional thresholds are being refined, by considering further information on landslide events extracted from local archives (mainly, Fire Brigades of Cosenza and Catanzaro); moreover, aiming at defining sub-regional thresholds for sectors with homogeneous environmental characteristics, the correlations between landslide locations and the available informative layers is being investigated, by applying the same hydrological approach.

The calculated thresholds may be utilized by Authorities of Civil Protection for managing landslide risk at regional scale.

ABSTRACT

Studies regarding an active basin-and-fan system located in South Calabria, along the southern side of the Aspromonte Massif, near San Lorenzo (Reggio Calabria) are reported, Fig. 1. The rocks cropping out in the study zone belong to the Stilo Unit (BONARDI *et al*., 1984) and are mainly represented by phyllites and shales.

Fig. 1 – Satellite image of the San Lorenzo landslide-fan system.

The morphological and sedimentological evolution of the active basin-and-fan system indicates how relevant can be short-terms trending and cyclical modifications of such systems, though maintaining a constant overall aspect (SORRISO-VALVO, 2010).

Anthropic interference is also relevant in either passive and active sense, natural processes dominating in the feeder basin area, whilst check dams exert a strong control on fan deposition processes and again natural stream erosion processes dominate in the fan tip zone.

As a general result, though being now quite impossible to measure the volume of parent rock actually eroded from the basin slopes during the considered time period in an accurate way, there is evidence of large volumes of debris being eroded, transported along the drainage system to the fan and main streambeds, and from there evacuated by recurrent floods (Fig. 2).

The great deal of debris budget transiting on the stream-fan system, stands for a level of hazard for flash floods, hyperconcentrated flows and debris flows much higher than that inferable from one-time visual survey. In addition, the check dams built in Seventies, being buried, are no longer so relevant as regards the magnitude of processes on feeder channel and the fan. This may explain why local residents continue to use the areas close to on or around the fan and do not perceive the level of danger they are exposed to, should a major trigger event occur, capable to suddenly mobilize a large amount of debris, either from the incipient landslides in the basin scar or from stream beds budget.

Key words: *risk analysis, debris flow triggering, debris flow propagation, Sicily*

METHODOLOGY

In this study an integrated modeling approach based on a geotechnical stability model, that identifies the areas potentially subjected to shallow landslides, and a two-dimensional debris-flow routing model, that identifies flooded area, is presented. Results from the models, i.e. hazard and risk maps, can be reported using a GIS interface. This methodology was tested in the Mili catchment located in North-Eastern part of Sicily, Italy, where a catastrophic debris flow affected the alluvial fan on 11 March 2011.

Debris flow triggering

Study approach is based on a landslides census aimed to identify, for each detected landslide, discriminating parameters and predisposing factors (CASAGLI *et alii*, 2004; ABBATTISTA *et alii*, 2005; *Leoni et alii*, 2009). Discriminating parameters are parameters of a morphometric and lithological order, consisting respectively of:

- original slope gradient in the niche zone (i.e. prior to the occurrence of the phenomenon);
- lithology in which the landslide rupture surface is imposed.

These parameters may be defined as discriminating, as the combination of certain slope interval and certain lithotypes is the necessary, but not sufficient, condition for a slope to be susceptible to a given typology of landslide. The discriminating parameters are surveyed in all landslide source areas and summarised in tables, differing in each landslide typology.

Predisposing factors may be detected in the set of geomorphological, geological, lithotechnical, hydrogeological and land use factors which contribute, to different extents, in quantifying slope susceptibility to landslides. They are detected in each censused landslide

Each factor has been mapped and implemented as a layer in a GIS project. Through to GIS overalying of these factors, which is assigned a degree of susceptibility through a susceptibility function, the susceptibility map of the area it was obtained.

An empirical formula to estimate the run out of potential events was obtained comparing the volume and run out of past events (RICKEMANN, 1997). Deriving from the susceptibility map, the high susceptibility areas and knowing the thickness of the soil and, then, the volume, the run out distance of potential events were estimated.

According to run out and to the morphology of the propagation area of the flow, are selected those triggering, where the material enters the hydraulic network;

Debris flow propagation

To simulate the propagation of the debris flow within the hydraulic network and on the alluvial fan an hyperbolic single-phase fluid model in 2D form (ARONICA *et alii*, 2012) has been used. This model, originally written for the propagation of water flooding, is based on the DSV equation and it is capable to simulate the 2D flow of a single-phase fluid by considering a different set of equations for modelling friction terms instead of classical Chèzy formula:

$$\frac{\partial H}{\partial t}+\frac{\partial (uh)}{\partial x}+\frac{\partial (vh)}{\partial y}=0$$

$$\frac{\partial (uh)}{\partial t}+gh\frac{\partial H}{\partial x}+ghJ_x=0$$

$$\frac{\partial (vh)}{\partial t}+gh\frac{\partial H}{\partial y}+ghJ_y=0$$

where $H(t,x,y)$ is the free surface elevation, u and v are the x and y components of flow velocity, h is the depth of debris flow, J_x and J_y are the friction terms in the x and y directions.

For modelling friction terms TAKAHASHI (1991) equations have been here adopted according to the dilatant fluid hypothesis developed by BAGNOLD (1954). Hence, the friction terms are computed as the sum of two terms related to the shear stresses, i.e. turbulent and dispersive (BRUFAU *et alii*, 2000, NAEF *et alii*, 2006).

$$J_x=\frac{u\sqrt{u^2+v^2}}{\left(\frac{2}{5d}\frac{1}{\lambda}h\right)^2\frac{1}{a_B\sin\phi}\left[c+(1-c)\frac{\rho}{\rho_s}\right]gh}+\frac{n^2u\sqrt{u^2+v^2}}{h^{4/3}}$$

$$J_y=\frac{v\sqrt{u^2+v^2}}{\left(\frac{2}{5d}\frac{1}{\lambda}h\right)^2\frac{1}{a_B\sin\phi}\left[c+(1-c)\frac{\rho}{\rho_s}\right]gh}+\frac{n^2v\sqrt{u^2+v^2}}{h^{4/3}}$$

(*) Dipartimento di Ingegneria Civile, Università di Messina, Italy

(**) ENEA - Italian National Agency for new technologies, energy and sustainable economic development, Italy

(°) Consultant geologist, Italy

The model equations are solved by using a finite element technique with triangular elements. The free surface elevation is assumed to be continuous and piece-wise linear inside each element, where the unit discharges *uh* and *vh*, in the x and y directions are assumed to be piece-wise constant. The spatial and temporal variation of debris flow discharge is included as a source term (upstream boundary condition). Dry bed conditions are assigned in the computational domain as initial conditions.

Debris-flow risk and hazard assessment

In the scientific community, it is widely agreed to define risk as the expected number of lives lost, persons injured, damage to property, or disruption of economic activity due to a particular natural phenomenon. In mathematical terms this definition can be translated as the product of hazard, vulnerability and exposure (European Union, 2007; ISDR, 1999; USACE, 1996):

$$R = H \cdot V \cdot E \quad (9)$$

Here, hazard (H), represents the physical and statistical aspects of the flooding. It depends on many variables such as return period, extent and depth of inundation, flow velocity, duration of flooding, product of water depth by flow velocity, hydrodynamic forces, (GENTILE *et alii*, 2008, SANTI *et alii*, 2010, see also references in MERZ *et alii*, 2007). Vulnerability (V) means the degree of loss to a given element or set of element at risk resulting from the occurrence of flooding event of a given intensity. It is expressed on a scale from 0 (no damage) to 1 (total loss). Exposure (E) , or value of the element at risk, represents the real damage to human lives, properties and assets.

The methodology used in this work to delineate debris-flow hazard is based on the above definitions and the Flood Management Plan for Sicily (REGIONE SICILIA, 2004), which refers to four distinctive hazard classes (namely H1, H2, H3, H4) for three different return periods (50, 100 and 300 years). Those indexes use the depth of flooding (*h*) as an indicator to evaluate the intensity of a flood since this is considered the flood characteristic that has the biggest influence on flood induced damage. Now, considering event intensity depending only on flow depth does not seem fully appropriate for debris flow, since the flow velocities may be very high and can have a dramatic effects on everything the flow impacts. For this reason, here, the total hydrodynamic force per unit width (impact pressure) has been considered as a better indicator for event intensity. This force can be expressed in the form:

$$\Sigma_{tot} = \rho_m \left(u^2 + v^2\right) + \frac{1}{2} \rho_m g\, h$$

where $\rho_m = c\rho_s + (1-c)\rho$ is the density of the solid-liquid mixture. Table 1 shows the hazard classes combining together Intensity and Probability (H = P x I).

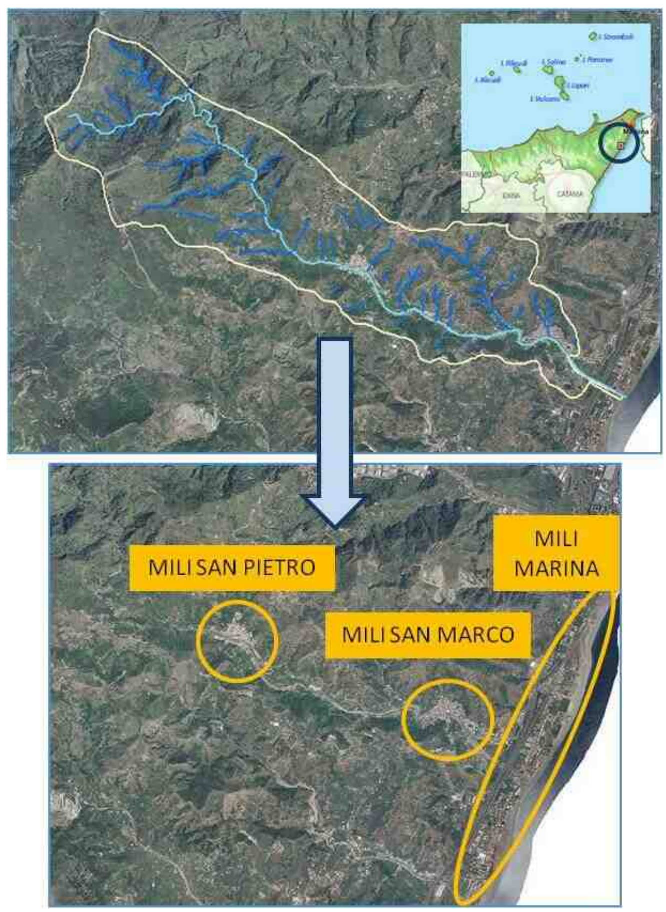
Tab.1 - Hazard classes

Intensity	Probability		
	T= 50	*T = 100*	*T = 300*
h < 0.1 m	H2	H1	H1
Σtot < 20 kPA	H3	H2	H2
20 kPa < Σtot< 35 kPa	H4	H3	H2
Σtot > 35 kPa	H4	H4	H3

As regards the exposure (E) of Equation 9 the Flood Management Plan for Sicily refers to four distinctive classes (namely E1, E2, E3, E4) according to a qualitative estimation of people, buildings, structures, etc. under risk.

THE CASE STUDY

The proposed methodology was applied to map the debris flow risk on the Mili alluvial fan where the small villages of Mili San Pietro, Mili San Marco and Mili Marina are located (Fig. 1). The study area lies on the N-E part of Sicily, near the town of Messina. The area of the catchment is approximately 5.7 km^2, rising to around 610 m above sea level, and the main branch of the river is about 7.2 km long.



Application of the proposed methodology

An inventory map of more than 100 debris flows was produced, trough geomorphological and morphometric survey and aerial photos analysis. Almost all events are triggered on the gneiss and micaschist litology. The range of slope in which are set the triggering areas is from 40 ° to 60. The thicknesses of coverage material involved were no longer than 2 meters and on average are about 0.4 meters. 100% of the phenomena affect terraced areas, of which the majority in abbandoned terraces. Most of these occur in areas with convex shaped slope.

Statistical analysis of maximum rainfall depths recorded at Alì Terme and Camaro rain gauge stations permitted to choose the Generalized Extreme Value (GEV) as statistical distribution for this variable and to estimate its parameters using the method of L-moments.

The Monte Carlo procedure was applied though the generation of 300 precipitation events and then, after a rainfall-runoff transformation, of 300 flood hydrograph. The debris flow hydrographs (to be used as external inflows at apex of alluvial fan) were derived simply by rescaling to the calculated debris volumes the liquid discharge.

The definition of the finite element mesh boundary was based upon the morphology of the study area in order to cover alluvial fan, to leave the blocks and the single houses out of the domain and to take in account internal barriers and hydraulic discontinuities. The total domain area is about 0.75 km^2 and was discretized in 58816 triangular elements. The geometric features (x,y,z coordinates) of 33093 nodes have been derived from the Digital Elevation Map (DEM) with 2m resolution.

For each synthetic debris flow hydrographs maximum values of flow velocities, water depths and impact pressures were computed in each node and element of the computational domain in order to derive the event intensity. Through a frequency analysis made on these variables, quantiles for return periods of 50, 100 and 300 years were obtained and the corresponding hazard values were derived based on the classification showed in Table 1. Furthermore, by combining the hazard and the exposure maps the final risk maps was obtained.

Shallow landslides in the southern Messina province (north-eastern Sicily, Italy): inventory map, historical records and susceptibility assessment

FRANCESCA BOZZANO (*), CARLO ESPOSITO (*) & GABRIELE SCARASCIA MUGNOZZA (*)

Key words: Archive research, north-eastern Sicily, shallow landslides, susceptibility assessment.

INTRODUCTION

On October 1st 2009, a severe rainstorm struck the Messina province (north-eastern Sicily, southern Italy); the rainfall reached the maximum intensity in the area near the southern boundary of Messina city. According to available data from the S. Stefano di Briga monitoring station, the rain gauge nearest to the "epicentral area", 225 mm of rain fell during October 1st in few hours, between 04:00 pm and 12:00 am. The highest intensity peaks were of 53 mm/h on a one hour basis and of 38 mm/h on a three hours basis. Available preliminary studies (REGIONE SICILIANA & DIPARTIMENTO DELLA PROTEZIONE CIVILE, 2009) highlight that the highest return periods (i.e. > 300 years) can be assessed taking into account the cumulated rain over the whole event (about 9 hours). In addition, it is worth stressing that more than 100 mm of cumulated rain fell in the same area during the antecedent 25 days (5 – 30 September), as testified by the same rain gauge.

Such an intense rainfall event triggered several flash floods and slope instabilities, mainly consisting of debris slide/debris-flow phenomena, which implied an overall toll of 31 deaths, 6 missing persons, beyond huge damages to structures and infrastructures.

The main objectives of our study can be summarized in: i) detailed inventory map of the landslides triggered by the October 1st event; ii) analysis of archive data, aimed at verifying the exceptionality of the event; iii) preliminary assessment of the most relevant predisposing factors and the related shallow landslide susceptibility assessment.

The analysis focused on 7 catchments within the area affected most intensely by the rainstorm: two main and five minor catchments (Fig. 1), with a total area of about 25 km^2, which directly connect the Peloritani Mounts to the sea. Common features of these catchments are the small size (not exceeding 10 km^2), elongated shapes with steep slopes, low order streams, short time of concentration, and discharge directly into the sea.

With reference to the geological setting, the study area is mainly made up of Paleozoic metamorphic rocks, such as phyllites, schists and paragneiss, with few and small outcrops of sedimentary deposits of different age and composition (marls, clays and calcarenites). The structural setting is featured by main fault lines, primarily with normal kinematics, quite parallel to the coast line and related to the structuring of the Peloritani Mounts (LENTINI *et alii*, 2000).

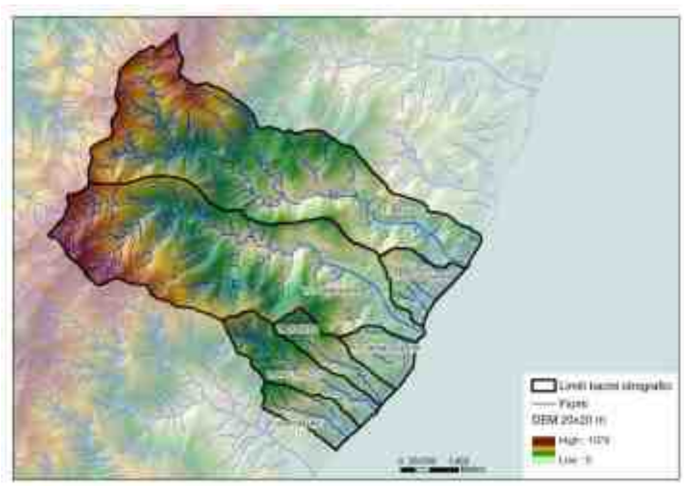

Fig. 1 – Study area.

MAPPING OF THE EVENT

As a first step, a detailed inventory map of the slope failures triggered by the October 1st event was set up. This activity was possible by integrating information from high resolution ortophotos and a digital elevation model taken immediately after the event with subsequent field surveys. Beyond few rockfalls, most of the surveyed slope failures

(*) Dipartimento di Scienze della Terra; Centro di Ricerca CERI – Sapienza Università di Roma.

(more than 1600, covering an area of about 1.7 km^2 if scar, transportation and deposition areas are considered) involved a the thin (0.5-2 m) regolith cover and were of the debris/soil-slide, debris avalanche and debris-flow type (Fig. 2), according to the classification by HUNGR *et alii* (2001). In particular, the debris-flows commonly represent the evolution of debris/soil-slide clusters which converged at the head of narrow and steep chutes. Such debris-flows in their turn often fed (debris) floods which affected the main streams until the outfall directly into the sea.

Fig. 2 – Aerial view of the shallow debris slides/debris flows occurred upslope the village of Giampilieri.

HISTORICAL RECORDS OF RAINFALL TRIGGERED INSTABILITIES

Another important step of the research arose from the necessity to answer the question: is it possible to consider the 2009 event as an exceptional one? The question is not trivial since the official land-use planning documents available at that time basically depicted the study area as a no hazardous one, while the area was hit by a similar event in 2007. In addition, a preliminary geomorphological mapping carried out by the photo-interpretation of stereo couples taken before the known events (Volo Italia), highlighted the presence of many landforms and deposits ascribable to shallow landslides and flow-type phenomena. In order to acquire the largest number of information regarding similar phenomena which affected the area in the past, a systematic activity of "historical" data collection was performed. For this purpose the available sources were: scientific publications, archives of local churches, websites, AVI Project (CNR-GNDCI), newspapers, technical reports from local Authorities (e.g.: PSAI), IFFI Project (ISPRA). Unfortunately, the State Archive of Messina was closed for all the duration of our research. It is worth stressing that this kind of research was simply aimed at qualitatively assess the potential for rainfall-triggered landslides occurrence in this area rather than to quantify the actual return periods, also due to the obvious larger amount of information in the 21st and 20th centuries with respect to previous centuries.

As a result, it was possible to find information about at least 45 landslide and/or flood events which affected the area in the period spanning from 17th century to October 1st 2009, thus depicting an area particularly prone to this kind of events. A particular mention is due to the document provided by Prof. Pietro Cuppari who made a presentation at the *Reale Accademia dei Georgofili* in 1856 where he described the "quadruple rainstorm" that affected the Messina province. In this document it is possible to read a very detailed report on the event in terms of causes, effects and predisposing factors, as the Author refers to the too intense exploitation of the narrow alluvial plains for agricultural purposes which caused the narrowing of river beds with the obvious consequences in terms of damages due to floods. The Author also mentions the role of bad agricultural practices along the slope as possible predisposing factors for slope failures.

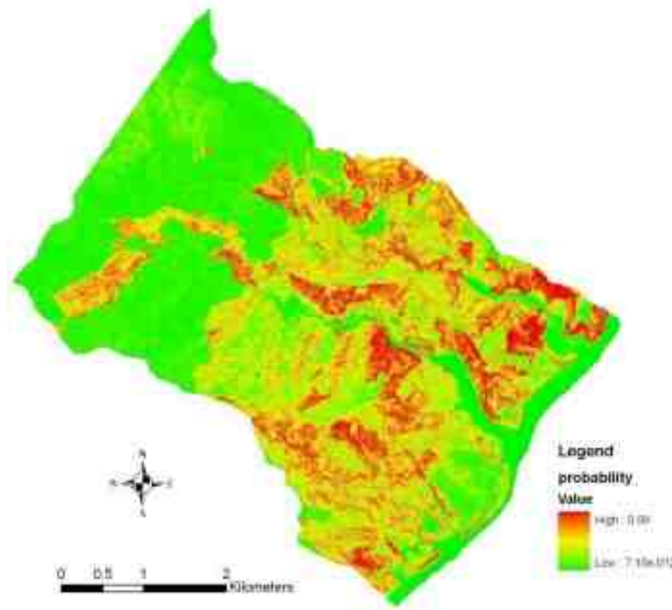

Fig. 3 – Shallow landslides susceptibility map

LANDSLIDE SUSCEPTIBILITY ASSESSMENT

Finally, a shallow landslide susceptibility analysis (Fig. 3) was carried out by means of logistic regression on the basis of the inventory map, where the detachment areas were purposely set apart. As independent variables use was made of: lithology, land cover, distance from faults, slope, aspect, curvature, flow accumulation and topographic wetness index. The information about the state of preservation of agricultural terraces, which are widespread in the area but are often abandoned was also added. Such an information was possible by photo-interpretation and represented an implementation of the land-cover informative layer. As a result it was possible to provide a relative ranking of the predisposing factors which highlighted the importance of curvature, topographic wetness index, parent bedrock, slope, and the relative importance of the state of preservation of agricultural terraces within the land cover classes.

INTRODUCTION

In recent years many geological, geomorphological and hydraulic engineering studies have focused on assessing landslide hazards in mountain and hill areas, and flood hazards in the floodplains. Less attention has been paid to hazard assessment in foothills, where flooding processes occur within alluvial fans (SANTANGELO *et alii*, 2011; 2012; SANTO *et alii*, 2002; SCORPIO, 2011; ZANCHETTA *et alii*, 2004).

On the 7th of October 2011, an extreme rainfall event occurred in the Marzano Mt. area (Southern Apennines) and reactivated alluvial fans at the outlet of two mountain basins named Vadursi and Matrura, respectively (Fig. 1). The event caused several damages to buildings, river bank structures and agricultural crops.

Immediately after the flood event, an accurate geological, geomorphological and stratigraphic survey has been conducted in the flooded area as well as in the upslope catchments. The spatial distribution of the debris during the event has been heavily affected by the anthropogenic structures.

The Vadursi creek has been confined in a riverbed dig within the alluvial fan and coated by gabion walls and check dams. The Matrura creek, at the apex of the alluvial fan, is diverted toward east and toward agricultural land, without any defined receptor.

During the surveys, important data about the space-time dynamics of the event were gained from local eye-witnesses. Some elderly residents also reminded a similar event occurred in the early '90s.

The aim of this study is to describe the flood event from geological, stratigraphic and hydraulic perspectives and to assess the reactivation of the alluvial fans accounting for the modifications of the terrain induced by the infrastructures.

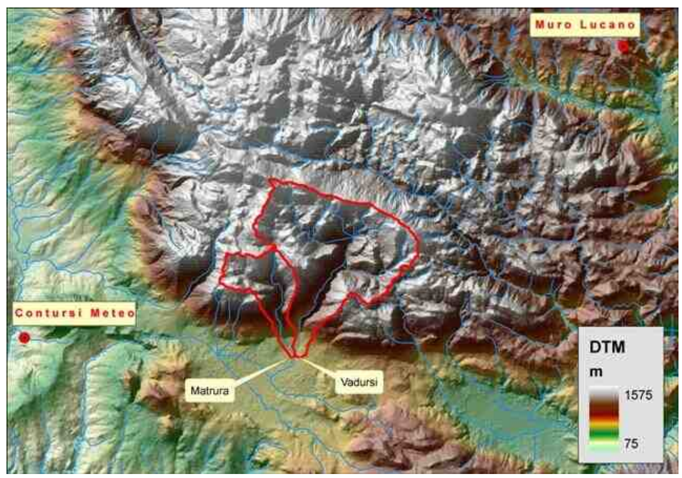

Fig. 1 – Study catchments

EVENT DESCRIPTION

The rainfall event has been characterized by three main pulses in three hours. Rainfall data collected by local raingauges in Contursi Meteo and Muro Lucano (see Figure 1) show that rainfall was characterized by strong spatial gradients, affected by the large plateau of the Massif Eremita-Marzano. The maximum observed return period is about 140 years in three hours.

From field observations and local witnesses it is possible to argue that the flood event in the Matrura creek was characterized by three waves occurred in the evening of the 7th of October 2011, between 18:00 and 22:00. These three flood waves had different impacts within the alluvial fan. In the first stage, occurring around 18:00, the flood wave consisted mainly of water, which excavated the riverbed up to 2 m in depth. Around 19.30, a second peak flood occurred, with a higher concentration of sediments which deposited over a large sector of the alluvial fan. The third flood wave, occurred around 22:00, was

3) Department of Earth Sciences, University of Naples Federico II, Largo San Marcellino 10, Napoli, Italy.

constituted by water which redistributed the debris deposited during the previous flood wave.

During the field survey, the particle distribution has been assessed by visual inspection of both the recent and the ancient deposits. Ancient deposits have been observed along the erosion gullies generated during the flood. The facies of the ancient deposits have been reconstructed as well as the depth of the sediment deposits during the flood has been assessed. These data were used to define the dominant type of sediment transport, *debris flow* or *water flood* (e.g. COSTA, 1988).

The type of dominant processes changed across the alluvial fan. In the apex area, the main deposit consisted of coarse debris with thickness up to 1,5m. In this zone, the flux had the characteristic feature of a *debris flow*. The stratigraphic sections show a chaotic debris cluster of weathered limestone material with an inverse gradational particle distribution: from 10-20 cm on the top horizons to 60-80 cm in the deeper horizons. The debris covered part of the agricultural lands and also accumulated against house walls facing upslope, with maximum depth of about 5 m. Moving to the centre of the alluvial fan, it was possible to observe several depositional lobes, elongated in a radial manner downslope. These depositional lobes were mainly constituted by debris with a significant sandy-loam fraction. In the central part, these lobes present an alternation of layers with fine and coarse sediments along the main propagation direction while progressively finer sediments in the lateral sectors. In some circumstances the lobes appear interdigitated, being the flux patterns influenced by the local morphology as well as by the roads.

The median sector of the fan has been mainly interested by characterized by water flood or by erosion gullies which have been subsequently filled (*cut and fill*). These have been mainly generated by those fluxes which gained more erosion capacity after they released most of their sediments in the apex sector. In the bottom sector, the flux spread across large and almost flat agricultural lands, distributing shrubs, silty material and gravel mobilized over short distances.

For what concerns the Vadursi creek, the flood remained confined in the river bed dig in the ancient fan and confined by gabion walls. However, most of the gabion walls collapsed in the upper sector, being undermined by excavation at the base. In the lower sector, where the slope is below 5%, the flood deposited the transported sediments. The deposit was also enhanced by the backwater induced by a bridge, which partially obstructs the river cross section.

DISCUSSION

Teglia flood event is a significant example of alluvial fan reactivation at the toe of a mountain basin characterized by limestone bedrock. This type of catchments and hydrogeological hazards are very common in the Southern Apennine (SANTANGELO *et alii*, 2011; 2012).

Teglia flood event also evidenced the scarce prevention action planned in these areas, despite their relatively frequent occurrence, as witnessed by local residents as well as historical documents. Similar events occurred in 1870, 1929 and 1977. The event in 1929 was characterized by rainfall spatial and temporal patterns very similar to the one occurred in 2011.

Fig. 2 – Alluvial deposit observed close to the wall of house facing upslope (a) and in the riverbed (b) of Matrura creek; c) the debris deposited in the riverbed of the Vadursi creek and observed damages to the gabion walls.

The gathered data show that the erosion and depositional processes varied significantly across the alluvial fan, being influenced by the longitudinal distance from the apex and the lateral distance from the cannel. Depositional processes, typical of debris flows, occurred in the apex and in the median zone of the alluvial fan, with the deposition of significant amounts of coarse material (thickness up to 3m). In the outer zones, water flood prevailed. Infrastructures in the apex zone (residential and livestock structures) affected the depositional processes, enhancing the accumulation of material against the walls facing upslope. Similar processes, but at smaller scale, occurred around the olive trees, with debris lobes with a height up to 1.5 m. Roads and agricultural terraces also influenced the flood propagation in the external sector of the alluvial fan.

Hydraulic infrastructures contributed to reduce the damages, by diverting part of the fluxes far from the local villages. In the case of the Vadursi creek the flood waves were completely conveyed by the artificial river bed, although the riverbank structures collapsed almost completely.

Further studies will be devoted to calibrate a methodology for zoning flood hazards in alluvial fans, accounting for the anthropogenic structures.

ACKNOWLEDGMENTS

Rainfall data and figure 1 has been taken from the event report of the Centro Funzionale della Regione Campania.

Simplified assessment of risk and alarm levels in Debris Flow

CIARAVINO G. (*) & CIARAVINO L. (*)

Key words: *alarm threshold, debris flow, risk matrixes, slope monitoring.*

INTRODUCTION

Debris flow has increasingly attracted the attention of researchers and public administrators because of the growing frequency and danger that this phenomenon has displayed in recent years. This increased frequency and danger is in part due to changes in the characteristics of the extreme events we have witnessed (climate change) but, above all, it is related to modifications in the hydrogeological and environmental balance caused by human interventions.

The complex study of rapid flows (both debris and mud flows), which began with the first truly systematic Japanese studies (TAKAHASHI, 1977, 1991) is advancing primarily along two broad paths. The first aims to determine the rheological properties and the dynamic laws of debris flow which make it possible to employ mathematical models in order to investigate flow (and arrest) problems and design issues for works that can contain and/or manage the volumes set in motion. The second path calls for researchers to define criteria that make it possible to identify the critical conditions that trigger debris flow.

Public authorities responsible for land management, on the other hand, are interested in simple tools that can be easily applied in both technical and administrative terms in order to: i) identify areas at real and/or potential risk; ii) determine technical standards for the assessment and design of structural and non-structural interventions for risk mitigation; iii) set up alarm systems to integrate into civil protection plans.

RISK ASSESSMENT MATRIXES

The risk parameter is normally identified in the value of the damage that may result in elements distinguished by a given vulnerability to the occurrence of an event of given danger.

Risk evaluation is thus a hierarchical assessment that is not absolute but relative, since it is linked to the nature and vulnerability of the various elements in play and also to the particular event and its level of danger.

This hierarchy is normally based on the acknowledged primary value of human life and, as a result, the risk assessment matrixes are built on the interaction between the level of danger P and the vulnerability of the exposed anthropic elements E. The various levels of danger P and the vulnerability of anthropic elements E are identified in order to obtain the level of risk R. In particular, the following four increasing levels of danger P (moderate, medium, high, very high) can be determined for the Territorial Reference Units (TRUs) which are homeogeneous in terms of morphological and lithological characteristics for the slope processes: i) P1, slopes characterised by factors predisposing for low-intensity evolutionary phenomena, medium-intensity inactive phenomena (inactive debris mud fan), or medium/high intensity and low magnitude phenomena (very limited volume set in motion); ii) P2, slopes characterised by factors predisposing for medium-intensity evolutionary phenomena, high-intensity but medium magnitude phenomena; iii) P3, slopes characterised by factors predisposing for high-intensity and high magnitude evolutionary phenomena, inactive rapid mudflow, active slow flow, slow flow supply area, quiescent flows, rapid flow supply area in predominantly clay soils, rapid flow in predominantly argillaceous marl soils; iv) P4, slopes characterised by rapid mudflow, quiescent rapid mudflow, rapid mudflow supply areas.

The magnitude M (degree of the event's impact) of the gravity processes is linked to the displaceable volume W and to the velocity V of this mass: M = f (W , V).

The magnitude is substantially related to the thickness of the slope layers, to possible limit slopes and to the kinetic energy of the displaceable masses.

The estimation of these parameters is dependent on the knowledge - including historical knowledge - of the specific characteristics of the basin and the drainage network and is generally performed through empirical criteria.

In the most general case, in which instability may affect a basin surface larger than that of the drainage network alone, the displaceable volume W can be estimated empirically by means of the relation ((SEMINARA & TUBINO, 1993) :

$$W = G_S \odot W_S \odot S \, .$$

In this formula S is the basin's surface area (Km^2), G_S is a

(*) Department of Hydraulic, Geotechnical and Environmental Engineering, University of Naples Federico II, Italy.

corrective coefficient for the basin's specific solid contribution (varying from 0.5, for $S=10Km^2$, to 3.0, for $S=0.1Km^2$) and W_S is the specific displaceable volume per unit of surface area (variable between 30,000 and 100,000 m^3/Km^2 depending on the geological characteristics of the slopes' top layers).

In the case of rapid mudflow, the velocity V may be estimated in a first approximation (TAKAHASHI, 1991) by means of Manning's relation (in uniform flow):

$$V = K^{3/5} \odot (Q/B)^{2/5}$$

In this equation $K= N_M^{-1} (\sin\theta)^{1/2}$ and $Q= Q_L \odot C^*/(C^*-C_\infty)$; in these relations N_M is Manning's coefficient (with experimental values between 0.05 and 0.10 $s/m^{1/3}$), θ is the slope of the transport section, Q is the total flow, Q_L is the liquid flow, C^* and C_∞ are the maximum packing volumetric concentration in the solid phase and the equilibrium volumetric concentration in the solid phase, respectively, and B is the width of the transport section.

The vulnerability of the exposed elements E is generally classified through the following criteria: i) E1, environmental heritage with substantial absence of anthropic infrastructure and activities; ii) E2, scattered houses, network infrastructure and roads (motorways, main roads and local roads); iii) E3, towns, areas with production facilities and important technological plants; iv) E4, major cities and significant cultural heritage sites.

The risk assessment matrix set up using the above degrees of danger P and vulnerable elements E is shown in Table 1.

	P 1	P 2	P 3	P 4
E 1	R 1	R 1	R 2	R 2
E 2	R 1	R 2	R 3	R 3
E 3	R 2	R 2	R 3	R 4
E 4	R 2	R 3	R 4	R 4

Tab.1 - Risk assessment matrix

The matrix identifies the following levels of risk R: i) R1 (moderate risk), areas in which expected anthropic and social damage is null, and the economic and environmental damage is slight; in these areas only phenomena of slight intensity and magnitude can be expected; ii) R2 (medium risk), areas in which expected anthropic damage is still null, but there may be slight damage to buildings (without compromising their use), to network infrastructure and roads (without jeopardising their functionality) and to the environment (without interrupting economic activities); in these areas low-intensity phenomena (setting even large volumes in motion) and medium intensity and medium magnitude phenomena can be expected; iii) R3 (high risk), areas where there is a possibility of human injury (but without loss of lives), damage to buildings (seriously compromising their use), to infrastructure (causing reduced functionality), interruption of socio-economic activities and significant damage to the environment; in these areas high-intensity and medium magnitude events can be expected; iv) R4 (very high risk), areas in which there may be loss of human life, serious damage to buildings (including collapse), to infrastructure (with loss of functionality) and to the environment, with the destruction of socio-economic activities; in these areas events of high or very high intensity and magnitude can be expected (rapid mudslides).

ALARM THRESHOLD ASSESSMENT MATRIXES

As already mentioned, a third technical-adminstrative action lies in the setting up of alarm systems that come into operation prior to the occurrence of slide phenomena for use as part of civil protection plans.

A number of prediction methods implementing this action have been put forward in recent years; the most innovative and significant methods in terms of the results obtained seem to be those linking soil stability models to water seepage and transport models (MONTGOMERY D.R. & DIETRICH W.E. ,1994; DIETRICH & MONTGOMERY, 1998; DIETRICH et alii 2001).

A slope stability model is generally based on the validity of Mohr-Coulomb's law which defines the soil's shear strength τ:

$$\tau = c_\tau + (\sigma - p_W) \cdot \tan\Phi$$

In this equation, c_τ is the soil's effective cohesion, σ is the normal stress, p_W is the interstitial water pressure, and Φ is internal friction angle. Neglecting c_τ (in favour of safety), the previous relation yields (ROSSO, 2002) :

$$(\rho_S \cdot g \cdot z \cdot \cos\theta) \cdot \sin\theta = (\rho_S \cdot g \cdot z \cdot \cos^2\theta - \rho_w \cdot g \cdot h \cdot \cos^2\theta) \cdot \mathrm{tag}\Phi$$

In this equation ρ_S and ρ_w are the soil and water densities, respectively, g is the acceleration due to gravity, z is the height of the soil layer, θ is the slope, and h is the groundwater level (with reference to z). By obtaining the h/z ratio from this relation, instability conditions are highlighted even in the event of unsaturated soil:

$$h/z = (\rho_S / \rho_w) \cdot (1 - \mathrm{tag}\theta / \mathrm{tag}\Phi) .$$

In particular, stability depends on the groundwater level when $(1 - \rho_w / \rho_S) \cdot \mathrm{tag}\Phi < \mathrm{tag}\theta < \mathrm{tag}\,\Phi$: i) the soil layer is stable if $(1 - \rho_w / \rho_S) \cdot \mathrm{tag}\Phi < \mathrm{tag}\theta < \mathrm{tag}\Phi$ and $h/z < (1- \mathrm{tag}\theta / \mathrm{tag}\Phi) \cdot \rho_S / \rho_w$; ii) the soil layer is unstable if $(1 - \rho_w / \rho_S) \cdot \mathrm{tag}\Phi < \mathrm{tag}\theta < \mathrm{tag}\Phi$ and $h/z > (1 - \mathrm{tag}\theta / \mathrm{tag}\Phi) \cdot \rho_S / \rho_w$.

It can also be noted that displacement processes are triggered when rainfall causes the slope's surface layer to become heavier and seepage determines neutral pressures that cancel out the cohesion and friction forces.

It therefore appears to be initially useful to determine a matrix for the assessment of a warning threshold A (further subdivided into four fields, from moderate to very high) linked to a weather event severity parameter H, a function of the rainfall intensity, and a soil state and property parameter F, a function of the h/z ratio. These parameters should be calibrated to every single TRU (characterising the geometry and the hydrological properties of the soil), which calls for specific investigations.

Proceeding concisely (taking into account the values that most frequently arise in events triggering displacement phenomena on the slopes of basins in the Mediterranean), for the matrix reported in Table 2, we can hypothesise assigning the H parameter with the values H1, H2, H3 and H4, when the rainfall intensity thresholds of 10, 20, 50 and 100 mm/hr are respectively reached.

	H 1	H 2	H 3	H 4
F 1	A 1	A 1	A 2	A 3
F 2	A 1	A 2	A 3	A 3
F 3	A 2	A 3	A 3	A 4
F 4	A 3	A 3	A 4	A 4

Tab. 2 - Alarm threshold assessment matrix

The more complex F parameter can be assigned the following values as a preliminary step and in the absence of specific assessments: F1 corresponding to the ratio $h/z < 0.25$; F2 corresponding to $0.25 \leq h/z < 0.50$; F3 corresponding to $0.50 \leq h/z < 0.75$; F4 corresponding to $h/z \geq 0.75$.

Use of this matrix is complementary to the installation, in the single TRU, of monitoring instruments (rain gauges and piezometers) which are needed (in addition to the characterisation of the soil's geometry and hydrological properties) in order to calibrate the parameters H and F and to define warning thresholds in the civil protection plan.

The utility of and necessity for monitoring instruments on slopes in limit conditions are highlighted by the results obtained in a piezoemetric and pluviometric measurements campaign lasting five years and conducted on a sliding slope stabilised by means of drainage operations An analysis of the measurements taken, moreover, shows the considerable speed with which water levels in the piezometers rise after weather events (a significant factor for stability which may elude predictive models). This phenomenon may be determined by the presence of underground fractures or of fractures that may open without showing any visible signs on the slope; although apparently closed on the surface, these constitute 'highways' for the underground movement of water and may, therefore, cause instability that only suitable instrumentation can forecast.

In conclusion. the main characteristic of these simplified matrixes lies in the small number of parameters in play and, thus, their ease of application. The analysis conducted has highlighted that this tool is of considerable help in: i) subdividing the area into zones with differing risk levels for technical and administrative purposes; ii) planning risk mitigation strategies by means of simple and substantially objective tests; iii) determining the economic and financial investments needed to safeguard the local area; iv) establishing guidelines and coordination strategies; v) setting up warning systems with tests and instrumentation that can be read in time scales that are compatible with an alarm situation.

Factors influencing the alluvial/colluvial fans development of the Caserta Plain (southern Apennines, Italy)

SALVATORE IVO GIANO (*) & MARIA LUISA PUTIGNANO (*)

Key words: *Fans evolution, Geomorphology, Stratigraphy, Campanian Plain, southern Italy.*

INTRODUCTION

The role played by tectonics and climate in the Quaternary fans development is widely discussed (RITTER *et alii*, 1995; FROSTICK & REID, 1989; ROBUSTELLI *et alii* 2009; GIANO, 2011, among others); conversely, few data are available on volcanic areas where the explosive eruptions represent one of the main factors controlling the fan growth (ZANCHETTA *et alii*, 2004). The emplacement of pyroclastic products constitutes an important source of sediment supply in volcanic areas. In fact, these deposits can be reworked by means of fluvial processes or landslides in the whole volcanic hinterland. In this framework, eruption episodes in association with climate and tectonic processes represent the main factors that trigger catastrophic floods and flows in volcanic areas.

The Campanian Plain (Fig. 1) is a broad and complex coastal graben affected by NE-SW, NW-SE and E-W-trending normal faults. This fault system developed from Late Pliocene (IPPOLITO *et alii*, 1973) to Early Pleistocene times (CINQUE *et alii*, 2003) in all the Tyrrhenian sector of the Apennine chain. The filling deposit of the Campanian Plain consists of marine, transitional, and continental sediments and interbedded volcanic products. These latter come from the volcanic activity of several eruptive centres of the volcanic district of Campi Flegrei, Somma-Vesuvio, and Roccamonfina. The volcanics interbedded in the sedimentary infill of the Campanian Plain represent a valid tool both for chronostratigraphic correlations and dating of the sedimentary successions.

Several generations of fan systems are arranged in the area between Caserta Plain and Tifatini Mountains (Fig. 1). Such an area provides the most suitable landforms for a study of the interaction among tectonics, climate and volcanic activities. The genesis of the fans in the area is typically associated with the sediments supplied by the dismantling of the pyroclastic deposits of the several eruptions that started in Early Pleistocene (ZANCHETTA *et alii*, 2004).

Detailed study undertaken on fan deposits of the adjacent areas have pointed out a strong control of both eruptive activity and climate on the fans development (ZANCHETTA *et alii*, 2004). Conversely, few data are available on the role played by the climate - which was responsible of the fan growth - and by the tectonics of the mountain front - which controlled the parameters of the drainage basin. The influence of the both tectonic and climatic contribution in the fans development has been investigated in the Campanian Plain, using a morphotectonic and stratigraphic approach. The knowledge of the role of these factors on the fan evolution will contribute - together with the data on the eruption activity and the base level fall - to a quality upgrading of the risk assessment in this area, which was strongly modified by human activities and is characterized by a high density of population.

Fig. 1 – Geological sketch map of the Campanian Plain. 1) Mesozoic to Cenozoic carbonate units; 2) volcanic products; 3) Ignimbrite Campana deposits; 4) Quaternary marine to continental deposits; 5) faults. In the frame the study area.

GEOLOGICAL AND GEOMORPHOLOGICAL SETTINGS

The development of the Campanian Plain is the result of the Miocene eastward migration of the Apennine thrust-and-fold belt and its extension to the south-east, which have been

(*) Dipartimento di Scienze Geologiche, Università degli Studi della Basilicata, via Ateneo Lucano, 10, 85100 Potenza. E-mail: ivo.giano@unibas.it; m.putignano@alice.it.

induced by the opening of the Tyrrhenian basin (PATACCA & SCANDONE, 1989). The Campanian Plain has been the object of several important studies regarding the interaction between volcanism, tectonics and sedimentation. The volcanism developed along the master faults distributed both on the edge and in the inner side of the Plain (ROLANDI *et alii*, 2003 and references therein). Both clastics and volcanic infill of the Campanian Plain exceed 3000 m in thickness. These deposits were the target of several studies in the last years (ROMANO *et alii*, 1994; PUTIGNANO *et alii*; 2007; SANTANGELO *et alii*, 2010). The Late Pleistocene morphoevolution of the Campanian Plain was strongly controlled by the emplacement

Fig. 2 – Bedrock channel filled by carbonate-rich deposits of the first fan systems. The bedrock is formed by the Campanian Ignimbrite.

of pyroclastic products produced by the eruption of the Campanian Ignimbrite (ROLANDI *et alii*, 2003). These products are of a trachytic-phonolitic composition and are dated 39.28$\pm$0.11 ka (DE VIVO *et alii*, 2001). Moreover, the Campanian Ignimbrite products have concurred both to the infill and to the final emersion of the northern and central sectors of the Plain.

The Caserta Plain is bounded from north to east by the southern calcareous edge of the Tifatini Mountains. Their tectonically-controlled front has a straight and retreated slope profile with an angle of about 35°. Its eastern side is covered by pyroclastic deposits related to the Campi Flegrei and Somma-Vesuvio eruptions. At the foot of the Tifatini Mountains front, the pyroclastic products of the Campanian Ignimbrite are interbedded with talus and fan slope deposits. Starting in Late Pleistocene times, both breccias and pyroclastic deposits formed a wide glacis, whose present slope gradient ranges between 0.2° and 15°. The glacis covers he piedmont area between the foot of the Tifatini Mountains and the Volturno alluvial plain. In the lower portion of the glacis, the Campanian Ignimbrite products are covered by the pyroclastics of Neapolitan Yellow Tuff emplaced at 15 ka (DEINO *et alii*, 2004) and by alluvial deposits. Several eruptions occurred after the Neapolitan Yellow Tuff emplacement in the last 15 ka, which concurred to the final geomorphological evolution of the Campanian Plain.

GEOMORPHOLOGY AND STRATIGRAPHY OF THE FANS SYSTEMS

After the emplacement of both the Campanian Ignimbrite and Neapolitan Yellow Tuff pyroclastic products, the piedmont area of the glacis recorded intense erosion by sheet washing and fluvial processes that were responsible for a complete removal of the upper part of Neapolitan Yellow Tuff deposits. In the area of study, three fan systems have been recognized on the basis of both morphological features and stratigraphic assemblage. The fan systems are not currently active, are locally covered by colluvial deposits or, in places, by palaeosol (PUTIGNANO *et alii*, 2007). The first fans system is located in the upper and middle sectors of the glacis. The apex of fans is inset at the foot of calcareous mountains and the feeder channel cuts the carbonate bedrock. The fans slope is vertically incised by the main channel that forms terraced units. The fan deposits cover the Campanian Ignimbrite and are lithologically composed of both carbonate-rich and volcanoclastic-rich deposits. It is worth noting that only in the Casolla site the fan deposits are placed on the Neapolitan Yellow Tuff. The first fans system was formed by fluvial-dominated fans related to debris flow processes (Fig. 2). The second fans system crops out in the middle sector of the glacis. The shape of these fans is very different from the shape of the first group: they are cylindrical and coalescent, hence with a length/width ratio greater than the ratio of the first fan system. As a consequence, the depositional lobes are not identifiable due to the large area of coalescent fans. The fans succession is prevalently formed by volcanoclastic deposits. These deposits originated by the reworking of both weathered volcanic products and palaeosols. The transport processes inferred from the sedimentary structures of the fan deposits are gravity-driven, such as mass flow. Therefore the fans of this group should be included in the colluvial fans typology. The third group of fans is placed in the middle to lower sector of the glacis. The apex of each fan is located in the mouth of the distributary channels belonging to the first and second fans. In fact, these channels entrench both the upper and middle sector of the glacis. The third group of fans are not incised by channels and are prevalently volcanoclastic-rich. The transport processes responsible for the fans deposition should be ascribed to hyper-concentrated flows.

RESULTS AND CONCLUSIONS

The reworked pumice clasts of the fluvial succession pertain to both the first and third fan deposits. The pumice shows an aphyric structure, are highly vesicular and light-grey coloured. These characteristics have allowed us to assign these pumices to the Campanian Ignimbrite. For this reasons the alluvial fan deposits of both the first and the third group were originated by a reworking of the Campanian Ignimbrite products. The pumice clasts of the second group of fans are strongly weathered and reddened, and they are included in a colluvial reddish sandy-silty matrix. Also in this case the pumice clasts belong to the Campanian Ignimbrite, as well as the matrix, which derives from the upper strongly weathered part of the Campanian Ignimbrite.

The deposits that shaped the three fan systems of the Caserta Plain are younger than the upper Late Pleistocene, because they unconformably rest on the Neapolitan Yellow Tuff, which is dated 15 ka. The morphological correlation among the fan systems has allowed us to assign the carbonate-rich fans of the first group to the oldest fan systems. The second group of fans is a colluvial fan systems and its slope is poorly incised by rill/gully channels. The transversal profile of these channels is concave, suggesting a more recent infilling and the absence of fluvial incision. These channels supplied the third fan systems placed in the lowest reach: the apex of each fan of this group is placed to the mouth of the channels.

The Late Pleistocene to Holocene sea levels oscillations did not influence the fan system development, as it is shown by the fact that the younger fan group is not incised by the backward fluvial erosion: only the "normal fluvial erosion" was active during the fan development. From upper Late Pleistocene to Holocene, tectonic and volcano-tectonic activities, together with the climate stages, did strongly control the evolution of the fan systems that produced the sedimentary fan bodies of the Caserta Plain.

Gravity and pyroclastic flows on sea coasts: analytical solutions and estimations for the Caribbean

IRINA NIKOLKINA (*), EFIM PELINOVSKY (**)

Key words: *Gravity flows, pyroclastic flows, Savage-Hutter model, Soufriere Hills Volcano.*

Gravitational flows like submarine and aerial landslides, debris avalanches and pyroclastic flows from volcanoes are recognized as an important tsunami source; eleven tsunamis are associated with volcanic activity in the Caribbean. The solid block model is applied to describe the motion of the pyroclastic flow under the joint action of gravity and Coulomb friction. Special attention is paid to characteristics of the pyroclastic flow generated by Soufriere Hills Volcano (Montserrat, Caribbean Sea) in likely directions. The Savage-Hutter model is applied to describe gravity driven shallow water flows in inclined channels of parabolic-like shapes modeling avalanches moving in mountain valleys or landslide motions in underwater canyons. The Coulomb (sliding) friction term is included in the model. Several analytical solutions describing the nonlinear dynamics of avalanches are obtained: the nonlinear deformed (Riemann) wave, the dam break problem, self-similar solutions and others. Obtained analytical solutions can be used to test numerical models and to highlight basic mechanisms of avalanche dynamics responsible for tsunami. Proposed estimations of the parameters of pyroclastic flows and tsunami induced by landslides can be useful for evaluation of characteristics of the flow and for building regional hazard maps.

Experimental study on parameters affecting propagation of a channelized debris-flow

DONATELLA TERMINI (*)

Key words: *Debris flow, runout, geometrical parameters, laboratory research.*

INTRODUCTION

As it is known, debris flows travel long distances and cause damage in vast areas. They are characterized by extreme rapidity of propagation and by the ability to move high quantity of fluid mass.

Recent advances in theory and in experimental research have allowed the assessment of the physics of the debris flows. On one hand, analyses of flows of dry and solid- fluid mixtures (Azana et al, 1999; Spinewine et al., 2003) have provided a foundation for a comprehensive debris flow; on the other hand, experimental data have highlighted the limitations of the theoretical models. In particular, many laboratory experiments have been conducted to study the rheological behavior of high concentration granular–liquid mixtures and to estimate peculiar characteristics of the mixture itself (see as an example Aragon, 1995; Armanini et al., 2005).

The major part of the experimental studies analyze the basic kinematic conditions which determine the phenomenon evolution (among others Adrian, 1991; Ahn et al., 1991).

But the prediction of the runout distance of a debris flow is an important element both in the identification of potentially hazardous areas and for the evaluation of mitigation structures.

The point is that runout estimation strongly depends on some input parameters (volume, velocity, frictional factors,..) that are often difficult to estimate. This parameters are useful in numerical modeling.

The aim of the present work is to give a contribution on understanding of the propagation phenomenon of the debris flow and the input parameters in runout estimation.

The analysis is conducted with the aid of experimental data collected in a laboratory flume appositely constructed at the Dipartimento di Ingegneria Civile, Ambientale e Aerospeziale – University of Palermo - Italy. Propagation conditions are analyzed for different granular concentration. The research activity is addressed to evaluate the influence of different parameters such as the slope, the angle between the main channel and the tributary, in order to understand how they affect the propagation of the debris flow and the deposition.

Debris-flows dominated fan delta system at Amalfi Coast, Southern Italy

CRESCENZO VIOLANTE (*), ELIANA ESPOSITO (*), SABINA PORFIDO(*), MARCO SACCHI(*), FLAVIA MOLISSO(*) & SALVATORE MAZZOLA(*)

Key words: *Fan-delta, Costiera Amalfitana, flash flood, Debris flow*.

INTRODUCTION

The study area is part of the Sorrento Peninsula, a major Quaternary morpho-structural unit of the western flank of the Southern Apennines consisting of a steep and elevated mountain range (up to 1444 m) that separates two major embayments of the eastern Tyrrhenian margin, namely the Naples and Salerno bays. It is mostly formed by a pile of Mesozoic carbonate rocks, covered by Tertiary to Quaternary siliciclastic and pyroclastic units, and is deeply cut by a complex pattern of bedrock rivers and channels characterized by small catchment areas that are very high relative to the base level. These rivers show a distinct seasonality and torrential behaviour (ESPOSITO *et alii*, 2004a,b; VIOLANTE, 2009), with main delivery areas into the adjacent marine shelf.

The Costa d'Amalfi is located about 20 km south of the Somma-Vesuvius and has been repeatedly mantled during the last millennia by the pyroclastic products of the volcano. The most recent explosive eruptions of Vesuvius, particularly the AD 79 Plinian event, have accumulated loose pyroclastic material over large areas of the Campania region, thus creating favourable conditions for volcaniclastic debris to generate debris flows and flash floods in concomitance with rainy periods. In particular, during the Plinian eruption that destroyed the Roman cities of Pompei, Stabiae and Herculaneum in AD 79, the study area was covered by up to 2 m of pyroclastic air-fall tephra (SIGURDSSON *et alii*, 1985; CIONI *et alii*, 1999) now occurring as weathered levels up to a few metres thick or as deeply incised streamflow deposits (locally called *Durece*) up to 30 m thick along the stream valleys (CINQUE & ROBUSTELLI, 2009) and mostly re-deposited as alluvial fans and coarse fan deltas at mouth of main streams.

Natural disasters resulting from debris flows and flash floods are an intimate part of the study area as testified by maritime Roman villas buried by flow deposits. In more recent times, heavy damage was produced by a number of catastrophic and less catastrophic floods, documented both in the historical and environmental records. Geological and hydrological data point to elevated fluvial bed load transport strictly associated with sediment delivery from slope to streams in conjunction with rainstorm events. The slides involve a water saturated mass of materials rapidly flowing all the way down to the coast. Erosion and transport of material causes major physical changes and exposes coastal communities and human activity to hazard with potential damage to property and infrastructure, and loss of life.

DATA AND METHODS

This study is based on marine and terrestrial geological data integrated with analysis of historical sources. The Costa d'Amalfi inner shelf was investigated using a very high-resolution (IKBSeistec), single-channel reflection survey and a multibeam survey. The seismic data include a grid of more than 100 km of very high-resolution (uniboom) reflection profiles acquired using the IKB-Seistec profiler that allowed resolution of reflectors spaced 20 cm apart. The bathymetric data were collected using a hull mounted Reson 81250 multibeam sonar in the frame of a joint project between IAMC-CNR, INA (Texas, USA) and the Centro di Storia e Cultura Amalfitana (Amalfi). The insofied area resulted in a bin size of 5 m after processing. The overall control for the stratigraphy and depositional setting of the late Quaternary depositional sequence comes from an extended dataset that includes multibeam bathymetry, side-scan sonar imagery, single-channel sparker and chirp-sonar profiles, sediment cores, and integrated biostratigraphic and chronological data acquired by the IAMC-CNR between 1997 and 2004.

Ground truthing of seismic records was provided by the detailed analysis of three gravity-cores (C90, C106, C106_12) collected on the outer shelf off the Amalfi coast, as well as by the general description of a number of supplementary cores recovered from the mid–outer shelf of the northern Bay of Salerno. ^{14}C accelerating mass spectrometry (AMS) measurements were performed with a system based on a tandem accelerator (9SDH-2, National Electrostatics Corporation) with a maximum terminal voltage of 3 MV.The reconstruction of historical flood chronology of the Amalfi coast, is based on a

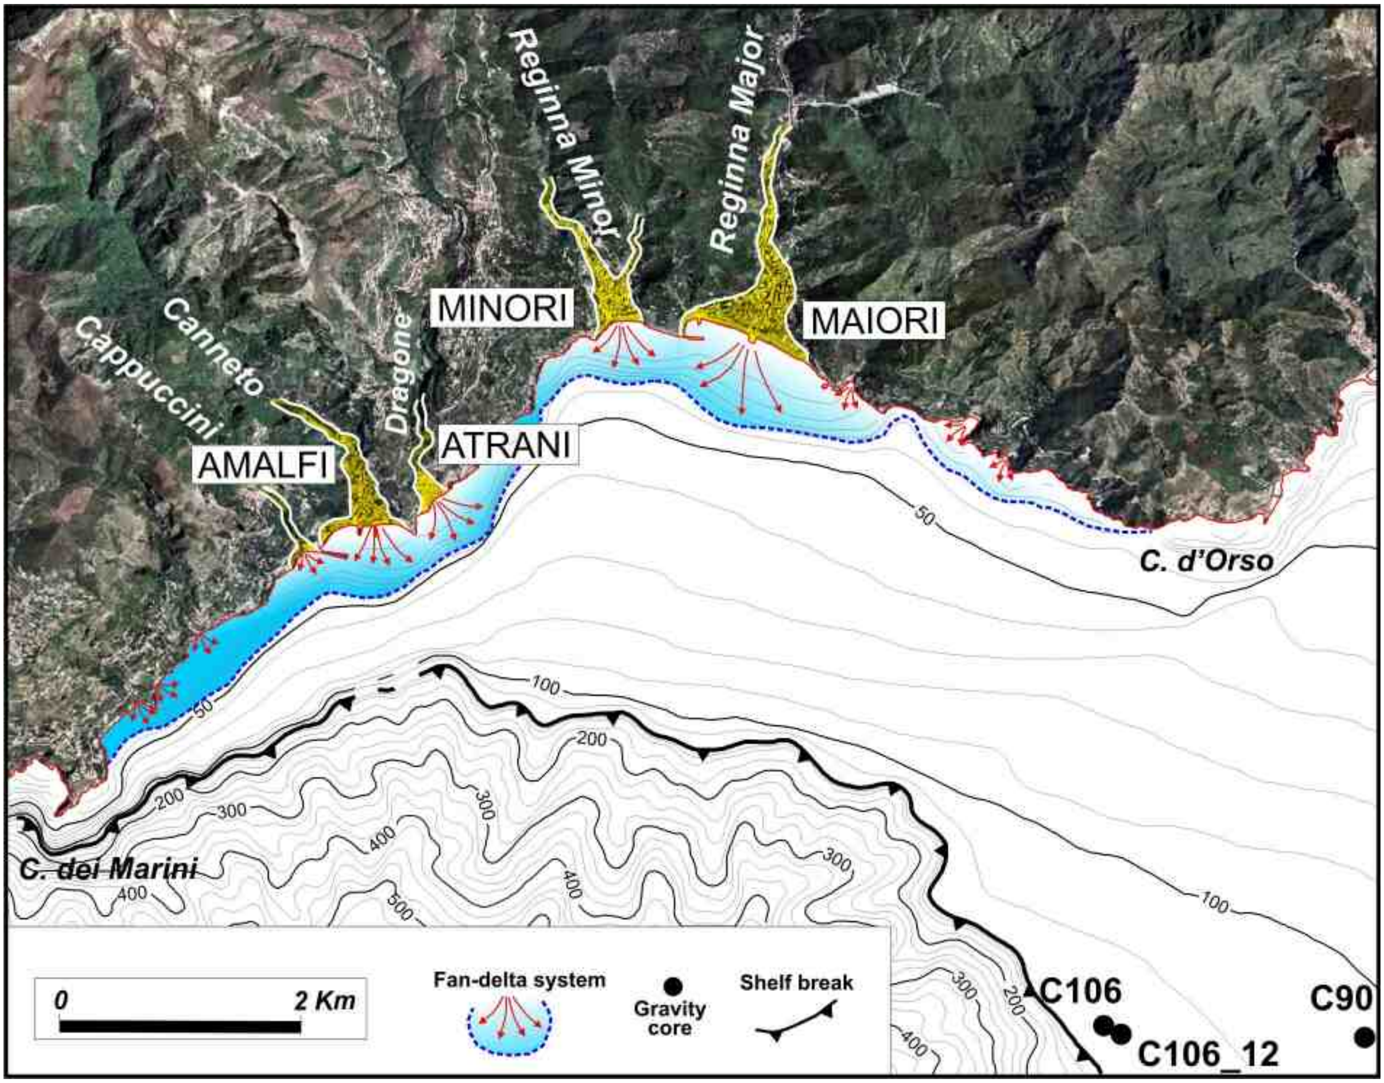

Fig. 1 Sketch-map of the alluvial fan-delta system of the Amalfi cliffed coast between Conca dei Marini and Capo d'Orso, with location of gravity cores illustrated in this study. Modified from Sacchi *et alii*, 2009.

great variety of historical sources concerning the period between the 16th and the 20th centuries, that allowed the identification and classification of 106 floods occurring during the last five centuries within the Amalfi coast (PORFIDO *et alii*, 2009). The information obtained from historical data concern the river locations, the exact dating and duration of flood events, the level of damages incurred by public and private structures, the number of victims, the flood extent, the geological-induced phenomena and the prevailing meteorological situation.

THE AMALFI FAN-DELTA SYSTEM

Sediment availability on the Amalfi coast strictly associates with volcanic watershed disturbance resulting from the famous AD 79 Somma-Vesuvius eruption. The pyroclastic fall-out event following the eruption deposited up to 2 m of erosion-prone volcaniclastic material on the steep coastal slopes causing conditions of increased geomorphic instability. The flood sequence is well documented in the fan-delta systems developed at the mouths of the main streams dissecting the Amalfi coast (fig. 1; SACCHI *et alii*, 2009; VIOLANTE, 2009; VIOLANTE *et alii*, 2009).

The individual deltaic bodies are about 1 km^2 wide and a few tens of metres thick. They display a generally conical morphology with a delta front slope of approx. 20° and foreset inclination of between 15° and 30°. Gravity core data and subaqueous investigations showed that the fan deltas are mainly composed of volcaniclastic deposits deposited after the AD 79 Plinian eruption of the Somma-Vesuvius. During this time interval of approx. 2000 years, both sea-level oscillation and tectonic subsidence/uplift were practically negligible in terms of influence on the overall stratigraphic architecture of the inner shelf system, and the main factor controlling stratal geometries and patterns, were likely the rates and modes of sediment supply.

The prominent gravity-driven instability and deformation of sediments detected at various stratigraphic levels within the delta slopes suggest that the stratal geometry of the fan deltas was dominantly dictated by the effective transfer of sediments by hyperpicnal (e.g. inertia, turbidity) flows directly fed by river floods. This implies a primary control by streamflow episodes that have provided conspicuous sediment yields to the coastal area, concomitant with the famous AD 79 Somma-Vesuvius eruption.

The major change detectable in the Amalfi fan deltas is represented by an unconformity surface occurring in the early medieval time, possibly associated with the onset of a period of climatic cooling, known as the Early Medieval Cool Period (*c*. AD 500–AD 800), that developed immediately after the Roman Warm Period. Further minor changes in the stratal patterns of the delta foresets indicative of high streamflow activity, are consistently imaged by the seismic record in all the individual fan deltas of the Amalfi coast. They may be correlated with the Medieval Warm Period (*c*. AD 900–AD 1100) and the Little Ice Age (*c*. AD 1400–AD 1850).

Building vulnerability assessment under landslides actions: Castellammare di Stabia case study

GIULIO ZUCCARO (*), ANTONIO SANTO (**), FRANCESCO CACACE (*),
DANIELA DE GREGORIO (*) & GIUSEPPE DI CRESCENZO (**)

Key words: *flow-type landslides, hydrogeological vulnerability assessment, Southern Apennines.*

INTRODUCTION

Within the SafeLand European Project ("Living with landslide risk in Europe", EU FP7, 2009-2012) a model for damage impact evaluation of the building structures hit by rapid landslides has been developed by PLINIVS Study Centre of the University of Naples on behalf of AMRA.

In this paper, an application of the model is showed. Castellammare di Stabia town (Campania region, southern Italy). has been chosen as case study. The impact damage scenario is shortly reported.

HAZARD

Castellammare di Stabia town is subjected to a hydrogeological hazard caused by the alluvial deposits of volcanic origin laying in the area. In fact, it rises on a volcanic alluvial plain, in the Gulf of Naples, delimited by Lattari Mountains (South) and Sarno River (East).

The landslide phenomenon has been analyzed through a numerical model, based on DAN-W calculation code (HUNGR, 2002), able to assess the flow kinematic characteristics from the height and the topographical section (outline) of the reliefs.

The calibration model has been pursued through the geometrical data relating to the flow-type landslides (HUNGR, *et alii*, 2001) in pyroclastic deposits occurred in the Campanian Apennines (SCOTTO DI SANTOLO, 2000).

Two landslides types are assumed: unchannelled and channelled. In particular, the "channelled flows" have been schematized by a 2D model, while the "unchannelled flows" have been schematized by a 3D schema characterized by a triangular shape, with a constant section linearly increasing in function of an apical angle of 30°.

Moreover, the model requires the estimation of the potential material volume that can be initially displaced in case of landslide activation. In this perspective, the empirical approach proposed by DE FALCO *et alii* (2011) has been adopted. On the basis of the morphometric data analysis of 213 flow-like landslides occurred in Campania in recent centuries, the study furnishes the mathematical functions between the height H and the area A_f of the detachment and erosion-transport zones.

The most susceptible areas are identified by using a landslide-triggering susceptibility map, and then in each case the height H was estimated. This height is the difference in level between the point on the slope with highest susceptibility and the first break at the foot of the slope. Using the statistical correlation between H and A_f, both calculated and for historical landslides, it is possible to evaluate the area of a potential landslide on a slope.

Finally, potential volumes are calculated by using A_f and a constant thickness of the pyroclastic cover for the whole slope.

The landslides dimensions have been determined for the Voellmy rheological model, with a constant turbulence coefficient ξ equals $100ms^{-2}$ and friction coefficient μ equals 0.03 or 0.06. The erosion phenomenon has been neglected. In addition, for the landslide geometry the following hypotheses have been adopted:

$$H_a = H; \qquad H_a = H/2; \qquad H_a = H/3; \qquad H_a = 2/3H.$$

Where: H_a and H are, respectively, the landslide and the slope heights with reference to the altitude of the top of the detachment zone (crown level).

The results are furnished through diagrams which allow to determine, in function of the distance x_f between the landslide front and the crown, the speed v_f and the height h_f of the front and the maximum height h_{max} of the landslide between the front and the crown.

On the basis of the model described, a hazard map relating to Castellammare di Stabia town has been produced, like reported in Figure 1. In this map, the basins B (orange) for the channelled flows, the slopes V (green) for the unchannelled ones and the relative invasion sectors (sky-blue) are identified.

(*)PLINIVS Study Centre for the Hydrogeological, Volcanic and Seismic Engineering, University of Naples "Federico II, Naples, Italy

(**) Department of Hydraulic, Geotechnical and Environmental Engineering, University of Naples "Federico II, Naples, Italy

Research developed in the framework of the European project SafeLand "Living with landslide risk in Europe" (EU FP7, 2009-2012).

VULNERABILITY OF BUILDINGS

The pressure applied by the landslides on the walls of the affected buildings is almost always able to cause, even at the limits of the invaded area, the collapse of non-structural elements and damage due to the invasion of the flow inside the building. Whereas, in the presence of high speed, a strong probability of serious damage to structures is likely to occur, this in some cases leads to the collapse of buildings.

It has been observed from previous events that the buildings response to the stress induced by a landslide does not only depend on the strength characteristics of the structure, instead by the resistance hierarchies between structure and secondary elements, such as windows and infill panels.

In order to simulate the real behaviour of the buildings, it should be therefore investigated at first the individual elementary vulnerabilities (structure, buffering, window frames) and then to trace vulnerability curves corresponding to different combinations of the element resistance.

In this perspective, the three following categories of vulnerability factors and the respective vulnerability curves have been identified:

1. Vertical structure typology (classes: A_V, B_V, C_V, D_V, E_V, F_V), classified in masonry buildings and framed-structures with infill walls.
2. Infill panels in framed buildings typology (classes: A_I, B_I, C_I), classified on the basis of material, thickness (between 25 and 40cm) and embedding type in the structural frame.
3. Openings typology (classes: A_O, B_O, C_O), classified in function of size, material and presence of protection screens.

To analyze the effects of the landslides on the buildings, the flows action has been schematized as a horizontal dynamic pressure *p* uniformly distributed along the impacted area with a flow front equals the interstorey height and intensity furnished by the following relation:

$$p=1/2\rho v^2 \qquad (1)$$

where: ρ is the flow density, assumed equals $15 kgm^{-3}$; and *v* is the flow speed, determined according to the hazard model illustrated in the previous section.

In addition, the impact produced by the dragged objects (boulders, garbage bins, vehicles, etc.) has been taking into account, assuming a contact area of $25\times25 cm^2$.

The study of the vertical structures and the infill panels resistance has been conducted through limit state Theoretical Calculation Model (ZUCCARO *et alii* 2000), modifying geometrical parameters (number of floors, distance between walls, height of intermediate landing, inter-story height, reinforcement percentage, thickness of infill panels, etc.) and construction characteristics (material, floor's stiffness, connections between walls, frame stiffness etc.). On the other hand, for the openings a series of experimental breakthrough tests has been performed (ZUCCARO *et alii*, 2000, SPENCE *et alii*, 2004a, b, ZUCCARO *et alii*, 2008).

The results obtained have been combined in a specific computational procedure, based on the probability of triggering the most common mechanisms of collapse as a function of lateral pressure and typological characteristics.

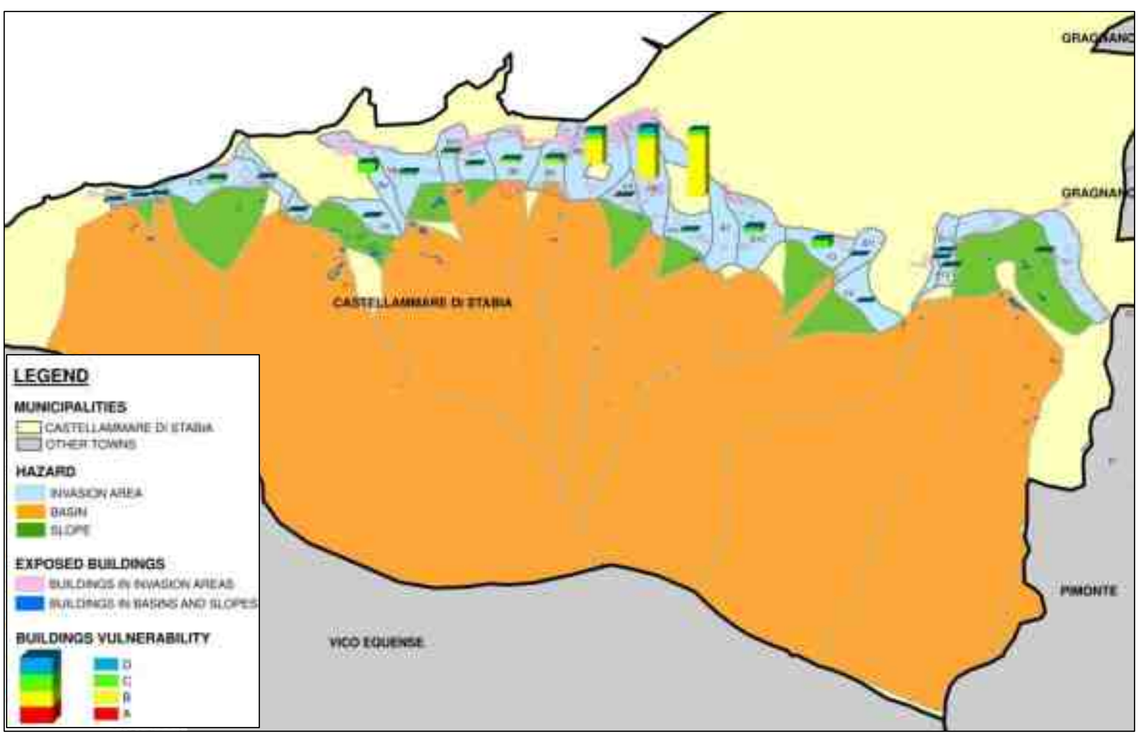

Fig. 1 – Castellammare di Stabia: Hazard and Vulnerability map.

The final outcome of the numerical and experimental analysis is constituted by vulnerability curves with reference to the three categories of vulnerability factors (Vertical structures, Infill panels and Openings) and a their probable combination in a unified category (A, B, C, D, in descending order of vulnerability).

The results obtained for the case study are illustrated by the histograms in Figure 1.

SCENARIO ANALYSIS

In Castellammare di Stabia case, combining hazard, vulnerability and exposure (in terms of number and typologies of buildings), the percentage of expected damage on the buildings has been determined (Figure 2). The following damage scale has been assumed: D0 -no damage, D1 -negligible or slight damage, D2 -moderate damage, D3 -heavy damage, D5 -very heavy destruction.

The response of Sele coastal plain to storm impacts

GUIDO BENASSAI (*), GIANLUIGI DI PAOLA (**),
PIETRO PATRIZIO CIRO AUCELLI (°) & ALESSANDRO MAFFUCCI (*)

Key words: sele river coastal plain, wave climate, wave run-up, vulnerability index

The analysis of the response of Sele coastal plain to storm impacts is here presented. This coastal zone (approx. 32 km), was selected as a study area for vulnerability assessment due to its low-lying topography and high erosion level (ALBERICO *et alii*, 2011; AUCELLI *et alii*, 2012).

The short-term response was examined in terms of both run-up and potential erosion, calculated on the bases of the numerical simulation of a significant storm with an annual return period, in order to identify areas with different response for a given storm type. For this analysis, two indicators have been estimated: run-up (as a measurement of potential inundation capacity) and potential erosion (as a measurement of potential beach retreat), calculating the response along the beach profiles realized between 2008 and 2009.

In addition, the coastal response to long-term erosion has been evaluated through the calculation of beach erosion rates derived by comparing multi-temporal and multi-scale aerial photographs.

The results were given in terms of a coastal vulnerability index which allows the identification of the more exposed coastal areas and the classification of the vulnerability of the coastline, both in terms of long-term and short-term erosion.

In the paper, after a brief description of the morphological features of the different stretches of coastline, the offshore wave climate has been examined, in order to establish the return period of the wave storms associated with their direction of propagation. This evaluation has permitted to classify the wave storms simulated in the winter 2010, and to select a significant one associated to the annual return period: the wave numerical simulation associated to this storm have been propagated along each profile in order to calculate the short-term coastal response.

The wave run-up and potential erosion calculation have been performed on each profile, with the STOCKDON *et alii* (2006) and KRIEBEL & DEAN (2003) equations, respectively, taking into account the sea level increase due to the different meteomarine factors, and the storm duration, which controls the short-term coastal vulnerability.

Coastal vulnerability to long-term erosion was assessed by comparing photogrammetric flights of different years. The first comparison regarded the coastline digitized from IGM 1954 topographic charts in 1:25,000 scale and the orthophotos obtained during 1998 in 1:10,000 scale. The results, performed by ISPRA (2006), gave a first-order computation of the coastline trend. The second comparison, made in the present study, regarded more recent shoreline positions (2003-2009) in order to update the previous trend.

Finally, in the last part of the paper, an erosion index has been associated to each physical beach response, and the score of each index has been determined on the base of previous studies. Consequently, the single scores relative to each index have been added and a global vulnerability index has been obtained, giving the opportunity to classify the coastal vulnerability in terms of both short-term and long-term erosion.

In figure 1 an example of numerical simulation of the wave storm of 17-18 December 2010 is given: the data evidence the presence of high intensity winds ($Vv \geq 10$ m/s) and low pressure corresponding to the peak of wave storm ($Hs = 5$ m).

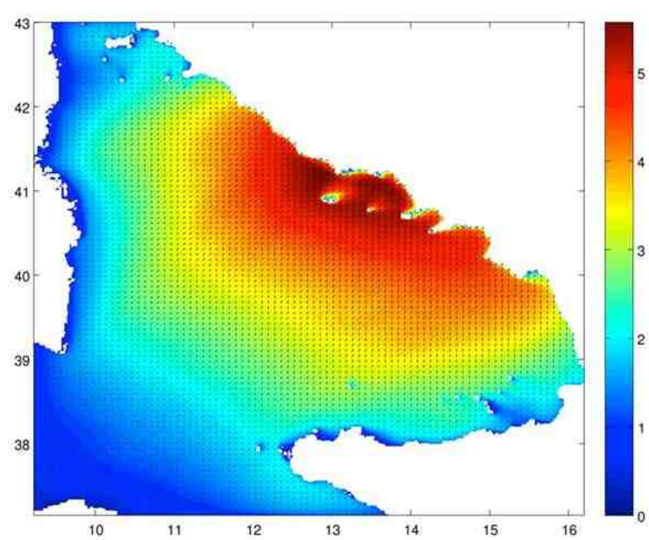

Fig. 1 – Simulation of the 17-18 December 2010 storm on the Gulf of Salerno.

(*) Dipartimento di Scienze Applicate, Università degli Studi di Napoli "Parthenope", Napoli

(**) Dipartimento di Bioscienze e Territorio, Università degli Studi del Molise, Pesche (IS)

(°) Dipartimento di Scienze per l'Ambiente, Università degli Studi di Napoli "Parthenope", Napoli

These circumstances induce an increase of mean sea level, as shown in the paper. This event was reported because it produced high sea level that affected the coastal area and so can be considered representative of annual wave conditions, as shown in the offshore wave climate study.

The storm of 17-18 December 2010, reported in figure 2, was taken as a test for the calculation of the coastal vulnerability, taking into account that for the run-up calculations, only an additional increase in water level due to inverted barometer and wind set-up has to be added, while for the beach retreat calculations, reported in the paper, additional increase due to wave set-up has to be added to obtain the whole mean sea level.

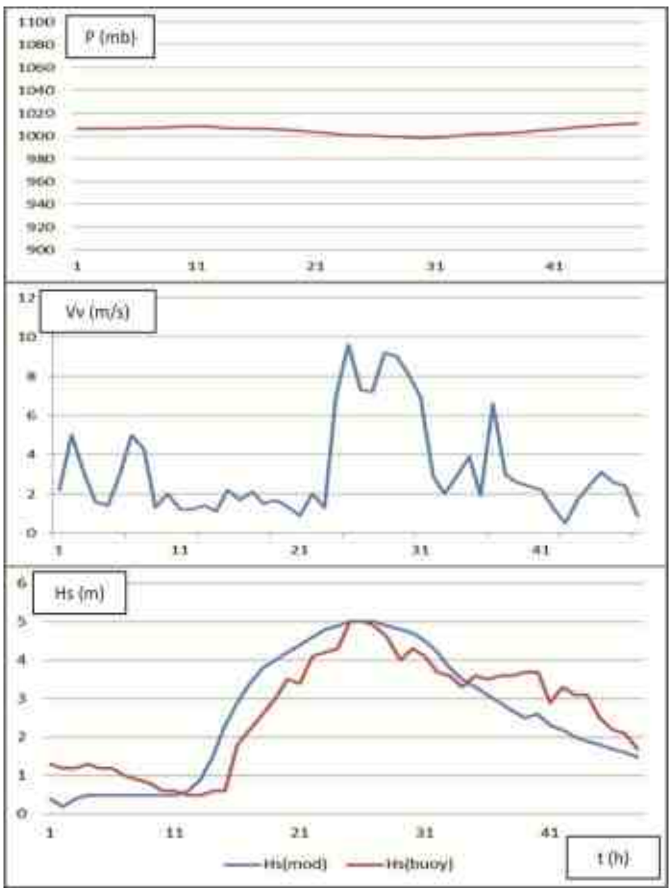

Fig 2 – Time history of the 17-18 December 2010 storm on the Gulf of Salerno.

The results of the run-up and potential beach erosion calculation on each profile, which constitute the physical beach response, heave been transformed in a short-term vulnerability index. The same has berm made for the long-term erosion measurements, which have been transformed in a long-term vulnerability index.

Finally, the single scores relative to each index have been summed in a global vulnerability index in order to classify each profile in terms of coastal vulnerability.

The examination of the results reported in the paper shows that the erosional trend of the coastline from Salerno to Agropoli increases from North to South, with an erosional peak at the mouth of Sele river, where some damages to man-made structures have been experienced. Southwards to the Sele mouth, the trend is inverted, with an evident stability of the last sector of coastline. In this general trend, the critical situations at the river mouths are more evident, whit higher values of the vulnerability index.

THE PROPOSED EROSION INDEX

In comparison with similar studies, which make use of the mean wave height to determine a coastal vulnerability index (GORNITZ *et aii*, 1994), the present study couples the coastal geomorphological features with numerical simulations of the wave storms which affected the coastal area to obtain the wave run-up distance (associated with coastal flooding) and the beach retreat (associated with short-term erosion). This short-term coastal vulnerability is added to the usual long-term one, based on erosion/accretion chart data.

The results of the run-up and potential beach erosion calculation on each profile, which constitute the physical beach response, have been transformed in a short-term vulnerability index (I_R and I_{Ru}), according to DI PAOLA *et alii* (2011) and BENASSAI *et alii* (2009). The same has been made for the long-term erosion measurements, which have been transformed in a long-term vulnerability index (I_E). The classification of the run-up index (I_{Ru}) was based on the computation of the run-up width, made non-dimensional with the beach width, giving the following scores: high (> 80%), moderate erosion ($60 \leq I_{Ru}$ <80%), low ($40 \leq I_{Ru}$< 60%) and stability (< 40%).

The classification of the short-term beach retreat index (I_R) was based on the computation of the retreat width, made non-dimensional with the beach width, giving the following scores: high (> 50%), moderate erosion ($30 \leq I_{Ru}$ <50%), low ($15 \leq I_{Ru}$< 30%) and stability (< 15%).

According to a common literature trend, the long-term rates (I_E) were grouped into 4 categories: high erosion (> 2.0 m/yr), moderate erosion ($1.0 \leq I_E$ < 2.0 m/yr), low wrosion ($0.5 \leq I_E$< 1.0 m/yr) and stability (< 0.5 m/yr).

The synthesis of this value is shown in tab. 1.

Variables	Stability 1	Low 2	Moderate 3	High 4
I_R (%)	< 15	15 – 30	30 – 50	> 50
I_{Ru} (%)	< 40	40 – 60	60 – 80	> 80
I_E (m/yr)	< 0.5	0.5 – 1.0	1.0 – 2.0	> 2.0

Tab 1 – Range variables for the evaluation of vulnerability index

Finally, the single scores relative to each index have been summed in a global vulnerability index in order to classify each profile in terms of coastal vulnerability. The results are given in the table 2.

Profiles	I_R	I_{Ru}	I_E	I_W
P1	1	4	2	7
P2	2	3	2	7
P3	3	4	3	10
P4	3	3	3	9
P5	1	3	4	8
P6	4	3	4	11
P7	4	4	4	12
P8	2	2	1	5
P9	1	1	1	3
P10	3	1	1	5

Table 2 – Calculation of coastal vulnerability index.

The examination of table 2 gives rise to the following general considerations. The erosional trend of the coastline from Salerno to Agropoli increases from North to South, which an erosional peak at the mouth of Sele river, where some damages to man-made structures have been experienced. Southwards to the Sele mouth, the trend is inverted, with an evident stability of the last sector of coastline. In this general trend, the critical situations at the river mouths are more evident, whit higher values of the vulnerability index.

The Sea-storms Database: a project for the governance of coastal areas

LORENZO CALABRESE (*), DAMIANO FONTANA (**), MARICA LANDINI (*), PAOLO LUCIANI (*), FRANCESCO MARUCCI (*), STEFANO MONTI (**), LUISA PERINI (*) E GIOVANNI SALERNO (*)

Key words: *sea-storm*, *coastal risk, coast management, database.*

INTRODUCTION

The "sea-storm" term here refers to an event with marine weather conditions exceeding predefined thresholds and/or with significant impacts on the coast, such as flooding, erosion, damage to infrastructure, etc.. The nature and severity of impacts are often conditioned by the morphology and land-use of the coast. In addition to the physical setting, the settlement assumes a great importance in determining critical conditions for potential damage. In Europe there are over 70 million people who live along the coastal areas and represent about 16% of the population (Eurosion, 2004); even in Italy there has been a recent exploitation of the coast particularly after the last World War. In Emilia-Romagna urbanization in the costal strip (here defined as an area extending for about 1,5 km from the shoreline) increased of 500% in the last 60 years (Lorito et al. 2010).

Such level of urbanization is problematic in relations to natural marine dynamics as the sea-storms. In addition, expected climate changes could increase the likelihood of the occurrence of critical situations..

The physical characteristics of the phenomena have been analysed within several projects even if there are still needs of knowledge (AA.VV., 2009, Masina & Ciavola , 2011).. The the most important lack concern the discontinuity of the time series and the heterogeneity. . Besides it is still difficult to compare the real occurrence with parameters valuated through models (Decouttere et al., 1997, Yu et al., 1998).

Nowadays, further work must be done to relate the intensity and trends of sea-storms to damaging effects on the coastal territory

The Emilia-Romagna has long been engaged in studies and projects aiming at a better knowledge of characteristics of the events, impacts and involved areas in order to reduce the possible negative effects.

(*) Servizio Geologico, Sismico e dei Suoli – Regiona Emilia-Romagna.

(**) Epoca s.r.l.., Bologna.

To give some answers to these important issues, the Region Emilia-Romagna partecipated in the project MICORE, Morphological and Impact COastal Risks induced by Extreme storm events, funded under the Seventh Framework Programme (www.micore.eu) One of the outputs produced by the project was the catalogue of historical sea-storms, which is an organized collection of data on events that have caused significant impacts on coastal areas (Perini et al., 2011). This data collection allows to perform statistical analysis on the recurrence of the events, on the physical characteristics of sea-storm, on the affected areas and damage type, etc..,. The catalogue was crucial to identify the critical thresholds of sea-storms impacting the Emilia-Romagna coast and to detect vulnerable sites (Perini et al., 2011, Armaroli et al., 2012).

This experience has highlighted the need for more deep and well-structured knowledge on the characteristics of sea storms and their effects, also in order to better support the activities of civil protection

A first prototype of the Sea-Strorms Database has been build up using data stored for the catalogue.

The implemented version here presented integrates the structure of the prototype with forecast data and should facilitate the uploading, the access and the processing of the data. The Sea-storm Database should be a tool used by the various institutional actors involved in the management of storm events (SGSS, EPA, Technical Services, Civil Protection, municipalities) with the aim of integrating resources and matching information about an event by using a common and interactive web tool.

THE DATABASE DEVELOPMENT

The development of this tool was based on several phases, and the procedure adopted for the design of the database is shown schematically in Fig. 1.

In the first phase we identified the characteristics that the database should have both in static terms (archive mode: what kind of data will need to store and use) and in dynamic terms (analysis mode: what kind of operations will be performed on archived data). This step was extremely complex and a correct definition of objectives was essential to ensure the operation of the database.

In the second phase, the conceptual framework defined above was translated into a computerized database management.

The system architecture is composed of three sections:

- Forecast section: contains the results provided by the predictive models, both with regard to the physical characteristics of event and to the expected impacts on the coast.
- Measurements and surveys section: contains all measurements taken during and after each event, both for sea and weather parameters and for the impacts occurred.
- Sea storms data section: includes for each impacting event predictions measurements and other informations (cilvil protection actions, media news, thematic mapping, etc.), providing output reports by event, by year by location and by damage.

The data collection process is currently being tested using data collected for the construction of the catalogue of sea-storms. Meetings are also ongoing with the various operators involved in the project, with the aim of including any specific requirements not already identified

The final product will consist of an online interface with access and functionality specific to each operators (login and password) both in the loading phase both during consultation and processing of data; an open public version is also provided.

Fig. 1 – The development procedure used for the implementation of the sea storms database

CONCLUSION

The catalogue of historical impacting sea-storms (Perini et al., 2011) has been a basic product to support the assessment of coastal risk in Emilia-Romagna. The Sea-Storm Database is its natural evolution in order to have an operational web-based tool for data access and analysis.

This system can be updated and shared and it can provide useful information to both the scientific community and those who have to define coastal management policies.

Messina Strait 1st October 2009 flash-flood generated submarine landslides

DANIELE CASALBORE (*), ALESSANDRO BOSMAN (*), FRANCESCO LATINO CHIOCCI (**) GABRIELE SCARASCIA MUGNOZZA (**), PAOLO TOMMASI (**) & ANDREA SPOSATO (**)

Key words: *hyperpicnal flow, multibeam, Scaletta, Giampilieri*.

INTRODUZIONE

On 1st October 2009, a small area in the Western Messina Strait was struck by very intense and concentrated rainfall causing flash-flood and countless small-scale mass-wasting events in the catchment area of steep subaerial creeks. This event generated dense and quick debris flows that destructively hit Scaletta and Giampilieri villages and then entered the sea.

The availability of multi-temporal bathymetric surveys for the whole Sicilian coast of the Straits, encompassing the area affected by the flood (Fig. 1a), allowed us to define the morphological variations produced by this catastrophic event. Moreover, this dataset coupled with the analysis of multibeam backscatter, ROV images and grab sampling was used to characterize the main instability features related to the passage of hyperpycnal flows as well as the surrounding submarine canyons.

The stress caused by the passage of hyperpycnal flows during the 1st October 2009 was able to produce a suite of mass-wasting features, encompassing shallow erosive scars, retrogressive bottle-neck slide on loose sediment and rock-fall on the gravelly bedrock at canyon sidewall (Fig. 1b, 1c and 1d, Casalbore et alii, 2011 and 2012). As mass-wasting features similar to those produced on 1st October 2009 have been identified at the headwall of regularly-spaced submarine canyons present in the neighbor coast and most of them are located in correspondence of Fiumara mouths, a key role played by flood-generated hyperpycnal flows in their formation can be envisaged (Fig. 1a). The volume involved in these slope failures is in the order of tens of thousands of m^3 and their frequency has been roughly estimated as one landslide each 25-50 years in a span of coast of about 5,5 km^2. Therefore, given the short recurrence time of these landslides and the development of retrogressive failures on canyon heads very close to the coast, the submarine setting should be carefully considered for a correct management of existing and wise planning of future coastal settlements.

Comparison between different approaches in granulometric analysis applied to Roccella Jonica longshore sediments (South Calabria)

A. CEFALÌ (*), A. PISCIUNERI (*), A. STAMILE (*), D. CARRÀ (*),G. STRATI (*), F. PROCOPIO (*)

Key words: *Granulometrc, Percentile, Facies, Normal.*

The characterization of sediments by always is a variable and controversial argument especially in the context of the study of the coasts and in the light of the various directives issued in Italy from various "AUTORITÀ DI BACINO REGIONALE" (ABR). This work wants to explore different methods of study proposed in the literature with an eye to those requested by the ABR Calabria. To do this you will take as an example the data of granulometric curves of the samples taken from Dr. Geol. Iacopino inherent the geologycal e sedimentologycal study of "*Il ripascimento dell'arenile del comune di Roccella Jonica con l'utilizzo del materiale ad est del porto. APQ Regione Calabria, Delibera C.I.P.E. 35/2005.*" The study has provided the levies of 88 samples along 16 transepts of marine sediments of which 30 onto the beach and 58 on the seabed, in order to define the tessitural characteristic of different granulometric populations of sediment, by granulometric and applied sedimentological, dynamic and modal analysis.

The beach of Roccella Jonica (RC) is located along the southern section of the Calabrian Ionic coast and is classified as a coastal alluvial fan plain interested by a general crustal uplift and simultaneous subsidence during all Quaternary period (FERRETTI *et alii*, 2003).

The coastline of Roccella Jonica (PISCIUNERI *et alii* 2008) is straight, and extends for about 8.5 km in the direction about SSW-NNE (coastal water of amplitude 180° between directions 60 ° -240° N), with a variable width from 10 to 100 m.

In the area, systems of NE-SO faults affect the physical geography, because it detects, concordant with the main tectonic, net alignments of peaks and saddles, embankments rectilinear and watercourses to linear development and perpendicular to the coast. The hydrographic network consists of numerous "fiumare" by short and straight course , whose basins have limited areal extent.

Because of their torrential regime, they occur periodic floods with an important solid transport to the sea, that also happens in the form of suspended load underlined by the wide turbid plumes, at times, some kilometers toward the breadth. The beach toward the inside, in the not anthopic area, is delimited, to from coastal dune cordons, lying parallel to the coastline.

The composition of the coastal sediments reflects that of river sediment of fiumare Amusa, Allaro and Precariti (IBBEKEN & SCHLEYER, 1991). The pebbles are constituted by granitic rocks, metamorphic rocks of low grade and sedimentary rokcs, form by siliclastic sediment and limestone, and reflect a provenience from the unit of "*Stilo*" terrain, which to rappresent the main tectonic units in this area. According to IBBEKEN & SCHLEYER (1991)the coastal portion of Roccella Jonica falls in the fluvio-coastal province from the "*Massiccio delle Serre*".

The seabed in the area in front of the coast of Roccella Jonica is characterized by a narrow continental shelf, the average width of 4 km, with the slopes of the order of 1° whose margin with the escarpment placed to an average depth of 120 m. It is delimited both north and south by deep canyons active affecting both the platform and the escarpment.

From the analysis of the marine climate was determined the wave climate of the coast considered, which has for the waves low (0.5 -2 m), medium (2-4m) and high (>4 m) respective directions 60-110° N, 110-160° N, 120-140° N. The currents are in direction NE-SW with drift sediments in this direction.

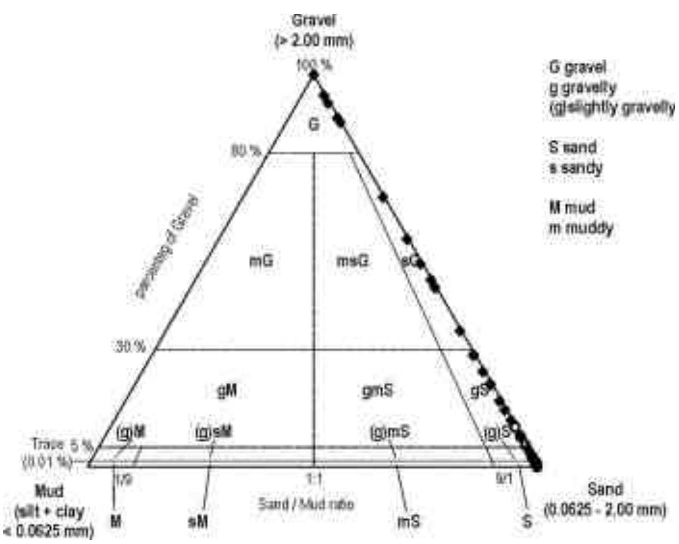

Fig. 1 – Classification on ternary diagrams of the samples taken.

The 88 samples were analyzed by sieving, by choosing an appropriate number of sieves that it cannot be too small for the analysis of probabilistic scale but also not to be too much for not

---

(*)Free Professional: Laboratory of coastal erosion and marine geology of the O. R. G. C.

(**)Free professional: He have authorized the use of the granulometric dates of 88 samples.

flatten excessively the curve of frequency distribution.

The different granulometric curves proposals were represented on the granulometric scale by UDDEN (1914) and WENTWORTH (1922) and subsequently amended by BLAIR & MCPHERSON (1999) through the use of the phi-scale ladder as defined by KRUMBEIN (1938).

The samples (fig. 1) were classified using the triangular diagram of FOLK ((1954).

From analysis of the triangular diagram the samples of emerged beach are composed of sand, sand gravelly and sand slightly gravelly, while the seabed sediment cover a broad classifying spectrum going from gravel to sand.

The different granulometric curves were parameterized through all the different statistical parameters for both via graphics, as proposed by FOLK & WARD (1957), and by the determination of the moments (FRIEDMAN, 1962). It was performed a comparison between the two methodologies which shows how there is a good correspondence between mean and standard deviation calculated by the two methods, but that the same is not found for skewness and kurtois. It has therefore chosen to use the data obtained for graphics method (fig. 2).

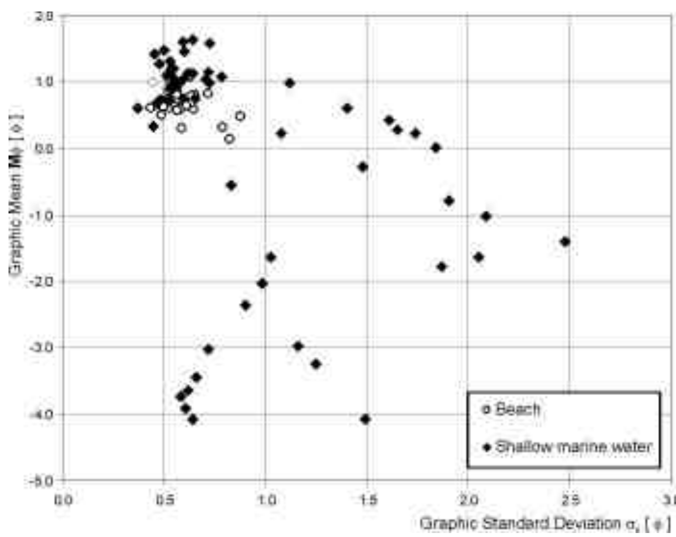

Fig. 2 – Comparison between the average and the standard deviation of the samples.

On the samples were carried out three different analyses: PASSEGA (1957, 1964 e 1977), VISHER (1969) and RIVIERE (1977).

PASSEGA (1957) plot the values of the 1° percentile as a function of the 50° percentile (median) by identifying different populations moving with different dynamics: particles that move by rolling on the bottom, gradated suspended and uniform suspension.

VISHER (1969) and RIVIERE (1977) analyze the particle size distribution curve in function of they "normality". The first identifies several tracts "normal" in which break down the curve to which they are linked different systems of transportation of the material.

RIVIERE (1977) based his analysis on the principle that the granulometric curves may not have a "normal" trend and that all can be traced back to a feature fictitious particle size dependented on the index of evolution granulometric N.

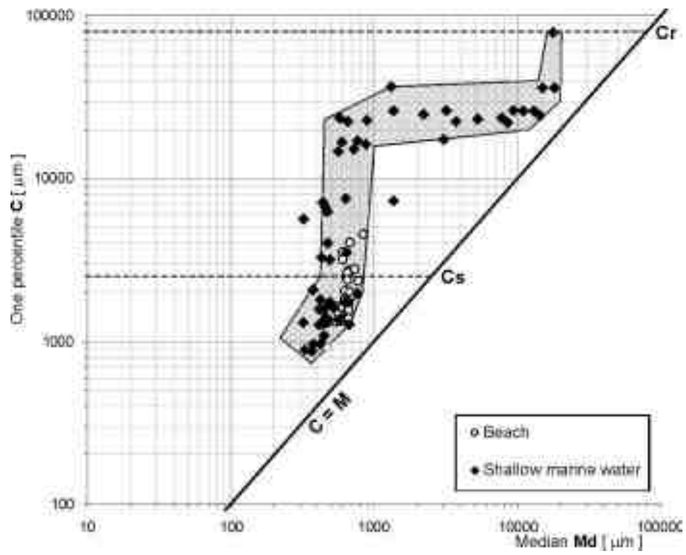

Fig. 2 – Diagram of Passega showing the evolution of the one percentile in function of the median.

From the analysis of the diagram of PASSEGA (1957) (fig. 3) it is possible to notice the presence of a population of "gradated suspension" composed of sand ,the maximum dimension of which is marked by the value Cs of the graph (about 2.5 mm): in this group there are part of the sediments of emerged beach and part of the sediments of the seabed. The remaining sediments are found on top of this group and are characterized by different types of transportation ranging from "gradated suspension" to rolling on the bottom (characterized by a maximum size Cr equal to about 7.0 cm).

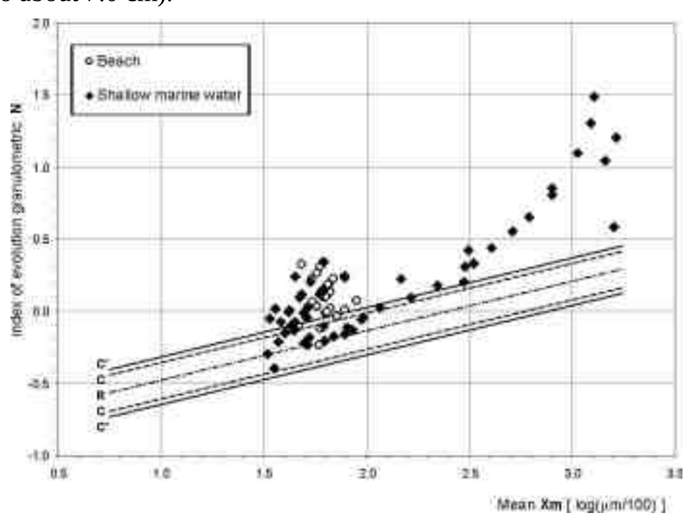

Fig. 4 – Diagram of Riviere showing the trend of the index of granulometric evolution N as a function of the average Xm

This characteristic is found from the analysis proposed by VISHER (1969), from which one can note a strong presence of the "population of saltation" (equivalent to "gradated suspension" of PASSEGA) with code variables of populations of "traction" and "suspension".

Finally, for each sample was determined the index of granulometric evolution N and the coarseness Xm as defined by RIVIERE (1977) in the "new model". In particular N was determined by setting to zero the function U derived from the feature fictitious particle size, and determining for subsequent iterations which value of N better satisfies the equation.

Were then plotted (fig. 4) the values of the index of granulometric evolution N as a function of the average Xm.

From the analysis carried out it may be noted the presence of both normal particle size in hyperbolic facies, corresponding to the terms "fixed suspension", an anomalous particle sizes in ultraparabolic facise.

Morfologia e dinamica delle frane sottomarine potenzialmente tzunamogeniche del margine meridionale sardo (Progetto MAGIC)

G. DEIANA (*), P.E. ORRÙ (*), E. PALIAGA (*) S. TODDE (*)

Key words: *Sardinia, Submarine landslides, Tsunami.*

INTRODUCTION

Tsunamis are tipically related to several triggering events including earthquakes generated along subduction zones extending up to several hundreds kilometers in lenght, the gravitational massive collapse of volcanic buildings, cliffs or submarine landslides (TINTI ET ALII, 1999; FRYER ET ALII, 2004; MCADOO & WATTS, 2004).

Until recent years, tsunamis associated with gravitational events, have been considered very rare, restricted to limited areas and with less energy than the earthquakes generated tsunamis.

Recent studies show that the landslides produced tsunamis can be frequent as much as those induced by earthquakes and are also able to generate extreme waves that may affect coastal areas (MCMURTHY ET ALII, 2004; LEE ET ALII, 2007). Considering the actual population growth and industrialization of coastal areas, these are important data implying that tsunami hazard should be studied not only in tectonically active areas, but also in passive margin contexts where gravitational processes can frequently occur (GARZIGLIA ET ALII, 2007).

Within the MAGIC project (Marine Geohazard Along the Italian Coast) during the “Sardegna 2009” and “Sardegna 2010” cruises, carried out with the R/V “Universitatis”, multibeam surveys with RESON 8160, high resolution seismic surveys by CHIRP Subbottom (500Hz/13,5kHz) and sparker surveys APPLIED ACOUSTICCSP2200 (10/2000 J) were carried out in the southern and western Sardinian margin at depths between -50 and -2200 m.

In this work several complex landslides, detected in the upper Sulcis slope and in the Cagliari gulf were analyzed.

(*) Dipartimento Scienze Chimiche e Geologiche – Università di Cagliari.

Lavoro eseguito nell’ambito del Progetto MAGIC CoNISMa, ricerca condotta utilizzando la nave oceanografica Universitatis.

GEOLOGICAL SETTING

The study areas are located respectively in the southern sector of Sardinian western margin regarding the Sulcis slope landslides and in the central sector of Sardinian southern margin regarding the Cagliari gulf landslides.

Sardinian western margin is characterized by an initial high-angle fault zones system setting and tectonic blocks wich later formed the western Sardinian continental margin (Oligo-Miocene), and an extensive rifting system (CHERCHI & MONTADERT, 1982; FACCENNA C. ET ALII, 2002; LECCA, 2000).

Sulcis slope consists of large paleozoic tectonic blocks, displaced from high-angle normal faults; the relative movement of these blocks has produced a series of basins, located both in the actual continental shelf both in the continental slope, probably evolved during the early-middle Miocene, whose filling is characterized by Mesozoic-Tertiary terrigenous carbonate sequence and syn-rift Oligo-Miocene volcano-sedimentary sequence.

Cagliari basin is the innermost part of the entire margin sedimentary system, defined and controlled by the tectonic blocks of the southern Sardinia continental margin, especially by the movements of Ichnusa seamount and Banghittu submarine blocks.

These marginal basins are the southern closure of the southern Sardinian Oligo-Miocene rift (CHERCHI &

Fig. 1 – South Sardinia – Study area location.

Fig. 2 – Tridimensional representation of Banghittu's morphology. Number one show the landslide niche. Number two show the body of the debris avalanche; the blocks drift from the crown zone for few kilometers

MONTADERT, 1982) reactivated during the Plio-Quaternary extensional movements associated with the opening of the southern Tyrrhenian sea.

UPPER SLOPE GRAVITATIONAL MOVEMENTS

Along the Sardinian southern margin and particularly in upper slope area several morphologies related to gravitational movements were observed, three differents events were presented for gravitational sliding movements, rock fall and rock toppling. In upper slope, 10 nm off the City of Cagliari two slip landslides were detected.

The northernmost has several detachment and is strongly tectonically affected. The deposit is characterized by an irregular bumpy surface. The detachement niche geometry is particularly articulated, is 2.5 km long and 1.5 km large at the crown. The landslide volume was estimated at about 80x106 m3.

The southernmost system presents a unique niche that develops in about 2 km wide by 500 m in length, and a deposit with creep surface estimated at about 50x106 m3 . The dominant process is the undermining meandering erosion at the deposit base by the Pula canyon.

Still in the Cagliari Gulf, off Pula coasts, the structural High "Banghittu" hosts collapse events that give rise to large blocks deposits debris avalanche type. Similar deposits have been studied and modelled in the upper slope of the Norwegian Fjords (Ilstad et al. 2004).

In the Sulcis upper slope an important complex landslide has been detected, this affects the incoherent Quaternary sedimentary covers (Orbulina Universa slope muds).

For these processes, the evolutionary model shows the presence of a basal lithoid substrate, an intermediate level of pliocenic fine sediments and a holocenic topping deposit affected by slumping.

Those are low-angle landslides involving sediments under hydro-plastic conditions in an area with a 5% average gradient.

The main body is characterized by the presence of three detachment niches, the largest is 5 km wide, separated by ridges, which give rise to a single deposit estimated 7 km3 in wich it is possible to detect different minor landslides reactivation.

EXTREME WAVES HAZARD IN COASTAL AREAS

The landslides described above affect volumes of sediment known to be compatible with the triggering of a tsunami.

The propagation of these extreme waves in the area would be in interference with numerous infrastructures in the proximity of the coast.

The most sensitive elements in the Cagliari gulf, besides the numerous port facilities and urbanized areas, appear to be the Sarroch petrochemical hub and all his related industrial sectors. Whereas in the Sant'Antioco area are exposed a town, a port and in perspective the pipeline and the one of the main pumping stations of the new Algeria-Sardinia-Tuscany pipeline "Galsi".

Geomorphology and sand provenance of the Tyrrhenian coast between Capo Suvero and Gizzeria (Calabria, southern Italy)

F. IETTO (*), E. LE PERA (*) & L. CARACCIOLO (*)

Key words: *sandy petrofacies, shoreline evolution, spit, Tyrrhenian coast, Calabria;*

This study analyzes the coastal dynamic and the historical recent evolution of the Tyrrhenian beach between Capo Suvero and Gizzeria Lido in the 1870-2010 temporal range. The aim is the reconstruction of the shoreline morphological evolution, and, also, the pre-burial factors influencing composition and texture of the clastic sediment. Moreover, this study examines sand beach composition between Capo Suvero and Gizzeria Lido:

a) to characterize the mainland petrological provinces and their dispersal pathways;
b) to verify how well sand composition reflects tectono-morphologic provinces.

In correspondence of the coast investigated the more meaningful morphological characteristics are represented by the spits of the "Maricello" beach (south of Capo Vaticano) and of Gizzeria Lido. Their growth is determined mainly by the longitudinal transport directed NW-SE and coincident with the direction of the reigning sea (IV quadrant). While the dominant sea, WSW direction (III quadrant), is characterized by heights of wave h>5m and fetch >1000 km.

The geomorphological analysis obtained by comparison of cartography, orthophotos, and GPS data, has allowed establishing the evolutionary trend is in substantial accretion (fig.1): the average rate of progradation has been estimated, in the last 140 year, of about +700m. Most accretion (about +1 km) was observed at the beach of Lido Gizzeria, while the minimum accretion (about +400 m) was recorded in the tract immediately south of Capo Suvero. Although the general evolutionary trend of the coast, from 1870 to 2010, shows a significant accreting, from the overlapping cartographic, in the range 1954-1983, can be observed the presence of accentuated erosional phenomena. In this range time, the spit of Gizzeria Lido, with growth direction to north, was completely eroded. In the same range of time the formation of a new spit, with direction of growth to south, has formed a sandbar 320m wide. Same morphological evolution is also observed for the "Maricello" beach with erosion estimated in -140m, and subsequent formation of a spit always growing to south. During the range time 1990-1996, both spit are welded to the beach, forming a coastal lake along the "Maricello" beach and a lagoon in Gizzeria Lido. Between 2000-2005 period, new erosion of both coastal bars has been observed, and subsequent formation of two new spits in the period 2005-2007 always with direction of growth to south. The closure of two new spits occurs during 2007-2010 time, with the formation of two new coastal lakes.

The highly dynamic evolution of the beaches between Capo Suvero and Gizzeria, has directed research towards the analysis of longshore currents and their sediment transport direction. For this purpose a study was performed on petrographic characteristics of the sands and a morphological study of the river mouths. Morphological analysis demonstrates that, from Capo Suvero continuing northward, all river mouths have deviations to south, whereas from Gizzeria lido to South, these have deviations northwards. These data suggest that the longshore currents, from Capo Suvero to north, are oriented to south, whereas from Gizzeria towards southern coast are oriented to north. Therefore along the coastal portion "Gizzeria-Capo Suvero", two littoral currents with opposite directions occur. This assumption could justify the high dynamics of the beaches, where the erosion of spits and subsequent their new formation happens very quickly and, sometimes, with opposite directions of growth depending on the prevailing currents (from North to South or from South to North). At this time this hypothesis, supported by direct observations, is subject to further investigation by the analysis of heavy mineral in the sands. The purpose of the analysis is to verify the possible mixing between the contributions sedimentary from the Savuto and Amato River, respectively at North and at South of the coast studied.

The analysed sands define a lithic ($Q_{21}F_{18}R_{61}$) metamorphiclastic ($Rg_{11}Rs_8Rm_{81}$) petrofacies including high proportions of fine-grained schists and phyllite grains. The comparison between backshore and shoreface sand composition records mainly enrichment in quartz and a decrease in lithic fragments, although sand beach petrofacies as a whole does not change.

In summary, geomorphology and petrography of coastal sediments along the Tyrrhenian coast between Capo Suvero and Gizzeria Lido showed the following characteristics:

- although the evolutionary trend of the coast indicate a significant nourishment, from the overlap of the maps, the occurrence of erosional processes are active between 1953-1983 period;
- compositional analysis of sands sampled along the coast have identified a lithic ($Q_{21}F_{18}R_{61}$) metamorficlastic ($Rg_{11}Rs_8Rm_{81}$) petrofacies determined by an abundance of

(*) Dipartimento Scienze della Terra, Università della Calabria

significant fine-grained schist and phyllites reflecting provenance from crystalline rocks of the Catena Costiera range. In terms of QFR composition, sand maturity changes from backshore [$Q_{21}F_{18}R_{61}$; $Rg_{11}Rs_8Rm_{81}$] to foreshore [$Q_{24}F_{21}R_{55}$; $Rg_{11}Rs_4Rm_{85}$] environment by active coastal processes affecting sand composition and texture.

Future coastal hazard scenarios. A case study in NE Sicily (Italy).

VALERIA LO PRESTI [(1)], ATTILIO SULLI [(1)], FABRIZIO ANTONIOLI [(2)]

Key words: C*oastal hazard, NE Sicily, uplift rate, canyon heads, relative sea level projections.*

ABSTRACT

The coastal dynamics is the result of several causes that contribute to change the balance of beach deposits over time.

The beach system is not always able to maintain coastal balance: the factors contributing to this phenomenon are to be found in both natural and anthropogenic spheres.

In this context we present the analysis of marine geology and coastal geomorphological data of a sector between Rocca di Caprileone and Tindari (north-eastern Sicily) with the aim to: i) determine their onland-offshore area relationships, ii) analyze which natural features may contribute to coastal retreat, iii) present coastal hazard scenarios.

Until fifty years ago the natural balance of this coastal area led to the formation of extensive sandy-pebbles beaches alternating with rocky coasts and pocket beach. The construction of harbours of Capo d'Orlando and Sant'Agata di Militello and of various coastal defense structures, and the regimentation of rivers (here called Fiumare), have permanently destabilized the natural conditions of the coasts. Currently the coastline retreat, started from about fifty years, is a unresolved problem and of increasing entity.

According to VECTOR Project methodology (http://vector.conismamibi.it/), we calculate the prediction of sea level rise for 2050 and 2100 (IPCC, 2007; Rahmstorf, 2007).

INTRODUCTION

In the study area active tectonics (NIGRO and SULLI, 1995; GIUNTA *et alii*, 2009) and seismicity (CHIARABBA *et alii*, 2005) outline the current morpho-structural configuration of marine-terraces system. Previous studies showed that different factors make particularly susceptible this sector:

[1] University of Palermo

valeria.lopresti@unipa.it

[2] ENEA, Casaccia, UTMEATER, Roma.

1) the coastal uplift rates, measured for late Holocene and Last Interglacial (LIG, 125 ka BP) (SCICCHITANO *et alii*, 2011; SULLI *et alii*, 2012);

2) the activation of submerged and emerged morphologies influencing currents and sediments dynamics;

3) the occurrence of heads of submarine canyons near to the coastline that behave as preferential escape of sediments from the coast (Fig. 1) (LO PRESTI, 2010);

4) big storms (Fig. 2)

5) human interventions on the coast.

Fig. 1 – Canyon head near to the coastline. Multibeam data overlapping on Google Earth image .

Previous studies (ANTONIOLI *et alii*, 2009; SULLI *et alii*., 2012; SCICCHITANO *et alii*, 2011) showed different Holocene and Last Interglaglial (125 ka) uplift rates, 0.36-0.50 mm/y and 1.2-1.6 mm/y, respectively westward and eastward of the Brolo plain. This again demonstrates the control of major tectonic lineaments which shall release coastal areas and determine decoupled tectonic responses of these.

It's clear that coastal sectors registering tectonic uplift undergo continuous morpho-structural rebalancing processes and that their clear evidences are perceived in the long term. This continuous rebalance is reflected in the "young" morphologies that we can observe both in marine and terrace sector. Morpho-bathymetric data shows submarine canyons slopes and heads continuously reactivated by small submarine landslides. The sediment mobilized by up-slope retrogressive mass failures leads to steep gradients of the slopes and pulls back coastward canyons heads. These processes have led to the actual configuration characterized by a continental shelf-slope system engraved by submarine canyons structures. Some canyons heads occurs a few hundred meters away from the coastline, directing bottom currents and constituting an important escape for the coastal sediments.

Gully erosion, channel-levee systems and major submerged dunes in the inner part of the continental shelf provide information on bottom currents dynamics and demonstrate the high energy of hydrodynamic forcing.

This coastal sector records among the major marine events in the north Sicilian coasts. Storms with waves of Hs=6 m are registered during winter months and produce severe damage both to roads and railway and towns along the coast (Fig. 2).

Fig. 2 – High energy storm (Capo d'Orlando country, NE Sicily).

VECTOR Project provides us with an innovative methodology to predict future scenarios of coast-line position using IPCC (2007) and RAHMSTORF (2007) eustatic prevision of sea level rise, tectonic uplift rate and glacio-hydro-isostasy (GIA) data. According to this methodology we calculated the sea level rise (SLR) for 2050 and 2100 (Table 1-2) considering the glacio-hydro-isostasy data of 0.50 mm/y (LAMBECK *et alii*, 2011) and the two uplift rates measured in this area (SULLI *et alii*, 2012):

Table 1

Year	Scenarios	Uplift rate (mm/y)	GIH (mm/y)	SLR (mm)
2050	IPCC 2007	+0.43	0.50	298.5
2100	IPCC 2007	+0.43	0.50	597
2100	Rahmstorf 2007	+0.43	0.50	1407

TABLE 2

Year	Scenarios	Uplift rate (mm/y)	GIH (mm/y)	SLR (mm)
2050	IPCC 2007	+1.4	0.50	250
2100	IPCC 2007	+1.4	0.50	500
2100	Rahmstorf 2007	+1.4	0.50	1310

RESULTS

The direct relationship between rivers ("fiumare") and submarine canyons, only some tens of meters far from the coastline, reveal that the latter control the sediment removal from the coast, acting as preferential path. Mobilization of sediments is favored by high storm energy. Nevertheless until now the coastal system has been able to maintain the natural balance.

Because the coastal retreat started in the last fifty years, despite large defense, and coinciding with human intervention, we hypothetize the anthropogenic factors could upset the precarious balance in this area.

Prediction of future scenarios, calculated by using VECTOR methodologies estimates 1.3-1.4 m sea level rise for the year 2100, leading to the flooding of portions of beaches and portion of coastal plains. The predicted sea level rise "breaks" some balance and triggers landslides in sensitive areas as rocky coast.

The effects of relict sand dredging for beach nourishment on sediment composition at a dredge site in the central Tyrrhenian Sea

NONNIS O. (*), PAGANELLI D. (*), NICOLETTI L. & GABELLINI M. (*)

Key words: *relict sand, environmental studies, grain size, Mediterranean sea.*

INTRODUCTION

In 1999, Regione Lazio local Authority charged ISPRA to carry out some research projects in order to evaluate the effects of relict sand dredging aimed at beach nourishment on marine environment. The first environmental pilot project involved a relict sand deposit located offshore Anzio, in the Central Tyrrhenian Sea (figure 1). In this area, previous mineral investigations had revealed the presence of a sedimentary body covered by pelitic layer of recent deposition. This was interpreted as a sedimentary wedge of probable sandy nature deposited during the first phases of sea level rise in protected-sedimentation areas and later covered by fine sediments (CHIOCCI & LA MONICA, 1996; BEACHMED, 2003).

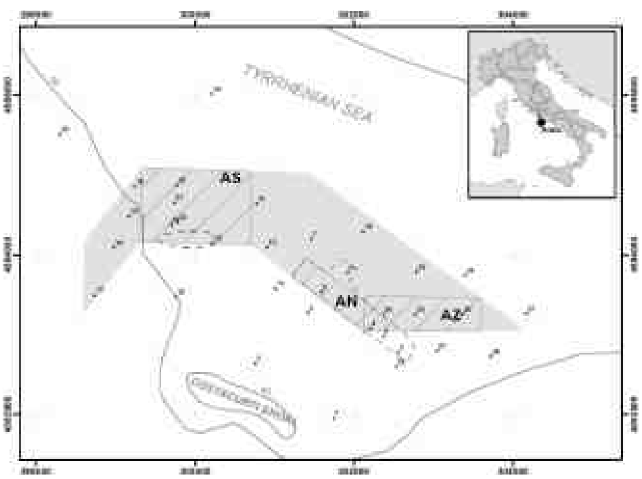

Fig. 1 – Polygon suitable for relict sand dredging (light grey), authorized dredging sites AN, AZ and AS (rectangles), area actually dredged in 1999 (dashed), sample stations (dots).

(*) ISPRA- Institute for Environmental Protection and Research, Via Vitaliano Brancati, 60- 00144 Roma

In Anzio area, dredging activities were carried out from 1999 to 2007 in three different and contiguous dredging sites (named AN, AZ and AS) (figure 1). During the 1999 dredging, the authorized area within site AN was dredged only partially, as the most intense dredging activities were carried out southeast of the authorized area. Further superficial dredging activities were carried out near the AN site and 1 km northwest of the authorized site, in proximity to site AS (dredged in 2007). In sites AZ and AS, instead, the operations respected the authorized boundaries.

For each dredging site environmental investigations were carried out by ISPRA before and after the dredging activities (table 1). These environmental studies encompassed bottom morphology and bathymetry, surface sediment grain-size and chemistry, water column hydrology and hydrodynamics, characteristics of the particulate matter and of the benthic and demersal fish assemblages (NONNIS *et alii*, 2002; 2011; BARBANTI *et alii*, 2005; MARZIALETTI *et alii*, 2006; NICOLETTI *et alii*; 2006; LA PORTA *et alii*, 2009).

In this paper we present and discuss the results of grain size analysis performed on 173 samples of surface sediments collected during 12 sampling surveys (table 1). In particular, this paper focuses upon the physical impact in term of grain size variation of surface sediment induced by relict sand extraction.

Table. 1 – Dredging activities and environmental surveys in the Anzio deposit.

It's well known, in fact, that the relict sand dredging may have significant physical (substrate and water column) and biological (benthic and demersal fish assemblages) effects on the marine environment (NEWELL *et alii*, 1998; 2004; HITCHCOCK & BELL, 2004; BARBANTI *et alii*, 2005; SANDPITT, 2005; HILL *et al*., 2011; TILLIN *et alii*, 2011).
The most important physical effects of relict sand dredging are related to substratum removal and include alterations to the nature of the seabed in terms of topography and sediment composition (NEWELL *et alii*; 1998; DESPREZ 2000; BOYD & REES, 2003). Intensive dredging activities can determine a substantial lowering of the seabed across a wide area. Such changes to topography and reductions in the depth of the seabed may have an impact on the local hydrodynamic regime, disrupting local current strengths and altering patterns of sedimentation (HILL *et alii*, , 2011). Instead, the removal of sediments from the sea bed, particularly when these overlay layers of different sediments, can have a significant impact on the overall sediment composition.

RISULTATS AND DISCUSSION

In site AN (dredged in 1999), the pre-dredging grain size analyses gave the following results: moving from north to south, the sediments first presented significant percentages of silt and clay, then they showed mixed granulometry (loam) and, in the southernmost sector, they were sandy, containing a significant biodetritic component. Within the more intensely dredged area, 4 months after dredging, sediments were found to be in general very pelitic: on 12 samples analyzed, only 2 presented significant and variable sand percentages (respectively 30% and 90%). These results can be interpreted with the specific technical methods of dredging that can cause the collapse of the overlying pelitic levels (NONNIS *et alii*, 2011). Slumping of the walls may also have occurred, and this may have been intensified by the significant depth of the holes caused by intensive dredging. Concerning the more superficially dredged sectors, surveys carried out 4 months after dredging revealed the presence of sandy sediments (40-50%) in two stations and very sandy in one station (<90%). In all three stations, a considerable increase in the fine fraction was recorded 9 months after dredging.

In the stations close to the dredged areas and in those located at a certain distance, 9 months after dredging the grain size distribution of the sediments were considerably heterogeneous and showed no significant trends. In various stations, however, it was possible to observe a decrease in the pelitic fraction and an increase in the sandy fraction.

Finally, in the control stations, the sediment samples collected after dredging showed a substantially unaltered distributions and a non-negligible increase in the pelitic fraction in the other station.

The surveys carried out on AZ site (dredged in 2003 and adjacent to site AN, dredged in 1999) before dredging indicate the presence of loam and silty-clayey sediments in the easternmost portion of the area (not affected by the 1999 dredging) and of heterogeneous sediments of variable grain sizes – ranging from silty clay to clayey silt and sand – in the western sector, partially dredged in 1999.

Within the dredged area, 4 months after dredging, are present sediments with very high percentages of sand (> 95%). Six months after dredging, a modest quantity of fine fraction (ca. 10%) was also observed an interpreted with the recovery of the shelf's sedimentation process. Indeed, after 6 months from the end of the dredging activities, this contribution to sediment characterization was fully restored and significantly active. In one station, which underwent heavy dredging in 1999, an important increase in the sandy fraction has been observed following the 2003 dredging operations.

In the stations, superficially dredged in 1999, results were variable: one station did not show any significant granulometric variations, while another station recorded an important increase in the sandy fraction.

In the area not affected by the 1999 dredging but dredged in 2003, sediments did not show any substantial granulometric changes. However, in this area, in one station, situated in southeast sector, sediments initially (after 4 months) showed an increase in sandy fraction and, subsequently (after 6 months), an increase in the fine fractions.

In the stations located in the northern, eastern and southern sections of the dredged area (not affected by the 1999 dredging), sediments did not show any substantial granulometric variations. In one station (and also not affected by the 1999 dredging), sediments initially showed an increase in sandy fraction (ca. 15% after 4 months) and, subsequently, an increase in the fine fractions (ca. 10% after 6 months).

In the AS site (dredged in 2007), before sand extraction, are found sediments with mixed granulometries (loam) with a typical bimodal distribution. Moving landwards, are present pelitic sediments (clay silt), while moving seawards and towards the Shoals has been observed a transition toward coarse sediments (clay sands), with a prevailing bioclastic composition in the sandy fraction.

Within the dredged area, 4 months after dredging, the sediments were very sandy (fine fraction < 5%), while 9 months after dredging, the fine fraction increased of 10%. This increase can be interpreted as a recovery of the shelf sedimentation processes, as already recorded in the AZ site.

On the opposite, the stations situated around the dredged site did not present any substantial grain size changes after dredging, except in a station located close to the westernmost border of the authorized area, that showed a 20% increase in its sandy fraction. The variations recorded in this station can be interpreted as the effect of the light dredging activities carried out in this sector. Another notable result outside the dredged area is an increase of 20% in fine fraction observed in a station located in the southern sector of dredging area.

CONCLUSION

The surveys carried out in the Anzio relict sand deposit - which has undergone three different dredging operations for the exploitation of a relict sand deposit aimed at nourishment– allowed to evaluate grain size changes of surface sediments related or caused by dredging operations.

Within the dredged areas, a clear granulometric variation in the surface sediments was observed right after dredging and was interpreted whit the outcropping of relict sands. Relating the non-negligible increase in the pelitic sedimentation, recorded as soon as 6 or 9 months after dredging, this could be explicated to the re-deposition of the turbidity cloud generated by the overflow, that conditioned by the presence and thickness of pelitic layer and also to the shelf's pelitic sedimentation.

The results of this study confirmed that one of the most relevant factors in determining granulometric variations seems to linked to both the site's characteristics (in terms of grain size of surface sediment) (Hitchcock e Bell, 2004) and to the operational methods of the dredging activity. Indeed it is well-known, according to (Hill) that the technical-operational methods are among the main parameters used to define the intensity and characteristics of dredging-linked disturbances.

The role of seabed mapping techniques in environmental monitoring related to relict sand dredgings for beach nourishment: the Anzio case

NONNIS O. (*), PAGANELLI D. (*), NICOLETTI L. (*) & GABELLINI M. (*)

Key words: *relict sand, environmental studies, geophysical investigations.*

INTRODUCTION

Beach nourishment with relict sands has been carried out for several years as a way to counter coastal erosion problems. It has proven to be a successful beach protection method (ISPRA, 2009) and it is considered to be one of the main tools for coastal management. It is however known that relict sand dredging may have significant physical and biological effects on the marine environment (seabed, water column and benthic and fish assemblages), especially in highly biodiverse environments and sensitive habitats, such as the Mediterranean marine-coastal system.

Within this framework, since 1999 ISPRA (formerly ICRAM) has performed specific environmental studies related to relict sand dredging aimed at beach nourishment of a deposit situated offshore Anzio (Central Tyrrhenian sea) (Figure 1), in order to assess the effects of relict sand mining on the marine environment (NONNIS *et alii*, 2011; PAGANELLI *et alii*, 2005, 2007; LA PORTA *et alii*, 2009).

The present study focuses on the physical impact of relict sand extraction, and aims to examine the results of acoustic investigations performed before and after the dredging activities in Anzio deposit. These techniques represent an essential tool for an effective management of the marine environment and are particularly useful to accurately study the impact of human activities on the seabed (BOYD *et alii* 2006, KRAUSE *et alii* 2010).

METHODS

Dredging activities were carried out from 1999 to 2007 in three different and contiguous dredging sites within the Anzio area (named AN, AZ and AS), showed in figure 1. During the 1999 dredging operations, the authorized area within site AN was dredged only partially, as the most intense dredging activities were carried out southeast of the authorized area. Further superficial dredging activities were carried out near the AN site and 1 km northwest of the authorized site, in proximity to site AS (dredged in 2007). In sites AZ (dredged in 2003) and AS, the operations respected the authorized boundaries.

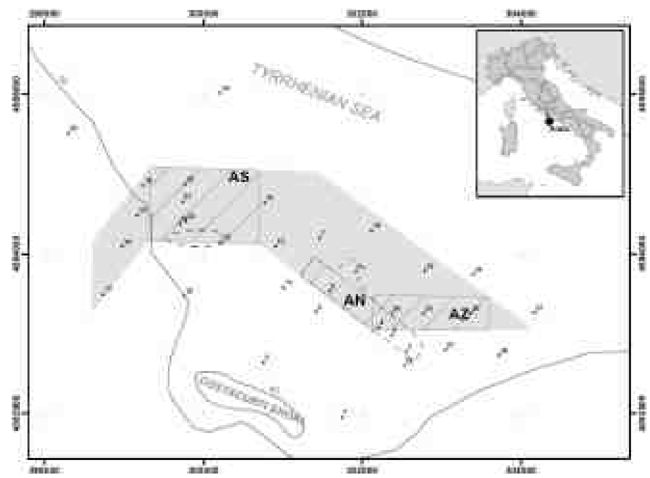

Fig. 1 – Polygon suitable for relict sand dredging (light grey), authorized dredging sites AN, AZ and AS (rectangles), area actually dredged in 1999 (dashed), sample stations (dots).

For each site, acoustic investigations (side scan sonar and multibeam) were performed before and after the dredging in seven surveys (table 1).

Site	Activities	Time
AN	SSS –MBES surveys	04/1999
	Dredging	06-10/1999
	SSS –MBES surveys	03/2000
	SSS –MBES surveys	11/2000

RESULTS AND DISCUSSION

The first geophysical survey was carried out in 1999, before the dredging of the whole polygonal area, which is much wider than the area authorized for dredging (AN site). The results showed a morphologically irregular sea bottom due to the presence of the Costacurti Shoal in the southern sector; the isobaths are generally oriented NW-SE and their depths vary between 40 and 70 m. The shoal, oriented NW-SE, is about 1600 m long and houses a meadow of Podisonia oceanica. Most of the study area proved to be characterized by the typical acoustic facies of sediments that are mainly pelitic, while the acoustic facies in a wide area to the NE of the Costacurti shoal indicates the presence of mainly sandy superficial sediments with a biodetritus component.

Geophysical investigations carried out after dredging of site AN (1999) highlighted the presence of dredging-caused tracks in an area oriented NW-SE, between 300 and 750m wide and 2000m long (figure 2).

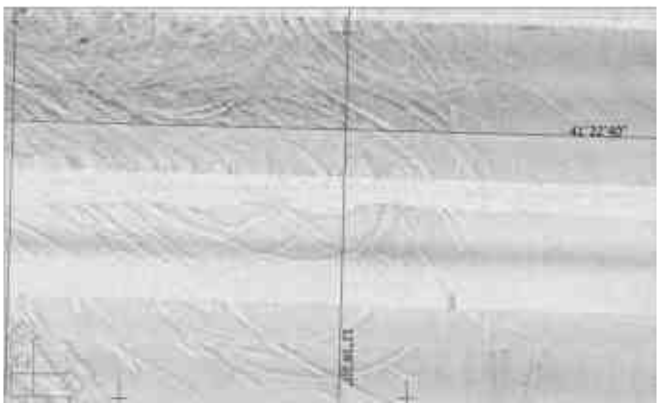

Fig. 2 – Side Scan Sonar image recorded in AN site after 1999 dredging, showing how the sector underwent more intense dredging and numerous tracks left by the dredge's head. Survey carried out in June 2002.

Within this area, a sector measuring about 300x900m underwent more intense dredging. This sector presented a pelitic sonar facies (due to the overlapping of the numerous tracks left behind by the dredge's head), and its bottom was 5÷6m deeper than it was in the pre-dredging period (-45m).

The heaviest deepening was observed at the base of the scarps, while the central zone was up to 2÷3m higher. Around this area, the bottom presented disturbances caused by extraction activities of lower intensity, and it was possible to observe the single tracks left behind by the dredge's head, lined up parallel to one another or crossing each other, all with a prevailing NW-SE orientation. These tracks were ca. 5m wide and 0,5m deep, down to a maximum of 1,5 m. Geophysical investigations showed that the dredging of site AN (1999) also caused a superficial removal in the southernmost section of the AS site (figure 5).

The second dredging operations were conducted in 2003 in a sector called AZ, that was adjacent to formerly dredged site AN. The geophysical analyses carried out before dredging were limited to the actual dredging corridors and revealed the signs of the 1999 dredging.

The surveys performed after removal activities defined the size and extension of the dredged area, which ended up being 1500x450 m wide. The area is characterized by a chaotic sonar facies with low backscatter features, due to the overlapping of the dredge tracks, and its bottom is deeper by ca. 7÷8m (51-52m of depth) than in pre-dredging period. In this case, too, the central portion of the removed area resulted to be higher, by 1-2 m, than the base of the scarp, which marks the area's deepest point. In the western extremities of the area, 25-30 single tracks (5-6 m wide) can be recognized, extending to the outside of the removed area in direction EW for 100-150m.

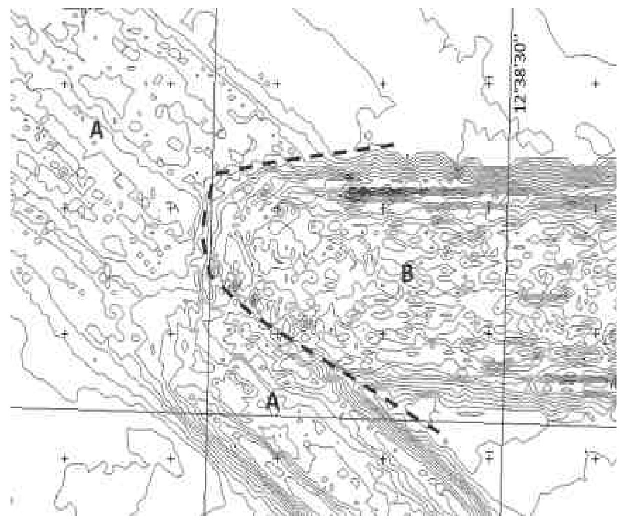

Fig. 3 – Bathymetric map showing the boundary (dashed line) between the AN site dredged in 1999 (A) and the AZ site dredged in 2003 (B). Multibeam survey carried out in May 2003.

These investigations highlight the partial overlapping between the area dredged in 2003 and that removed in 1999 (figure 3); in particular, the western portion of the AZ site is situated in close proximity to the northwestern extremity of the AN site, therefore a small part of the bottom removed superficially in 1999 was further dredged in 2003. Apart from this limited sector, no recent signs of the 2003 dredging have been found on the area dredged in 1999. This suggests that the boundaries of the authorized area have been respected.

Side scan sonar investigations carried out in the AS site area before dredging revealed medium backscatter features and showed the superficial signs left behind by the suction dredge in 1999. The bathymetric investigations (multibeam) carried out at the end of the removal activities allowed to define the size of the more intensely dredged area, which turned out to be about 850x950m wide, and is situated right by the signs left by the 1999 dredging operations. In this area, the bottom is characterized by a significantly irregular surface due to the presence of hills and depressions, created by the overlapping of a great number of holes left by the dredge; the deepest holes are found in the southern and western sectors. To the east of this area, it is possible to observe another sector about 900x400m in size, which underwent superficial dredging (figure 4).

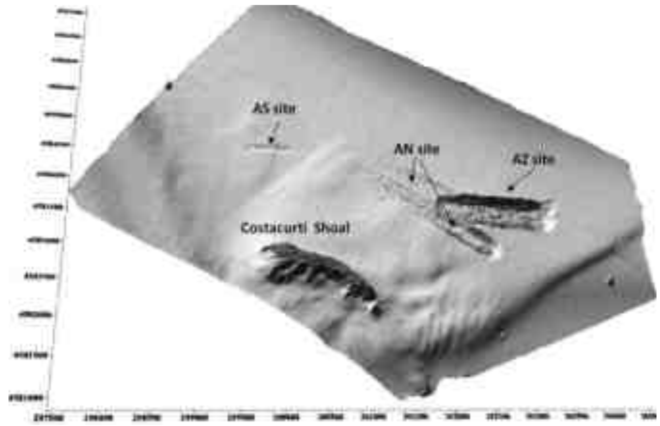

Fig. 4 – Dredging activities carried out in the Anzio area in 1999 (B) and in 2003 (C), and on the Costacurti Shoal (A) highlighted by Multibeam echosounder recorded in 2003.

CONCLUSION

The acoustic surveys carried out in the Anzio relict sand deposit allowed to evaluate the physical impacts of dredging on the sea bottom. In particular, these surveys highlighted that there is a clear difference, in terms of disturbance and deepening of the sea bed, between the areas that underwent intense dredging and those dredged only superficially (i.e. the areas affected by fewer dredge movements). In the Anzio case, unfortunately, the acoustic surveys did not provide information on any morphological recovery processes because of the limited number of *post operam* surveys, often carried out at a too soon after the dredging. Further, the low number of surveys and the time-scale used, both of which factors were dictated by economic factors, did not prove adequate for evaluating possible recovery processes in the long term.

In general, although the development of a depression generates a sedimentary trap that captures sediments from the adjacent areas (SANDPIT, 2005), recovery of the depressions generated by dredging is quite slow, especially in areas characterized by low hydrodynamics (HILL *et alii*, 2011; KRAUSE *et alii* 2010). Furthermore, recovery times are highly variable, and are often site-specific and dependent on the combination of local conditions, dredge type, dredge practices, local hydrodynamics, sediment composition and intensity of dredging (HILL *et alii*, 2011).

The use of mapping techniques, such as side scan sonar and multibeam echosounder, is an excellent tool to evaluate the possible recovery of the sea bed's topography in the long run, especially if these surveys are systematically repeated after removal activities (for example after 2, 5, 10 and 15 years).

In conclusion, based on what we just exposed, we can state that acoustic surveys are useful to clearly define the boundaries of the dredged area, and the entity of the dredging itself in terms of exacted volumes and possible recovery of the sea bed's topography. These surveys are also a valid support tool to manage the exploitation of relict sand deposits, with the aim of evaluating the possible recovery of the sea bed's topography after a dredging activity.

ISPRA's experience in environmental studies related to relict sand dredging for beach nourishment

DANIELA PAGANELLI (*), ORNELLA NONNIS (*), PAOLA LA VALLE (*), CHIARA MAGGI (*), LUISA NICOLETTI (*) & MASSIMO GABELLINI (*)

Key words: *environmental studies, relict sand dredging, beach nourishment, Mediterranean sea.*

Beach nourishment (a beach restoration method consisting in placing appropriate material on the eroded beach) has been carried out for several years as a way to counter the problem of coastal erosion, and is considered one of the main coastal management tools. The material used for nourishment can originate from various environments, such as riverbeds, quarries, coastal environments (dredging of river mouths and navigable canals), or relict sand deposits. Using relict sands has several advantages: it guarantees a higher availability of large quantities of sediments (millions of m^3) whose composition is potentially similar to that of the beach's native sands; in addition, the use of relict sands is economically advantageous, especially when using large volumes of sediment.
However, relict sand dredging activities for beach nourishment may have cause significant effects on the environment. The main physical effects are related to morphological and sedimentological changes on the sea bottom, and to the alteration of the chemical-physical characteristics of the water column due to sediment re-suspension (HITCHCOCK & BELL, 2004; SANDPIT, 2005; TILLIN *et alii*, 2011). The most relevant biological effects are instead related to the benthic communities and to the demersal fish assemblages, both associated with the sea bottom (VAN DALFSEN *et alii*, 2000; GREEN, 2002; NEWELL *et alii*, 2004; SPEYBROECK *et al*., 2006; COOPER *et alii*; 2011; HILL *et alii*, 2011). Removal activities could have significant effects, especially in the presence of habitats and/or species that are particularly sensitive to changes in their abiotic parameters and to environmental stress, such as *Posidonia oceanica* meadows (BOUDOURESQUE *et alii*, 2006). In Italy, the first relict sand dredging operations for beach nourishment date back to the last decades of the past century, and have involved about 14,7 millions of m^3 of sandy sediments (ISPRA, 2009) obtained from some relict sand deposits located both in the Adriatic Sea (9,1 million m^3) and in the Tyrrhenian Sea (5,6 million m^3).

Since 1999, ISPRA has carried out environmental monitoring studies related to relict sand dredging aimed at beach nourishment (Nonnis *et al*., 2002; 2011; Nicoletti *et al*., 2005; Marzialetti *et al*., 2006; Paganelli *et al*., 2007a; 2007b; La Porta *et al*., 2009) in some deposits located both in the central Tyrrhenian (3 dredging sites) and in the Adriatic Sea (2 dredging sites) (table 1). The environmental effects of beach nourishment along the Latium and Marche coasts were also analyzed (La Valle, 2006; La Valle *et al*., 2011; Targusi, 2011).

Table 1 – Environmental studies carried out by ISPRA related to relict sand dredging for beach nourishment, from Nicoletti *et al*. (2009).

Study Areas	**Environmental studies**		**Dredging activities**	**Environmental surveys**
	From	**To**		
Anzio (Rome), Tyrrhenian Sea	1999	2008	3	14
Montalto di Castro (Viterbo), Tyrrhenian Sea	2001	2007	2	9
Torvaianica (Rome), Tyrrhenian Sea	2003	2007	1	6
Ravenna, Adriatic Sea	2001	2004	1	8

The large collection of environmental data (related to bottom morphology and bathymetry, surface sediment grain-size and chemistry, water column hydrology and hydrodynamics, characteristics of the particulate matter and of the macrozoobenthic and demersal fish assemblages) and comparisons with the extra-Mediterranean experiences (CAMPBELL, 1993; VAN DALFSEN *et alii*, 2000; ICES, 2003; HITCHCOCK & BELL, 2004; NAIRN *et alii*, 2004, Newell *et al*, 2004) have provided the basis to create and propose an environmental methodological protocol that is suitable for the peculiar Mediterranean environment (NICOLETTI *et alii*, 2006; 2009).

This protocol foresees a specific environmental monitoring study, involving a characterization –or *ante operam*– phase and a monitoring phase, to be carried out in the dredging, transport and nourishment areas. The characterization study is subdivided into 3 phases: a bibliographic review on a regional scale, an experimental characterization study on a wide scale (related to the area containing the sand deposits), and an experimental characterization study of the dredging and nourishment sites. The monitoring study involves different surveys aimed at evaluating the effects of dredging and nourishment during activities, and the effects after activities in

(*) ISPRA- Institute for Environmental Protection and Research, Via Vitaliano Brancati, 60- 00144 Roma

the medium-long term (monitoring *post operam*). The environmental surveys to be followed and the parameters to investigate in each area and in each study phase are summarized in Table 2.

Compared to the data reported in the specific environmental protocols for extra-Mediterranean experiences (Campbell, 1993; ICES, 2003; NAIRN *et alii*, 2004, NEWELL *et alii*, 2004), the protocol we propose introduces some simplifications linked to the non-interference of relict sand dredging with coastal dynamics, and some innovations linked to the peculiar biotic and abiotic characteristics of the Mediterranean basin, mainly related to the chemical characterization of sediments in the dredging area and to the environmental monitoring of beach nourishment in the presence of *Posidonia oceanica* meadows (NICOLETTI *et alii*, 2009).

The possible effects that offshore sand dredging may have on coastal dynamics are controlled by various factors, such as the deposit's depth and its distance from the coast, the characteristics of wave motion, both offshore and nearshore, the size of the dredging site and the quantities of material dredged (HAYES & NAIRN, 2004; SANDPIT, 2005).

Due to the geographic position of sand deposits and the physical characteristics of the Mediterranean basin, dredging activities along the Italian continental shelf have a negligible effect on coastal dynamics.

Concerning the dredging area's chemical characterization, previous experiences have shown that the analysis of the total concentration of metals (commonly used in environmental characterization studies) is not enough to evaluate sediment quality in areas presenting high concentrations of a certain element (geochemical provinces). The present protocol therefore recommends the use of analyses that allow to examine the mobility of the metals present in the sediment, thus providing useful information about the quality of the marine sediments (MAGGI *et alii*, 2006; PAGANELLI *et alii*, 2007a).

When nourishment operations occur in the presence of *Posidonia oceanica* meadows, experiences have shown that certain characteristics and/or operational procedures, such as the dredge's draught, the timing of the dredging, the ways in which the dredge is kept in a certain position during operations etc., all of which are unknown in the planning phase (and therefore during the environmental characterization phase) may produce significant effects on the marine environment (PAGANELLI *et alii*, 2007b). Based on the above observations, environmental monitoring during operations becomes an essential tool to verify the actual effects on sensitive habitats, and regardless of the results of the *ante operam* environmental characterization studies, and this allows to intervene quickly and to minimize any possible negative effects.

Table 2 - Parameters to investigate according to the Environmental Monitoring Protocol related to relict sand dredging for beach nourishment (from Nicoletti *et alii*, 2009).

Legend: D = dredging area; N = nourishment are; T = transport area; (1) only in the area and/or in the stations situated within the dredging corridor; (2) only in the stations situated within the dredging area, should the sands to be used for nourishment be outcropping sands, thus lacking pelitic cover; (3) in at least 3 cores, to be extracted from the dredging area (as defined in the authorization request), should the sands to be used for nourishment be outcropping sands, thus lacking pelitic cover; (4) monitoring of the turbidity plume; (5) only in specific cases such as in presence of sensitive habitats.

Mapping of flood risk in Emilia-Romagna coastal areas

LUISA PERINI (*), LORENZO CALABRESE (*), GIOVANNI SALERNO (*) & PAOLO LUCIANI (*)

Key words: *flood directive, sea flood, coastal hazards, coast management, defence, GIS*

INTRODUCTION

The exceptional sea levels rise, caused by sea-storms especially when associated with surges, induce high risks of coastal flooding. For this reason the European Union included this topic as target of Directive 2007/60/EC (EFD), which has been transposed into the Italian legislation by means of law decree no. 49/2010.

The analysis carried out within EU Cenas (Yu *et alii* 1994) and MICORE (MASINA & CIAVOLA, 2011) have shown that storm surge phenomena frequently occurs in northern Adriatic and along the Emilia-Romagna coasts, in particular during the autumn and winter seasons. Surges are often associated with sea-storms, that contribute to sea-level rise producing a "wave set-up", which ranges between 10 and 45 cm along the Emilia-Romagna coast (DECOUTTERE *et alii* 1997). The catalogue of "historical sea-storms" realized within MICORE project, highlights that impacts due to flooding of beach, tourist infrastructures and even urban centres (fig. 1), are particularly frequent in lowland areas of the Ravenna and Ferrara provinces (PERINI *et alii* 2011). The catalogue provides GIS mapping of the impacted areas and damage analysis, indicating about 15 localities being particularly affected by sea-flooding.

According to the decree law n. 49/2010, the Geological Seismic and Soil Survey (SGSS) of the Emilia-Romagna Region, involved in the project by the "River Basin District Authorities", is processing the drafting of sea-flood hazard maps, which have to be delivered by June 2013.

METHODS AND RESULTS

In order to build up sea-flood hazard maps at a regional scale, as requested by EFD, the SGSS has developed an analysis model based on GIS technology that allows to perform a mapping in a timely and cost effective way.

It represents a first step of a more complex procedure which combine such a cartographic output with the historical data and with results provided through previous studies carried out by SGSS in collaboration with local Universities (ARMAROLI *et alii* 2007, ZANUTTIGH *et alii* 2011)

Fig. 1 – Valverde (FC) flooded in January 1986

The GIS analysis mainly consists in the intersection of the sea level surface, for each considered surge and sea-storm scenario (return period of 1, 10 and 100 years), with a high-resolution digital terrain model provided using LIDAR technique.

Surge, tide and wave set-up were considered to define reference sea levels and, in the absence of statistical analysis for the combined return period, the worst-case scenarios for T1, T10 and T100 were assumed, considering the sum as the simultaneous occurrence of the three effects. The values used are from previous studies (tab. 1, Yu *et alii* 1994, MASINA & CIAVOLA, 2011) and the comparison with real events recorded within the 'historical storm catalogue' has confirmed the validity of the method.

The following and more complicated step was the determination of an attenuation factor to express the dissipation of waves on the beaches and of the flood landward. This factor takes into account as dissipation forces, the distance from the shoreline and the altitude. The attenuation factor corresponds to a landward inclination angle of the sea level surface whose co-tangent has a value of 0.002 and it was determined using the maximum run-up and flooding lines observed during real past events.

The distance from the shoreline has not been considered as the Euclidean one, but it follows shortest paths for the water to reach the different areas (and therefore almost always greater than the Euclidean distance). This analysis was possible by

(*) Servizio Geologico, Sismico e dei Suoli – Regione Emilia-Romagna

using the ArcGIS tool "Cost Distance Spatial Analyst" . The altitude value was used as incremental dissipation factor for distance.

Tr (Years)	Surge	Mean high tide	Set-up	Total elevation sea surface
Tr 1	H critic = 0,61	0,4	0,22	1,22 m
Tr 10	H critic = 0,79	0,4	0,3	1,49 m
Tr 100	H critic = 1,02	0,4	0,39	1,81 m

Tab 1 – Sea level surface values considered in the three different scenarios

The result of the GIS models is a raster matrix in which each cell has a value as a function of the distance from the shoreline and of the depth from the reference sea levels. In the model, only areas below the sea level surface, connected to the shoreline, are included in the calculation and in the maps.

The dissipation is minimal for small distances and high values of depth (high water column) while the maximum is for large distances and shallow depths (low water column).

CONCLUSION

The proposed simplified method is a response to lack of time and resources and it has already produced a sea flood hazard map prototype of along the entire regional coast. It however required a basic data set, as high resolution DTM and sea-storm parameters analysis. A more comprehensive map can be obtained by considering historical data and run-up computation and measurements, that allow to validate and correct the model outputs.

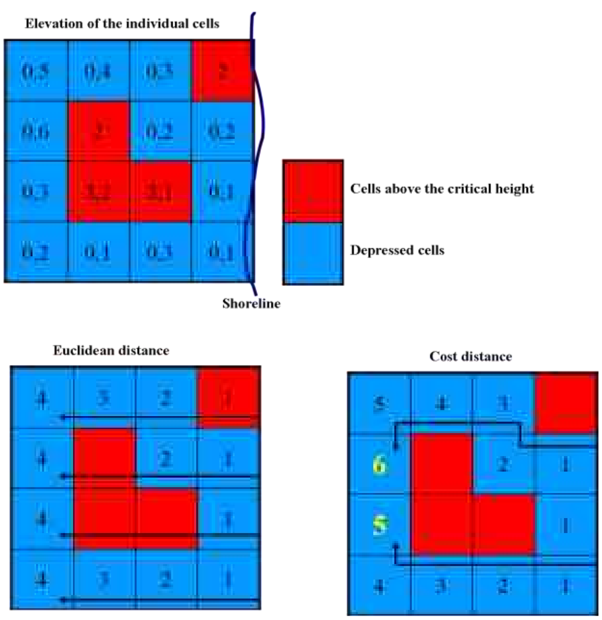

Fig. 2 – Applied method scheme

Fig. 3 – Example of map

The following step, indeed, will consist in the comparison of the sea-flood hazard map prototype with:

- Sea-storm hazard maps (T1-T10-T100 scenarios) based on run-up computation along 500 m spaced beach profiles (Perini *et alii* 2010).
- Maps of hystorical flooded coastal areas obtained by data stored in the 'historical sea-storm database'.

This activity is currently in process and it will be followed and completed by in situ GPS measurements of evidences of the next significant sea-storms as the run-up line.

Key words: *cellular automata, sand deposit/erosion, coastal erosion assessment.*

INTRODUCTION

Coastal erosion is a growing phenomenon that is increasingly causing difficulties both from environmental land management and social and economic point of views. Three processes are considered, over time scales consistent with natural hazard analysis: sea level rise, changes in storm climate, human interference. Such global causes are differently evaluated by scientific communities. Generally, such phenomena are addressed by PDE with classical approaches, only since recent times, alternative approaches had been used such as Cellular Automata (CA) methodology. In dealing with macroscopic complex systems, an extension of classical CA, i.e. macroscopic CA [DI GREGORIO S., SERRA R] were developed in order to model complex macroscopic fluid-dynamical phenomena, difficult to be modelled in other CA frames. Macroscopic CA can need a large amount of states that describe properties of the cells (e.g., altitude, depth of bottom sea, ..) called substates. The third dimension may be enclosed in substates for surface phenomena. In the past, the erosion problem by CA approach was described and modelled by: (D'AMBROSIO *et alii*, 2001) soil erosion by rain (SCAVATU model); (CHOPARD *et alii*, 2000) transport, deposit and erosion by sand and snow; (CHOPARD *et alii*, 2000; KUBO *et alii*, 2005) subaerial-subaqueous flow-like landslides (AVOLIO *et alii*, 2012). In this contribution, we aim to show, adopting CA, how it is possible to model and simulate dynamics of the coastal erosion complex phenomenon integrating empirical observation. After geomorphological considerations of the experimental site and a brief description of empirical observation and considerations, the very preliminar CA model RUSICA (RUdimental SImulation of Coastal erosion by cellular Automata) is sketched and then experimental results are described (CALIDONNA *et alii*).
Finally, some conclusions and perspectives of this work are outlined.

EMPIRICAL OBSERVATION AND CONSIDERATION ABOUT COASTAL EROSION IN A CA VIEW

Erosion of sandy beaches involves a redistribution of sand among the emerged and submerged coastal environments, which occurs mainly (but not only) during storms. The grains, which are re-suspended and transported by the waves and carried along shore and offshore, partially return to the beach after storms by the long-period swell waves during normal meteorological and oceanographic conditions. Exchanges between sandy beaches and dunes are fundamental to keep a morphological depositional equilibrium in the medium term. Many coastal areas of the world, both natural and anthropised, are presently interested by these processes and the most vulnerable sites are subject to drastic morphological and sedimentological changes even in the short term.
Such a complex phenomenology of coastal erosion is modelled by "macroscopic" CA viewpoint according to an incremental strategy: the RUSICA (RUdimental SImulation of Coastal erosion by cellular Automata) model is based from an original simple model that may be gradually enriched and/or more accurately refined in order to simulate the phenomenon evolution at a satisfying level of precision. Simplified hypotheses are here adopted and shortly described in the following.
Equivalent sand cover (an average type of sand) may be assumed without a continuous variation of sand properties. Water covers the shore from the sea level up to a height dependent on wind intensity and direction or/and tide height or/and sea current intensity and direction without explicit wave movement. Sand flows are averaged in time (no explicit turbulence and movement alternation), but along a computed direction between slope, wind

and current directions. The wind transmits energy from the sea surface eventually down to the sea bottom, depending on its intensity, type and sea depth. Shallow sandy/porous/rock-solid but irregular bottom involves larger energy loss. Such an energy permits (by turbulence) sand suspension in water up to a maximum possible quantity. When energy drops e.g. by water complex interaction with subaerial or submarine obstacles, sand sedimentation occurs.

Sand sedimentation and erosion may occur contemporary. Flows of free sand are determined according to a (corrected) minimization algorithm (DI GREGORIO & SERRA , 1999). Sand flow may overcome obstacles only when the slope is larger than a threshold according to the energy. Free wind generates free surface wind by propagation from the borders of CA: it implies that updating needs a shortest time step (less than a minute) only when the wind changes: this problem may be solved by introducing a coupled CA that works only when wind changes. Obstacles (cliffs, artificial barriers of different type) can locally affect wind direction and speed and sea current direction-speed.

THE RUSICA MODEL

The RUSICA model is a two-dimensional CA with hexagonal cells, with substates and the transition function defined as follows:

$$RUSICA = \langle R, G, X, S, P \rangle$$

- R identifies the set of regular hexagons, where the phenomenon evolves.
- G represents the cells at the border of R, where the wind could be generated.
- X = {(0, 0), (0, 1)(0,-1)(1, 0)(-1, 0), (1, 1), (-1,-1)} specifies the neighbourhood (the central cell and its 6 adjacent cells.
- $S = \{S_A \times S_D \times S_{TH} \times S_{WE} \times S_{SWE} \times S_C \times S_F \times SX_C \times SY_C \times SX_{FW} \times SY_{FW} \times SX_{SW} \times SY_{SW}\}$ is the finite set of states (of the finite automaton embedded in the cell) respectively: the cell altitude (or sea bottom depth), the cell sea water depth, the sand layer thickness, the average (for a step) kinetic energy of wind inside the cell, the average kinetic energy of sea water inside the cell, the sea water average sand concentration, the suspended sand flows, normalized to a thickness, from the central cell toward any adjacent cell, the x-y components of sea current speed, the x-y components of freewind speed, the x - y components of surface wind speed. Some third dimension substates are made explicit in the Fig. 1.
- $P = \{p_a, p_t, p_d, p_{et1}, p_{et2}, p_{slv}, p_{sm}, p_{sd}, p_{rs}\}$ is the set of the global physical and empirical parameters, which account for the general frame of the model and the physical characteristics of the phenomenon, respectively considering: the apothem of the cell, the time interval corresponding to a CA step, is the decay parameter for kinetic energy variation according the sea depth, the two energy transfer coefficients; parameter for sea level variation; two parameters of sand

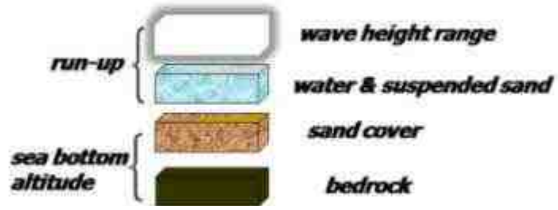

Fig. 1 – Vertical scheme according to the model substates, making explicit the third dimension

mobilization and deposit; and finally there is the relaxation parameter (0 1) for suspended sand flows.
- $\sigma: S^7 \rightarrow S$ is the deterministic transition function, composed by the following "elementary" processes:

1) Suspended sand outflows determination;
2) Variation of sand cover thickness and suspended sand concentration by sand cover mobilization and sand deposit; and
3) Composition of suspended sand concentration in the water inside the cell (remaining suspended sand more inflows) and determination of thickness of sand layers.

EXPERIMENTING EROSION CONTRAST

The study area, Porto Cesareo site, is located at the nord-eastern Ionian coast in the Apulia region in South Italy), which represents a significant example of Mediterranean type low-lying coastal landscape with different kinds of human activities and some important areas of environmental and archaeological interest.

Such a region, similar in geomorphology to some second-order physiographic unit in south-western Apulia Adriatic coast, is particularly prone to coastal erosion and marine inundation (DELLE ROSE *et alii*, 2011) From a morpho-sedimentological characteristic, gently sloping carbonate ramp are present as well as discontinues dunes, coastal dolines and water basin along the coast.

Porto Cesareo site was in equilibrium for several decades not showing particular and intense erosion phenomenon until 2009 year. Intertidal bars and coast line were at first modified and then destroyed in a very short temporal range.

Analysing meteorological and oceanographic data (2009-2011) there was not an evident correlation between wind intensity and direction and wave height in the open sea and erosion events/sand deposit. However, different wind direction from the south in some cases resulted in erosion or sand accumulation.

At the beginning of 2011 a contrast intervention was experimented, in the south zone of the bay, for three months in order to allow the intertidal bar reconstruction. A barrier under sea level was built with some controlled exits in order to modulate outflow currents. The removable barrier (70 cm high considering 90 cm water depth bathymetry) was built with

Fig. 2 –Area before erosion on the left high corner adjacent picture coastal in erosion phase red circled. Intervention area and barrier line grey dashed line.A particular of sand deposition after experimental intervention and turbulence effect after slopes on the right.

special bags (propylene 1000 lt. capacity) filled with sands (2.1 t. each weight). After about 45 days, in which the barrier was stable, the estimated accumulated sand in the bay was about $2500m^3$.

The accumulation occurred during three main severe storms (February – April 2011) with winds from the south, with intensity of 17Kn/hour. In a particular storm event, there was an additional effect as the sea level was very high (+ 0,17 m on zero elevation IGM) With removable bags, it was possible to tune the suitable control of outflows currents in the bay. The experimental intervention was guided by the turbulence behaviour in presence of obstacles/slopes as depicted in the figure 2. The measured bathymetry allow us to refine the model described in the previous section and actually still in development.

OBSERVATIONS AND FUTURE WORKS

In order to contrast coastal erosion, we decide to work in an alternative way by a Macroscopic CA approach: it permitted to plan experiments by a "low impact" method, by adopting an interdisciplinary approach and analysing the complex phenomenon of the sand erosion/transport/deposition.

Our choice, since first arrangement, resulted in contrasting erosion and also determine emerging processes for the whole complex system. CA RUSICA, defining a simplified model when opportune temporal scale and discrete steps in order to overcome turbulence regimes, represents a new preliminary empirical way to approach and simulate the coastal erosion. When turbulence regime and related dynamics is considered, it is possible to exploit the properties of the turbulent energy in presence of a slope (see Fig. 2). Taking into account this last issue, according the shoreline orientation and wind and marine currents directions, it was possible to put opportunely the contrast "removable" structures in order to transform a usual erosive event into an accumulation one. First experimental results comfort us and there is an ongoing work on data elaboration to populate the RUSICA model input allowing tuning, refining and validating the model. It is planned to further develop the model based on additional sites with similar morpho-sedimentological characteristics.

ACKNOWLEDGEMENTS

This research was partially funded by PON (Operational National Plan) 2007-2013 from MIUR (Italian Research Ministry of Research) project "SIGIEC: Integrated management system for Coastal erosion " ID: PON01 02651.

A New Cellular Automata Model for Simulating Landslides

MARIA VITTORIA AVOLIO (*) & VALERIA LUPIANO (**)

Key words: *Cellular Automata, Debris Flows, Modelling, SCIDDICA.*

INTRODUCTION

We present the latest version of the SCIDDICA Macroscopic Cellular Automata family models, specifically developed to simulate debris-flows type landslides. The latest model of the family, named SCIDDICA-SS3, inherits all the features of its predecessor, with the addition of a particular strategy to manage momentum. The introduction of the latter permits a better approximation of inertial effects that characterize some rapid debris flows. Many natural phenomena, like some complex fluid-dynamical phenomena, are difficult to be modeled through standard approaches, such as differential equations (STEIN, 1989). As a consequence, innovative numerical methods emerged from alternative computational paradigms such as Macroscopic Cellular Automata (MCA) (DI GREGORIO & SERRA, 1999). MCA are an extension of classical Cellular Automata (CA) (VON NEUMANN, 1966), and were developed in order to model many natural macroscopic events that seem difficult to be modelled in other CA frames.

DESCRIPTION OF THE METHODOLOGY

Some natural phenomena, such as debris flows, fall in the category of surface flows that evolve on large-scales, and are natural candidates to be modeled through two-dimensional MCA. CA proved to be a valid alternative to differential equations in simulating some complex natural phenomena (TOFFOLI, 1984; DI GREGORIO & SERRA, 1999). Among these efforts, the SCIDDICA MCA model family was developed for simulating landslides of debris-flows type and were first applied for simulating the Tessina slow-moving earth flow (AVOLIO *et alii*, 2000). SCIDDICA-SS3 is the latest version and derives from the need to improve the previous model (AVOLIO *et alii*, 2008), in order to better manage inertial effects. In SCIDDICA-SS3, by adopting an empirical strategy, the inertial character of the flowing mass is translated into MCA terms by means of local rules. In general, all SSx releases of the SCIDDICA family are an extension to combined subaerial-subaqueous flow-type landslides, with a new flows characterization by their mass centre position and velocity (AVOLIO *et alii*, 2008). These characteristics have allowed for a more appropriate characterization of momentum, allowing even for the description of its components along the direction of motion.

For MCA modelling purposes (DI GREGORIO & SERRA, 1999), landslides can be viewed as a dynamical system that evolves within a limited portion of the space, tessellated in regular cells (e.g. square, hexagonal). A state is defined for each cell that describes the physical characteristics of the corresponding portion of space. In particular, in the MCA framework the states of the cell are decomposed in substates, or rather the state of each cell can be expressed by the Cartesian product of all the considered substates, where each substate represents a particular feature of the phenomenon to be modelled (e.g., the altitude, depth of soil cover, thickness of landslide debris, landslide energy). Elementary processes constitute the transition function (τ) of the model: this is composed of a set of rules which describe local processes constituting the overall phenomenon. In addition, some parameters (e.g. the temporal MCA clock, the cell dimension, etc) are generally considered, which allow to "tune" the model for reproducing different dynamical behaviors of the phenomenon of interest, by taking in consideration their physical/empirical meaning. By simultaneously applying the transition function, τ, to all cells and at discrete steps, states are changed and the evolution of the phenomenon can be simulated. Natural macroscopic phenomena, which evolve by generating flows of material and involving surface-flows can be modeled through two-dimensional MCA, because the third dimension (i.e., the cell altitude) can be managed as a property of the cell (i.e. a substate). Thus, it is possible to consider characteristics of the cell (i.e. substates), typically expressed in terms of volumes (e.g. debris volume), here in terms of thickness. This simple assumption permits to adopt an efficacious strategy, by means of the Minimization Algorithm of the Differences (MAD) (DI GREGORIO & SERRA,

(*) Dipartimento di Matematica, Università della Calabria, Arcavacata di Rende, CS, Italy. avoliomv@unical.it

(**) Dipartimento di Scienze della Terra, Università della Calabria, Arcavacata di Rende, CS, Italy. valeria.lupiano@unical.it

1999) based on the hydrostatic equilibrium principle, in order to compute outflows of material (e.g. debris in the case of landslides) from a central cell to the neighbouring ones.

SCIDDICA is a family of deterministic MCA models, with hexagonal cells (Fig. 1), specifically developed for simulating flow-type landslides. Moreover, in the SS3 version, a new empirical strategy has been introduced which significantly improves the precision in the complicated computation of momentum for the flowing masses in the MCA context, where a macroscopic view was adopted.

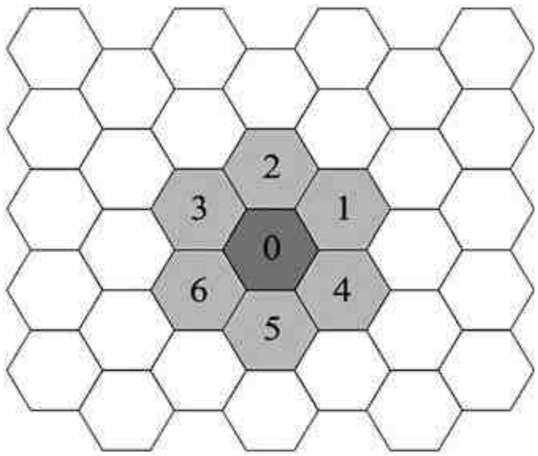

Fig.1 - Cellular

The starting point is the MAD, where outflows from a cell are computed in order to obtain hydrostatic equilibrium in the neighbouring. In a cell, inflows and mass inside are composed as quantity, mass centre, kinetic energy and momentum. Momentum introduces an alteration of hydrostatic equilibrium, which is translated in terms of the MAD by modifying fictitiously altitudes of adjacent cells: their altitude is opportunely lowered/raised according to the module and direction of momentum. Then, the computation proceeds by two stages:

a) Outflows toward the neighbouring cells are computed in the condition of different altitude alterations (Fig. 2): this represents the situation of flows that just can overcome obstacles, neglecting other interactions;

b) The part of mass that cannot overcome obstacles is considered to interact strongly with such obstacles, in a complicated play of hitting and bouncing, where momentum disappears and part of kinetic energy is lost. Because of lack of directionality and by considering the remaining kinetic energy, the MAD is again applied with identical altitude variation (proportional to residual kinetic energy) in the adjacent cells. This permits to compute outflows toward cells penalized by the direction of momentum in the previous stage.

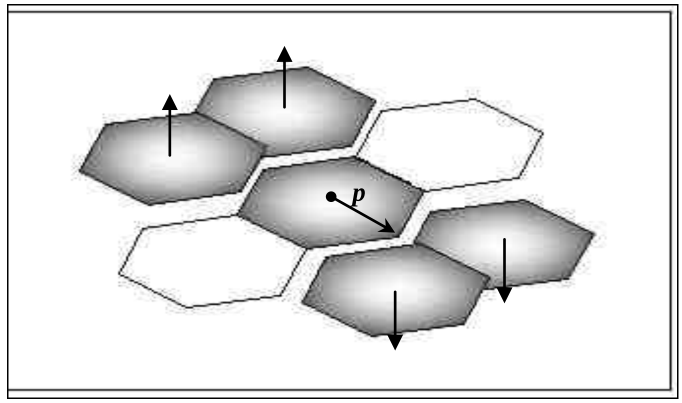

Fig. 2 - An example of cell elevation alteration for emphasizing inertial effects, where the central cell has a momentum ***p***. Shaded coloring indicate cells affected by the procedure. Vertical arrows indicate cell altitude alteration.

CASE STUDY: RESULTS AND DISCUSSION

SCIDDICA-SS3 was calibrated against the 1997 Albano lake (near Rome, Italy) event (Fig. 3a), which is a case of combined subaerial-subaqueous debris-flow (MAZZANTI *et alii*, 2007). This landslide occurred in the eastern slope of the Albano lake on the 7th of November 1997 after an intense rainfall event (128 mm in 24 hours), and began as a soil slide, mobilizing about 300 m^3 of fluvial material. The mobilized mass was channeled within a steeply dipping impluvium (about 40°) and thus evolved as a debris flow which entrained a large amount of debris material along the bottom of the channel and reached an estimated volume of some thousands of cubic meters at the coastline. A few amount of material was deposited at the coastline, while a greater quantity entered in water generating a little tsunami wave.

Simulations permitted to verify the general model and to calibrate adequately its parameters. In order quantitatively evaluate the simulation outcomes, experiments are compared with real cases by considering the following indicator e_1:

$$e_1 = \sqrt{\frac{R \cap S}{R \cup S}}$$

where R is the set of cells affected by the landslide in the real event and S the set of cells affected by the landslide in the simulation. The fitness function, e_1, considers a normalised value between 0 (complete failure) and 1 (perfect simulation).

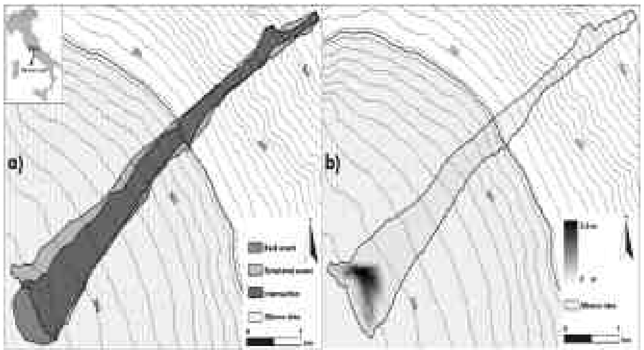

Fig. 3 - The 1997 Albano lake subaerial-subaqueous debris flow. (a) Intersection between real and simulated event; (b) Deposit thickness;

The simulation carried out with the SS3 model and here presented (Fig. 3a, 3b) has a value of e_1 equal to 0.82, which represents a very good, though preliminary, result.

CONCLUSIONS

SCIDDICA-SS3 seems to capture fundamental instances of modeling surface flow with regards to conservation laws of physics according to a less empirical approach. Results of first simulations are satisfying, even if more controls and applications to different cases need and parameters must be better tuned. Future research work is planned: for instance, coupling of different elementary processes must be improved, parameters have to be introduced independently from MCA time step and cell dimension by an opportune formulation of the transition function.

Geological investigation in the SE neighbourhoods of Rome aimed to an evolutionary model of cavity networks for hazard zonation

G. BIANCHI FASANI (*), E. DI LUZIO (**), F. BOZZANO (***)

Key words: *Geological modelling, cavity networks, void migration process , Rome*

INTRODUCTION

The south-eastern areas of Rome (Fig. 1) developed over a Middle Pleistocene volcanic multilayer featured by pyroclastic units erupted from the Albani Hills (VENTRIGLIA 1971, 2002; FUNICIELLO *et alii*, 2008; MAZZA *et alii* 2008; GIORDANO *et alii*, 2006).

The same area is featured by several underground networks of man-made cavities excavated in welded volcanic ashes known as "pozzolane" since the Roman Age. The "pozzolane" units were intensively used to produce a concrete when mixed to carbonate lime and water (*opus caementicium*). The concrete exhibits a consistent cohesiveness due to the high content of silica and alumina in the volcanic deposits.

The irregular and locally pervasive systems of underground quarries have been excavated till to years 1950-1960, that is during the last period of urban expansion. Such networks pose today a serious safety risk due to their interaction with anthropic activities and modern infrastructures.

The investigated area includes the territories of the 6, 7 and 9 municipalities (Fig. 1) for an overall extension of about 35 km^2. Cavities dataset were reported from literature (FUNICIELLO *et alii*, 1995; VENTRIGLIA, 2002), while the geological modelling was completed using stratigraphic logs from more than 1000 boreholes (VENTRIGLIA 1971, 2002 and unpublished data provided by the municipalities involved in the study).

Updated isobaths and thickness maps were drawn for the bounding surfaces of the main pyroclastic units ("Tufo Lionato", "Pozzolane Rosse", "Pozzolane Nere"). Then, a geostatistical analysis was performed in order to investigate cavities spatial distribution and the correlation with the local stratigraphic setting. Finally, the evolutionary model of void upwards migration outlined by BIANCHI FASANI et al (2011) was discussed for the area under study in the light of the main results from the geological modelling.

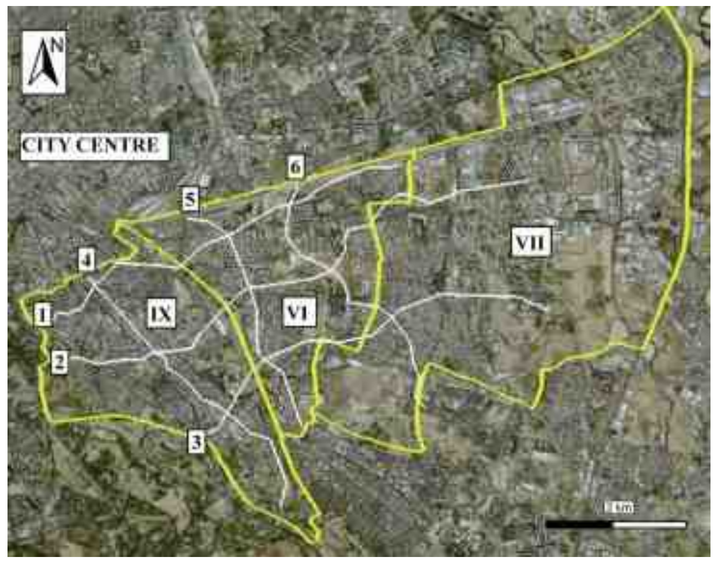

Fig. 1 – Google Earth map of the study area in south-eastern Rome. Yellow lines include territories of VI,VII,IX municipalities. White lines are cross section traces.

GEOLOGICAL SETTING AND MAIN CONSIDERATIONS

The Middle Pleistocene volcanic units featuring the local geological setting were the result of several eruptive phases belonging to the Tuscolano-Artemisio phase of the Colli Albani district (GIORDANO *et alii*, 2006; FUNICIELLO *et alii*, 2008 and references therein). Pyroclastic units have a general sub-horizontal attitude (Fig. 2). The "Pozzolanelle" and "Tufo Lionato" uppermost units (Villa Senni Unit in FUNICIELLO *et alii*, 2008) display sharp thickness variations linked to paleo-drainage networks. The underlying "Pozzolane Rosse" and "Pozzolane Nere" units instead show main thickness variations across the "Acqua Bulicante" Fault (Fig. 2). The "Pozzolane Nere" unit in particular is greatly thinned or even absent in the footwall zone due to post-faulting erosive process on horst areas.

All the aforementioned units lays above a basal, pyroclastic sequence of layered tuffs ("Tufi Antichi" unit). Such sequence on

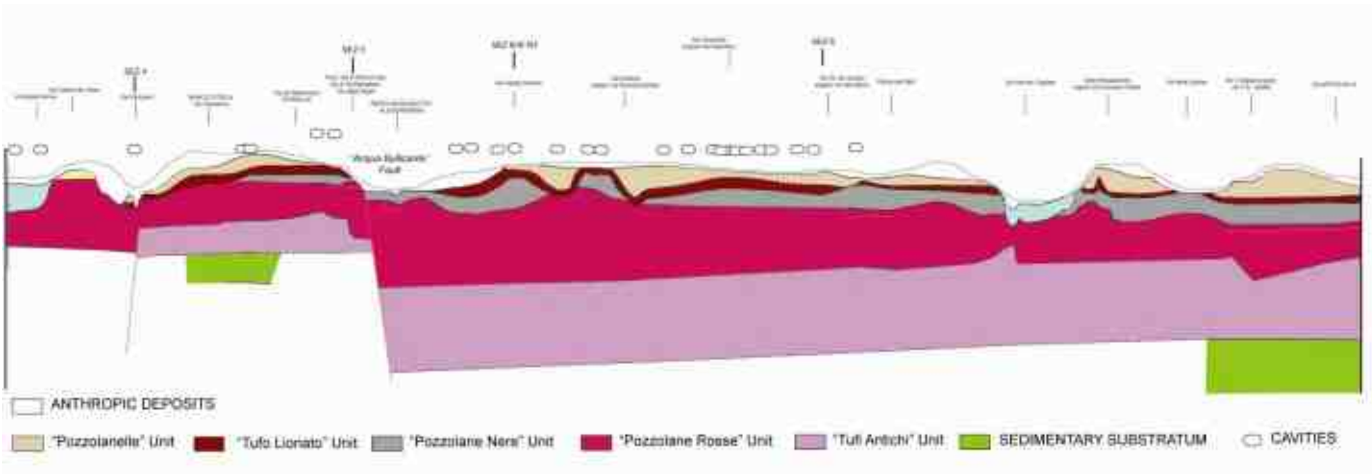

Fig. 2 – Cross section 3 (SW-NE direction, 10×vertical exaggeration). Surface projections of cavities are indicated.

its turn rests above the Plio-Pleistocene sedimentary substratum of the Roman area.

Within such a geological scenario, two main levels of cavities are found at different depths in the hanging-wall zone of the Acqua Bulicante Fault, actually into the “pozzolane” layers; in the foot-wall zone - i.e. in the westernmost areas of the study area - cavities are found within the “Pozzolane Rosse” and “Tufi Antichi” units. In both situations, The “Tufo Lionato” and “Pozzolanelle” units act as cap rocks; therefore, the analysis of their thickness variations is crucial for an hazard zonation.

MODEL OF VOID MIGRATION

An engineering-geology model of cavity networks was already described by BIANCHI FASANI *et alii* (2011) in a restricted zone within the study area. On the base of direct explorations, the authors propose an evolutionary model of void migration for cavities hosted within the “Pozzolane Nere” Unit. The model can be therefore better applied in the hanging-wall zone of the “Acqua Bulicante Fault”. According to it, collapses processes are strictly linked to the local volcanic setting consisting, of “pozzolane” layers alternated with palaeosoils (Fig. 3). The overall view of the phenomenon provides a first phase characterized by the degradation of the palaeosoil overlying the “Pozzolane Nere” unit determining the collapse of the entire level (paleosoil 1 in Fig. 3a). Where these first collapses occur, then the roof of the tunnel migrates upwards, till the Tufo Lionato lithoid bank is exposed working as a sort of beam (Fig. 3b). The subsequent evolution is mainly characterised by the formation of tension cracks in the central part of the intrados of the cavity and the consequent collapse of shaped blocks from the Tufo Lionato “plate” (Fig. 3c). This phenomenon implies that the roofs composed of the “Pozzolanelle” bank are now exposed. The last phase includes the multiple step collapses from the Pozzolanelle bank until the ground level is approached and a sinkhole is suddenly formed when the critical threshold of the cover thickness is reached (Fig. 3d).

Where available information on cavities locations and depths was included in cross section 1-6 to find those geological conditions that - according to the evolutionary model -could represent critical setting for the process of void upward migration.

CONCLUSION

This study was undertaken in the south-eastern part of Rome to investigate the relationship between the geological setting at subsoil and cavities distribution. Moreover, critical conditions of void migration were detected following the main lines of an evolutionary model outlined in a previous work. Main conclusion of this work are:

a) the spatial distribution of cavities seems to be influenced by the geological setting of the hosting “pozzolane layers” and the overlying cap rocks, both in terms of elevation of bounding surfaces and units thickness;

b) geological cross sections bearing cavities locations and depths allowed to spot many cases where critical conditions for the process of upward void migration are present according to the model.

Buried streams or undergorund artificial channels? Two Case Studies in Liguria (Vernazza and Monterosso al Mare, SP)

BARBARA DESSÌ (*), MAURO LUCARINI (*) ALESSANDRO TROCCOLI (*) & GIORGIO VIZZINI (*) *

Key words: *stream, flood, hydraulic, underground waterways, vulnerability.*

ABSTRACT

Taking as an example two case studies happened in Liguria (North Italy) during the recent flood events (autumn 2011), this work examines the mechanisms of floods which have often hit this area with special regards to the technical terminology.
In urban areas, hydrology is often glossed over by infrastructures, roads and buildings so that natural channels become undistinguishable. Two types of hydraulic solutions are frequently adopted: buried and diverted streams (*tombature*) and/or underground artificial channels (*tombinature*). The present work aims to explain and highlight the different uses of some hydrological terms that make often confusion even between technicians and researchers.
In Liguria has been revealing the fact that the intense processes of urbanization, also due to the growth of the tourism and consequential residential buildings, have hidden the original hydrographic pattern, increasing risk in coastal areas where torrential streams trigger flash floods. These phenomena can often evolve into debris flows or hyperconcentrated flows (COUSSOT & MEUNIER, 1996).
The conversion of natural streams into underground artificial channels do not solve the problems connected with torrents which instead provoke unexpected floods along underground waterways (*alvei-strada*) in the coastal towns. Sometimes, huge solid transport, in these streams, can cause "explosion" of underground artificial channels. In other cases, the burial and the consequent divertion of streams, in event of alluvial rainings, can allow the creeks to catch up their original course causing floods and great damages.
In both cases, the risk is high. In fact, recent episodes of flooding occurred on the Italian tirrenian coast have shown that the flood hazard never disappears completely but takes new forms and affects new territories in response to changing socio-territorial conditions (LARA *et alii*, 2010). These changes contribute to the reduction of historical memory, increasing the vulnerability of exposed population.

Data-driven modeling of earth science issues

ANGELO DOGLIONI (*) & VINCENZO SIMEONE (*)

Key words: *Data-driven modeling, evolutionary modeling, EPR-MOGA, groundwater response, landslide alert*.

INTRODUCTION

The conceptualization of an earth science system is usually approached by inferring models from observations and studying their properties. Models represent scheme of the earth system under investigation, based on some assumptions and rules, conjectured by the modelers. Building mathematical models for complex systems based on observed data is usually called system identification. The system represents an object in which variables of different kinds interact and produce observable signals, i.e. outputs. The system is also affected by external stimuli, i.e. inputs. In addition, there are further stimuli, called disturbance or noise, which can somehow affect the output.

Data-driven models are functional form of relationships between variables, where the numerical parameters in those functions are not known and need estimation (LJUNG, 1987). They are conceptual models whose mathematical structure could be known through conceptualization of physical phenomena or through simplification of differential equations describing the phenomena at stake. These models usually need parameter estimation by means of input-output data analysis, but the range of parameter values is normally known. Such models proved efficient and effective at modeling a number of earth science problems. However, their use is still confined and in particular some data-driven techniques are just marginally used. Here some applications of a data-driven are presented; these elicit interesting results and potentially larger usage.

DATA-DRIVEN EVOLUTIONARY MODELING

Evolutionary Modelling (EM) is a data-driven approach based on the evolution of a population of solutions, driven by one or more criteria. It generates a transparent and structured representation of the system being studied, i.e. symbolic regressions.

They works with a population of mathematical expressions, using operations similar to the natural evolutionary processes that operate in living organisms. The most frequently used EM method is the so-called symbolic regression, introduced by KOZA (1992). The technique creates mathematical expressions to fit a set of data using the evolutionary process of genetic programming. The EM process mimics natural selection as the fitness of the solutions in the population improves through the generations. The term fitness in this instance refers to a measure of how closely expressions fit the data points, according to one or more objective functions. A multi-objective technique, namely EPR-MOGA (Evolutionary Polynomial Regression) introduced by GIUSTOLISI & SAVIC (2009) proved effective at modeling problems related to groundwater dynamics (GIUSTOLISI et alii, 2008; MANCARELLA & SIMEONE, 2008; DOGLIONI et alii, 2011) and to geotechnical, structural and earthquake engineering (e.g. JAVADI & REZANIA, 2009). It is a two-stages methodology. The structural model identification is based on a Genetic Algorithm, afterwards the estimation of the constant values is made on the base of least square technique. The operator assumes the main structure of the models, potentially involved functions, maximum length of the polynomial structures, candidate exponents and objective functions. In particular EPR-MOGA can simultaneously optimize three objective functions at most. These are the minimization of the Sum of Squared Errors, the minimization of the number of monomial terms and the minimization of the percentage of input selected among the candidates given by the user. EPR-MOGA returns a set of equations from which it is necessary to choose that providing the better compromise between fitness to data and physical soundness. In fact, complicate structures can be poorly physically sound, even if highly fitting to data. Here three cases where EPR-MOGA was successfully applied are presented. In particular, these relate to porous and karst aquifer response to rainfall and to landslide alert. These cases aim at showing the potentialities of EPR-MOGA for earth science applications, in particular for those cases where timeseries or measured data are available.

(*) Dipartimento di Scienze dell'Ingegneria Civile e dell'Architettura, Politecnico di Bari, via E. Orabona 4, 70125, Bari, Italy. a.doglioni@poliba.it ; v.simeone@poliba.it

CASE STUDIES

The study of aquifers dynamics is a fundamental issue for the analysis of groundwater resources. However, the modeling of aquifer dynamics by physically based models is generally not simple, due to the lack of information and data. For this reason the use of data-driven modeling approaches, able to return explicit models starting from measured reasonably low cost data, could be a solution to this issue. EPR-MOGA is here used to model the response of two hydrogeologically different aquifers, located in the same climate environment in South-east Italy.

The studied aquifers are the porous shallow aquifer of Brindisi (GIUSTOLISI *et alii*, 2008; MANCARELLA & SIMEONE, 2008), and Lecce karst coastal aquifer (DOGLIONI *et alii*, 2011). The models aims at predicting monthly groundwater levels at time *t*, H_t, using as input data rainfall of the months before (P_t, P_{t-1}, P_{t-2}, … P_{t-n}) and groundwater level up to two months before the prediction (H_{t-1}; H_{t-2}). For both the cases, timeseries of monthly measures of rainfall heights and groundwater levels for 50 years are available. Among the equations returned by EPR-MOGA for Brindisi porous aquifer, the following one is the most interesting (MACARELLA & SIMEONE, 2008)

$$H_t = 10.1\cdot\sqrt{H_{t-1}} + 5.94\cdot10^{-6}\cdot P_{t-2}\cdot\left(H_{t-2}\right)^2\cdot\sqrt{H_{t-1}\cdot P_{t-3}\cdot P_{t-4}} - 25.3 \quad (1)$$

The model is characterized by a good fitness to data, both for short and long time predictions (Fig. 1). Moreover, it is interesting to observe that the equation encompasses 3 and 4-months before rainfall as well as the groundwater level

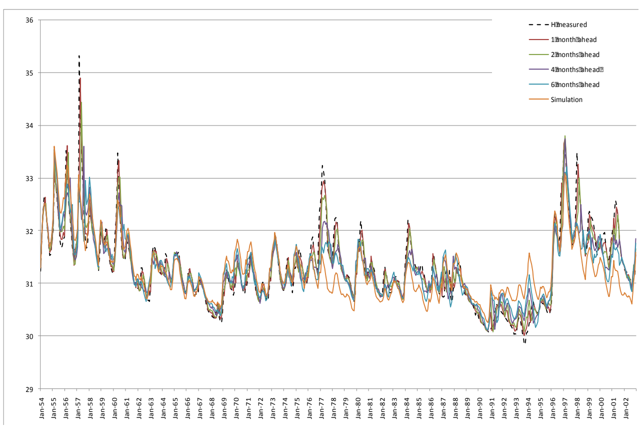

Fig. 1 – Modeling result of Brindisi aquifer.

antecedent to the predicted one. In addition the equation is strongly non-linear, in terms of relationship between rainfall and groundwater levels. This is consistent with the observed behavior of the aquifer. In fact, water table levels are not responsive to impulsive rainfall events; they are mainly conditioned by relatively long precipitation or dry periods.

The equation returned by EPR-MOGA for the case of Lecce coastal karst aquifer is (DOGLIONI *et alii*, 2011)

$$H_t = 0.0080995\cdot P_t^{0.5} + 0.9819\cdot H_{t-1} \quad (2)$$

Also in this case, the model fits quite well to data, both for long and short time predictions (Fig. 2). However, the predicted groundwater level is strongly related to level of the month before and to the rainfall of the same month of the prediction. This is consistent with an impulsive response of the aquifer to rainfall, which indeed is actually observed. In fact, this is a coastal karst aquifer, characterized by preferential flow paths of infiltration.

A further application of EPR-MOGA pertains landslide activation analysis. In particular the relationship between rainfall and landslide reactivation is investigated for a landslide located on a slope on the Adriatic coast of south Italy, close to the small town of Petacciato.

It is a large deep seated landslide (GUERRICCHIO *et alii*, 1996)

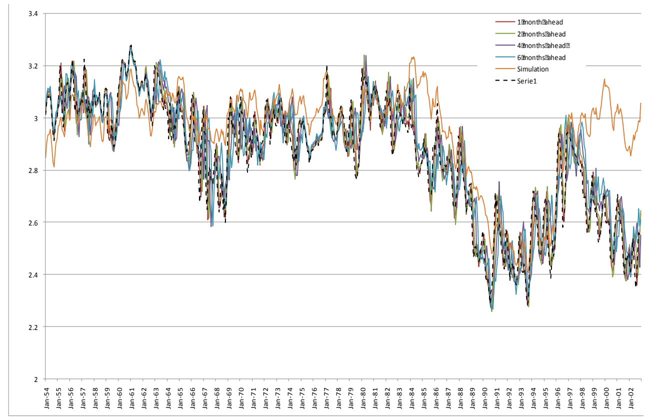

Fig. 2 – Modeling result of Lecce aquifer.

involving Plio-Pleistocenic marine overconsolidated blue-grey silty-clay deposits interbedded with silty-sandy layers, sometimes filled with high pressurized flowing water. The landslide is quite wide and characterized by a low steepness. It was observed that the landslide reactivated after long rainy periods, and then rainfall was assumed as a triggering factor even if there is not a clear relation between rainfall and landslide activation. For these reasons, the dynamic of the landslide is quite difficult to be interpreted.

Starting from the rainfall data, which are available for the last 110 years as daily records, and from 11 activation episodes, which range between 1932 and 2009, a model aimed at describing the reactivation as function of cumulative rainfall values was built up.

Therefore, cumulative rainfall values were constructed in order to account with long periods, up to 500 days. These were used as candidate inputs for the construction of a model, accounting for cumulative rainfall heights and their lags with the reactivation event. In words, the model returns 0 if no reactivation is forecasted and 1 when there is a reactivation, based on an input set made of cumulative values evaluated at different number of days before the reactivation date. The time lag and the cumulative values as well as the structure of the model are selected by the methodology, on a training set comprising 8 out of 11 events. The remaining 3 events are not involved in model construction in order to use them as a test set. The model selected among those returned by EPR-MOGA is (DOGLIONI *et alii*, 2012)

$$R = round\begin{pmatrix} 2.3712 \cdot P20_{30}^{0.5} \cdot P30^{2} \cdot P30_{30}^{2} \cdot P45_{5}^{-2} \cdot P45_{20}^{-1} \cdot \\ \cdot P60^{-0.5} \cdot P60_{10} \cdot P90_{10}^{-2} \cdot P90_{20} \cdot P90_{30}^{2} \end{pmatrix} \quad (3)$$

Equation (3) never return false positive reactivation. Moreover it just missed 2 out of 11 reactivations. From a structural point of view, it is interesting to observe that the model is monomial, even if involving several inputs. This somehow is consistent with the complex relation existing between rainfall amount and reactivation for Petacciato landslide. Finally, it is noteworthy that equation (3) cannot be straightly associated with physical interpretations due to its relative complex structure. However, it can be used for landslide alert, whereas rainfall scenarios are assumed.

CONCLUSIONS

Data-driven model applications for earth science issues were here presented, showing some specific case studies, where data-driven models were successfully used for modeling engineering geology problems, are introduced. The purpose of this work is to emphasize undiscovered potentialities of data-driven modeling applied to earth science, thus proposing a valid alternative to classical approaches. In particular, among data-driven models, the evolutionary multi-objective technique, EPR-MOGA, is here used in order to model the responses of two aquifers and landslide alert. The results achieved by EPR-MOGA emphasize how a data-driven approach can successfully model complex systems, starting from measured data. This is of particular interest for natural systems and specifically for earth science problems, since these often yield complex dynamics, which can be hardly approached by traditional physically based techniques.

It is also shown how a data-driven technique can be used both for prediction and for scientific knowledge discovery. Indeed, the models of groundwater response can be used for predictive purposes and at the same time they are consistent with the expected behaviors of the investigated aquifers. Therefore, they can be also used in order to understand how groundwater response is influenced by rainfall and how complex can be the response. On the other hand, the case of landslide alert modeling shows that EPR-MOGA is able to predict landslide reactivations, starting from measured data, however it is very hard to conjecture a physical interpretation of the model. In fact, in this case, the structure of the equation is highly non-linear and quite complex. This, on the one hand, emphasizes the complexity of the investigated landslide, on the other hand this can be meaningful of the involvement of purely interpolative terms. This highlights an issue typical of data-driven models, which are trained on specific data, and then it is not easy to generalize the models to other sites or data from other sites. However pushing data-driven models towards simple parsimonious structures can help to prevent from hyper-adapting models to data and thus to get relatively general equations.

Infiltration processes in fractured and swelling soils and their influence on the stability of surficial covers

ANNALISA GALEANDRO (*) & VINCENZO SIMEONE (*)

Key words: *capillarity barrier, dual permeability, fractured soil, infiltration processes, surficial soil slip.*

INTRODUCTION

Slope instability of surficial covers is often related to the loss of strength due to suction decrease in relation to rainfall infiltration processes. The response of surficial soil cover to rainfall infiltration is affected by several aspects related to the stratigraphy, physical and hydraulic properties of soil the presence of fracture and so on.

In cracked soils, water infiltration is accelerated by fracture (Šimůnek *et alii*, 2003) that in clayey soil can be subject to progressive closure as consequence of swelling phenomena. In case of a surficial fine-textured soil overlying a more permeable bedrock, at the interface between the two strata the fine soil stores water as consequence of the capillary barrier effect (Mancarella and Simeone, 2008).

This work presents and discusses the results obtained by a dual-permeability model, which accounts for fractures, swelling and capillary barrier effect in unsaturated soils with respect to slope stability. Results show how slope stability conditions can change depending on different scenarios induced by different rainfall events.

MATERIALS AND METHODS

The model

The adopted dual-permeability model (Galeandro and Simeone, 2010a, 2010b; Galeandro *et alii*, 2011) simulates water infiltration into fractured swelling soils overlying a more permeable layer. The model assumes that all the rainfall water infiltrates into fractures, from where itcan be laterally absorbed into the soil matrix (Fig. 1). Water flow in cracks is modeled by the kinematic wave equation, while Richards equations are used to describe lateral flow into the soil matrix. The model additionally implements a capillary barrier below the base of the surficial fractured soil. Water accumulates in cracks up to a maximum capillary height, while in matrix above the interface between layers until the reaching of a critical pressure head.

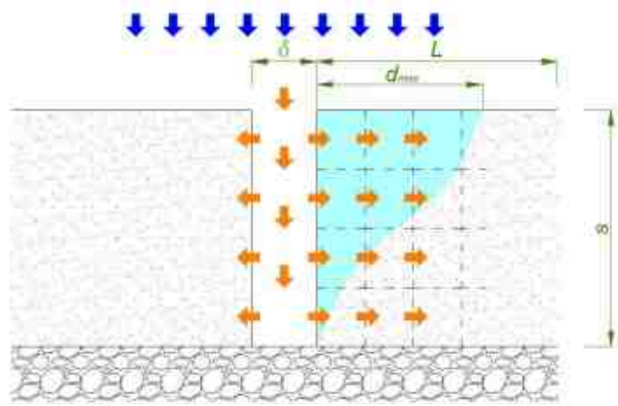

Fig. 1 – Conceptual model

The case study

As case study it has been considered a fractured sandy loam soil layer overlying a coarse sand. Fractures network and matrix features are summarized in Fig. 1 and Table 1. The system has been discretized into soil elements of small dimensions (1 cm x 5 cm).

The model has been used to simulate 6 rainfall events of different intensity and duration (Tab. 2): the event A_1-C_1 with a total rainfall height of 20 mm and events A_2-C_2 with a total rainfall height of 70 mm.

B_2	10	10	0.45
C_2	50	2	2.23

Tab. 2 – Rainfall events: intensities, durations and corresponding inflow rate in fractures

Results and discussion

For each event, it has been evaluated the maximum depth reached by water in fracture (z_{max}), the maximum horizontal diffusion of infiltrated water in matrix (d_{max}) and the time necessary to break the capillarity barrier in fractures (t_{break}). Table 3 summarizes results of the six simulations. It is evident how the maximum infiltration depth is strictly related to rainfall intensity and duration. For weak rains (event A_1), at the end of the rainfall the depth reached by the infiltrating water is small, but diffusion in matrix involves most of the interspacing between fractures.

It is interesting to observe that for the event C_2 the diffusion is not much larger than the event C_1, even if the total rainfall amount is three times greater. It shows that for severe rainfall intensities, also if the rainfall is prolonged, after an initial stage the diffusion process is quite slow, allowing the downward percolation of the most amount of water. Only for these two events there is a capillarity barrier breaks-out in fractures after 270 s (corresponding rainfall height of 3.7 mm) and in matrix after 370 s (corresponding rainfall height of 5.1 mm).

As consequence of swelling due to hydration processes, fractures start to narrow at the topsoil and the closure propagates toward the bottom according to water adsorption. Table 4 summarizes the percentage of closure at the topsoil and the average closure with respect to the entire thickness, for each considered event. Cracks narrowing is quite homogeneous for intense rainfall, while it is strongly irregular for weak rains. In this last case, soil starts to severely swell at the surface and can induce the closure of fractures, while the deeper portion of the layer is not reached by infiltrated water. For the weakest rain (2 mm/h, event A_2) the complete closure of cracks happens after 14.4 hours. For more intense precipitations, even if water diffusion and then the swelling are less significant, they involve almost the entire depth, so that the swelling is uniform and cracks rest almost parallel to the initial configuration, without reaching the complete closure, but a closure equal to 19% for the event C_1 and 33% for the event C_2. When water flow is very slow and does not reach the bottom (events A_1, B_1, B_2) or induces the complete closure of cracks (event A_2), the capillarity barrier never breaks-out in both domains.

Table 5 shows the averaged saturation degree at a depth of 20 cm, 80 cm and 150 cm for each rainfall event. At the end of event for the event A_2 it reaches a value very close to saturation (0.36 cm^3 cm^{-3}).

Test slope results and discussion

Total rainfall height (mm)		2 mm/h	10 mm/h	50 mm/h
20 mm	z_{max} (cm)	25	95	150
	d_{max} (cm)	39	26	13
	t_{break} (s)	no break	no break	270
70 mm	z_{max} (cm)	35	135	150
	d_{max} (cm)	40	33	16
	t_{break} (s)	no break	no break	270

Tab. 3 – Results: maximum depth reached by water in fracture z_{max}, maximum horizontal distance d_{max} reached by water in matrix and time t_{break} necessary to break the barrier in fractures.

Total rainfall height	Event	Closure at topsoil (%)	Average closure (%)
20 mm	A_1 (2 mm/h, 10 h)	83%	11 %
	B_1 (10 mm/h, 2 h)	38%	16 %
	C_1 (50 mm/h, 24 min)	19%	18 %
70 mm	A_2 (2 mm/h, 50 h)	100%	16 %
	B_2 (10 mm/h, 10 h)	70%	41 %
	C_2 (50 mm/h, 2 h)	33%	32 %

Tab. 4 – Results: crack closure percentage

	total rainfall height = 20 mm			total rainfall height = 70 mm		
S_r (%)	A1	B1	C1	A2	B2	C2
z = 20 cm	65,22%	39,13%	18,84%	85,51%	68,12%	33,33%
z = 80 cm	1,45%	1,45%	18,84%	1,45%	53,62%	33,33%
z = 150 cm	1,45%	1,45%	18,84%	1,45%	1,45%	33,33%

Tab. 5 – Results: Average saturation degree at a depth of 20 cm, 80 cm, 150 cm for each rainfall event.

To evaluate the influence of the different pressure head distribution related to the investigated rainfall events on slope stability, it has been considered a test slope characterized by an inclination β of 45°, a specific soil weight γ of 20 kN/m^3 and shear strength parameters c' and ϕ' respectively of 5 kPa and 25°. For this slope, according to the infinite slope approach, it has been evaluated the factors of safety when the slope is dry, assuming the failure surface at the depth of 20 cm, 80 cm and 150 cm. The corresponding basic factors of safety are equal to 25.83, 6.81 and 3.85.

Then, it has been evaluated the average degree of saturation at a depth of 20 cm, 80 cm and 150 cm (Tab. 5) and the corresponding pressure head at the end of each rainfall event. On the basis of the evaluated medium pressure head, it has been evaluated the decrease of the factor of safety for each different rainfall scenario at the different depths of the failure surface (Fig. 2).

The results show how weak and prolonged rains can seriously affect safety factor for a failure surface at the depth of 20 cm. For the events A_1 and A_2, the safety factor decrease is greater than 60% (reaching 88% for the more prolonged rainfall A_2). Indeed, the same events do not affect the safety factor at greater depth because the water infiltration does not reach that depth. It shows that prolonged weak rainfalls could lead to the saturation of the more surficial layers and can trig instability phenomena of the most surficial strata, being more dangerous than severe intensity rainfalls.

Event B_1 induces a decrease of safety factor only at a depth of 20 cm, lower than 40%. With the same intensity and at the same depth the influence become more relevant for more prolonged rainfall event B_2, when the safety factor decrease could be estimated of about 70%.

The most intense precipitations (50 mm/h) do not significantly affect the stability of covers at each considered failure surface for both events C_1 and C_2 ($\Delta FS < 35\%$).

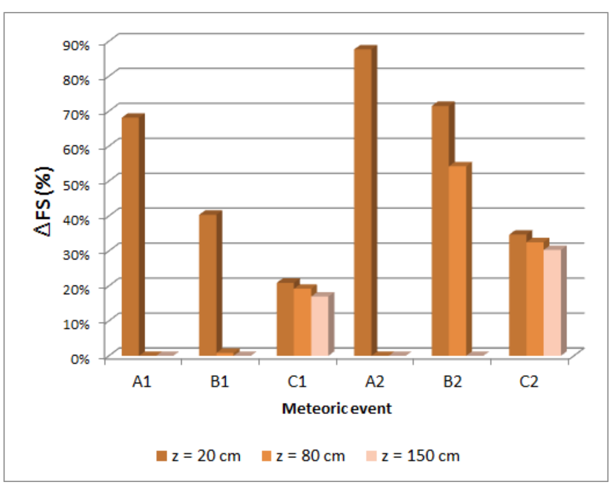

Fig. 2 – Decrease of safety factor for each rainfall event, assuming a failure surface at a depth of 20 cm, 80 cm, 150 cm

CONCLUSIONS

The paper provides results obtained by simulating infiltration processes in a fractured and swelling sandy loam for different values of rainfall intensities, by means of the dual-permeability model proposed by GALEANDRO *et alii* (2011). Results show how for intense precipitations, vertical flow in fracture reaches fast significant depth, while for weak precipitations it is initially limited to the first 20-30 centimeters at the topsoil. The swelling of soil elements is more regular for intense precipitations rather than for weak rains, leading to an uniform narrowing of cracks for the first case and a differentiated swelling concentrated at the topsoil with almost complete crack closure for the second case. Results also show how only for intense rainfalls, capillary barrier breaks-out and the breakthrough happens in a very short time.

In addition, results show how rainfall of different intensity and duration can significantly affect slope stability of surface fine-grained covers. A prolonged weak rain seems to be more dangerous than an intense one to trigger soil slip in the more surficial strata, leading to a more realistic and theoretically based scenario which could contribute to built-up more reliable approach to landslide risk analysis.

Evaluation of landslide invasion hazard through Cellular Automata at Gragnano (Sorrento Peninsula)

FEDERICA LUCA' (*), GAETANO ROBUSTELLI (*), ROCCO RONGO (*) & WILLIAM SPATARO (**)

Key words: *Cellular Automata, debris flow, hazard assessment, statistical analysis.*

INTRODUCTION

The ultimate aim of many landslide studies is the assessment of the risk to population and/or infrastructures. To achieve this goal, information on landslide hazard is required; it involves not only the evaluation of the travel distance but also of the location and timing of occurrence of the events (VARNES, 1984), and the magnitude or intensity of the potentially hazardous phenomena(GUZZETTI *et alii*, 1999).

These issues are addressed in our study that illustrates a method for evaluating high-detailed landslide invasion hazard on the basis of geological-morphological field survey, statistical analysis coupled with numerical simulations through Cellular Automata. The method has been tested on the northern sector of Monte Pendolo (Sorrento Peninsula) where pyroclastic covers, blanketing Mesozoic carbonate massif, were affected by debris slides–rapid earth/debris flows that reached the town of Gragnano in the last decades (MELE & DEL PRETE, 1999; DI CRESCENZO *et alii*, 2008).

The proposed approach for the evaluation of landslide invasion hazard, is used to predict where presumably future events could arrive, after the assessment of where and how frequently landslides will occur and how large they will be.

THE METHODOLOGY

By assuming that landslides will occur in the future because of the same conditions that produced them in the past (GUZZETTI *et alii*, 1999, 2005) a logistic regression method was implemented to investigate the relation between landslide spatial triggering and predisposing factors and predict the geographical location of future events. The obtained triggering susceptibility zonation correctly classifies 80% of landslides as evaluated by comparing the susceptibility map with failures not used to construct the model.

By considering the thickness of pyroclastic cover involved in the initial detachment as a proxy for landslide intensity and analyzing the frequency-size statistics of past landslides, a probability of occurrence was evaluated. Past landslide thickness distribution well fits with a log-normal probability distribution, as supported by the Kolmogorov Smirnov goodness of fit test. On this basis, a probability of occurrence was assigned to 0,5 m spaced thickness interval. Moreover, in order to drawn up in detail present day cover thickness, the study area has been widely surveyed integrating resistivity tomography, drillings and sonds. The pyroclastic cover disclosed a highly variable degree of preservation with thickness varying between 0.5m at the top of the slope and >15m at the foot of the hill.

Assuming that the recurrence of landslides for Monte Pendolo will remain constant in the future (CROVELLI *et alii*, 2000; GUZZETTI *et alii*, 2005), a temporal probability was evaluated from catalogues of historical landslides occurred in the study area by using a probabilistic-historic approach. After evaluating the average recurrence of phenomena dividing the total number of events listed in the historical data set by the time span of landslides, adopting a Poisson probability model, the exceedance probability of having one or more events was computed for different periods from 5 to 100 years.

Knowing the location of landslide triggering and the size of potential debris flows, the prediction of their path and travel distance was identified by using the latest release of SCIDDICA (D'AMBROSIO *et alii*, 2003a, 2003b), a family of deterministic models based on the Macroscopic Cellular Automata approach (DI GREGORIO & SERRA, 1999) and specifically developed for simulating debris flows. Among other characteristics, the Cellular Automata model is able to take into account phenomenological specifications such as energy dissipation, erosion and inertial effects. Moreover, the model is able to simulate the increase of downstream pyroclastic cover thickness through regolith erosion along the path. The simulation model was calibrated by means of a Genetic Algorithm based optimization technique and then validated against past landslides that occurred in the same

(*) Dipartimento di Scienze della Terra, Università della Calabria, Rende (CS) – Italy. {robustelli, rongo, luca}@unical.it

(**) Dipartimento di Matematica, Università della Calabria, Rende (CS) – Italy. spataro@unical.it

study area. The pre-landslide bed topography and the landslide path were used as input initial conditions together with the best-fit parameters. Maximum run out distances and simulated landslide areas acquired with the model were used for the purpose of comparison.

For landslide invasion hazard purpose, on the northwestern sector of Monte Pendolo, several possible source areas were hypothesized; for each of them, a simulation was carried out by assuming the total entrainment of the measured cover thickness. The simulations showed that landslide run out is strongly dependent on landslide volume and therefore on the pyroclastic thickness both involved in the initial detachment and eroded along the downstream path.

For each point affected by simulations, an overall invasion hazard (H) was calculated by overlapping the simulations and summing the product of the probability of spatial occurrence (p_s), the probability of landslide intensity (p_i) and the probability of landslide temporal occurrence (p_t) as follows:

$$H(x,y) = \sum_{j=1}^{n} p_s^{(j)} \cdot p_i^{(j)} \cdot p_t \qquad [1]$$

where n is the number of landslides that affect each (x, y) cell. In our approach, due to the limited extension of the study area, a triggering rainfall sequence can be considered spatially homogenous, so the term p_t assumes the same value for the whole slope while p_s and p_i vary from cell to cell. The three computed probabilities are supposed to be independent.

The probability that the town of Gragnano will be affected by future landslide in the next 5 years, supposing the worst case that is the total entrainment of the pyroclastic cover measured in the field is represented in Fig. 1. It clearly portrays that the most susceptible and hazardous sectors along the slope are located in the drainage lines while, at the footslope, the entire state road S.S. 366 is hit by landslides which reach Via Castellammare, the main road of Gragnano.

The model described in this study is topographically driven and requires a minimum amount of data, an important aspect not to understate. It must be stressed that the methodology can be applied also in other settings where the occurrence of debris flows involving the pyroclastic cover deposited on stable calcareous bedrock slopes could be supposed.

Modello geologico-tecnico della frana di Serra di Buda (Acri - Cs)

LUIGI BORRELLI (°) & GIOVANNI GULLÀ (°)

Key words: *Alterazione, Calabria, frana profonda, modello geologico-tecnico.*

ABSTRACT

La frana di Serra di Buda, localizzata all'ingresso dell'abitato di Acri (CS), interessa una porzione di versante costituito da rocce metamorfiche variamente alterate. Il fenomeno franoso ha subito tre recenti mobilizzazioni: nell'inverno 1998-99, nell'inverno 2004-05 e nell' inverno 2009-10. Nell'inverno 1998-99, in particolare, la frana ha causato l'interruzione della S.S. 660 che attraversa il versante ed ha prodotto gravi disagi alla popolazione (fig. 1).

Da un punto di vista litologico sul versante affiorano rocce metamorfiche di medio-alto grado, rappresentate da gneiss a biotite, granato e sillimanite e gneiss migmatitici a biotite ± muscovite, appartenenti entrambi all'Unità della Sila (MESSINA *et alii*, 1991) sormontati, a luoghi, da una copertura detritica.

L'analisi fotointerpretativa e le verifiche condotte in campagna hanno consentito l'individuazione dei principali elementi tettonici presenti sul versante in cui ricade la frana. Il versante è caratterizzato da un'elevata complessità strutturale dovuta alla presenza di faglie normali, ad orientamento N-S e legate al dominio tettonico del graben del Crati, che si sovrappongono a faglie ad andamento trasversale NW-SE e NE-SW ed a strutture di origine compressiva (thrust).

Il complesso assetto strutturale del versante, in particolare per la presenza di importanti discontinuità tettoniche a basso angolo (piani di thrust), affioranti in corrispondenza dell'incisione del T. Calamo con disposizione a franapoggio, rappresenta il principale elemento di predisposizione allo sviluppo della frana di Serra di Buda.

Lo studio della frana di Serra di Buda, di cui sono note mobilizzazioni già intorno al 1700 (ALMAGIÀ, 1910; SORRISO-VALVO *et alii*, 2005; TERRANOVA *et alii*, 2007), è stato avviato, con finalità di controllo in emergenza (SORRISO-VALVO *et alii*, 2005), a seguito di una attivazione avvenuta nell'inverno 1998-99 e di una successiva nell'inverno 2004-05 (GULLÀ *et alii*, 2004a; GULLÀ *et alii*, 2005; BORRELLI & GULLÀ, 2007a; BORRELLI, 2008).

Il tratto di versante interessato dal fenomeno franoso è ubicato in destra idrografica del T. Calamo, affluente destro del Fiume Mucone, ed è parte di un'area più ampia sede di un fenomeno di deformazione gravitativa profonda di versante tipo Sackung (SORRISO-VALVO & TANSI, 1996).

Le attivazioni più recenti, verificatesi circa negli ultimi dieci anni, hanno evidenziato, in particolare nell'inverno 2004-2005, il coinvolgimento di un volume dell'ordine di 5.000.000 m^3 con modalità cinematiche rese particolarmente insidiose dalla

Fig. 1 – Panoramica della frana di Serra di Buda.

Lavoro eseguito nell'ambito della Commessa CNR-TA.P05.012 (Responsabile G. Gullà).

presenza di condizioni morfologiche fortemente predisponenti ad una possibile evoluzione catastrofica (valanga di roccia). La presenza sul versante in frana di un'importante via di comunicazione (S.S. 660), determina, nelle fasi pre-rottura e rottura, una condizione di rischio elevato.

A seguito degli effetti sul versante prodotti dalla mobilizzazione del 1998-99 è stato possibile individuare una serie di elementi geomorfologici caratteristici del versante instabile (SORRISO-VALVO *et alii*, 2005). Successivamente alla riattivazione del 2004-2005, considerando anche gli approfondimenti di studio man mano compiuti (GULLÀ *et alii*, 2004a, b; BORRELLI & GULLÀ, 2007b; BORRELLI, 2008), sono stati condotti specifici rilievi che hanno permesso di delimitare l'area coinvolta dalla riattivazione del 2004-2005, identificandone le scarpate e le fratture di neo-formazione, la zona di corona ed i fianchi della frana.

La frana di Serra di Buda (estensione pari circa 12 ha) presenta una scarpata, a forma di V rovesciata, evidenziata da un gradino di altezza variabile da 1.2 m a 0.3 m e con uno sviluppo in pianta pari a circa 200 m. La scarpata di frana, legata all'ultima riattivazione, si sviluppa in maniera asimmetrica prevalentemente sul lato destro della frana e prosegue verso la S.S. 660, diminuendo man mano l'originario rigetto. Procedendo verso il basso è stato possibile individuare con precisione i fianchi della stessa, in quanto le scarpate laterali hanno prodotto danni rilevanti alla sede stradale. In corrispondenza del tratto stradale danneggiato il versante in frana presenta una larghezza di circa 200 m che aumenta procedendo verso valle sino a raggiungere i 450 m. In questa porzione di versante i fianchi sono stati ricostruiti tramite il rilievo delle scarpate laterali, di altezza variabile da 10 cm a 30 cm. Nella parte bassa del versante in frana, in corrispondenza del fianco sinistro, sono state rilevate una serie di scarpate, di altezza variabile da 1.0 m a 1.5 m, ortogonali alla direzione di massima pendenza ed alle quali sono associate, immediatamente più a monte, evidenti fratture di trazione. Alla base del versante la superficie di rottura affiora localmente messa giorno da frane superficiali di tipo scorrimento-colata. In particolare, la superficie di rottura trova collocazione nelle zone degradate e ridotte come consistenza a terreno associate alle strutture tettoniche a basso angolo che vengono a giorno in questa porzione di versante. Da quanto suddetto si può affermare che nella frana di Serra di Buda le superfici di taglio affioranti, sia lungo i margini sia all'interno del corpo di frana, mostrano un chiaro controllo strutturale.

I rilievi e gli studi geologico-strutturali, geomorfologici e del grado di alterazione, condotti con successivi e mirati approfondimenti (SORRISO-VALVO *et alii*, 2005; BORRELLI & GULLÀ, 2007a; BORRELLI, 2008), hanno fornito un quadro conoscitivo particolarmente significativo. Tale disponibilità, ha consentito di definire il modello geologico-tecnico del versante di Serra di Buda (fig. 2).

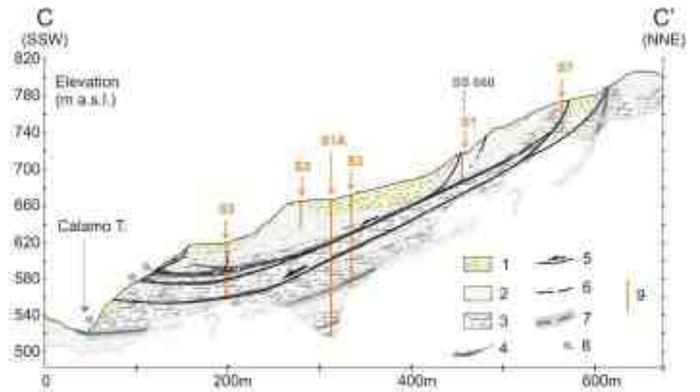

Fig. 2 – Modello geologico-tecnico della frana di Serra di Buda. Legenda: 1) terreni detritico-colluviali (classe VI); 2) rocce alterate (classi da II a V); 3) zone di roccia completamente degradata e ridotta come consistenza a terreno; 4) tratti argillificati; 5) superficie di scorrimento; 6) superficie di scorrimento in formazione; 7) zona di deformazione associata alla DGPV; 8) sorgenti; 9) sondaggi a carotaggio continuo.

L'analisi e la sintesi del modello geologico-tecnico, supportata dalle indicazioni desumibili dalle prove in sito e di laboratorio nonché dai monitoraggi conoscitivi, ha portato all'individuazione del modello geotecnico preliminare della frana di Serra di Buda (GULLÀ *et alii*, 2004a, b) ed al suo progressivo affinamento con l'utilizzo della modellazione numerica e con particolare riferimento al comportamento tempo-dipendente dei materiali presenti lungo le zone di rottura.

Lo studio condotto è di particolare rilievo poiché tratta di una categoria di frana (frana profonda) particolarmente rappresentativa e diffusa in contesti geologici strutturalmente complessi, quali la Calabria, dove affiorano rocce cristalline affette spesso da profondi processi di alterazione.

Procedura speditiva per la redazione di una carta del grado di alterazione a scala regionale

LUIGI BORRELLI (°), GINO COFONE (°) & GIOVANNI GULLÀ (°)

Key words: *Alterazione, Calabria, rocce cristalline, Sila.*

ABSTRACT

In Calabria l'elevata presenza in affioramento di rocce cristalline (38% circa rispetto alla superficie complessiva), spesso affette da profondi processi di alterazione, fa si che tali litotipi si possano presentare con caratteristiche marcatamente differenti e variabili in affioramento ed in profondità. Se facciamo riferimento alla resistenza meccanica si possono dunque riconoscere in uno stesso ammasso roccioso porzioni a comportamento litoide e porzioni che si comportano come una roccia sciolta. Ne consegue che nei contesti geologici caratterizzati da una rilevante presenza di rocce cristalline, quali la Calabria, l'assenza d'informazione cartografica riguardo alle condizioni d'alterazione rende poco efficace il supporto che la cartografia geologica può fornire alle attività di pianificazione del territorio, nonché per la programmazione generale di rilievi e di indagini di dettaglio.

Le procedure di rilievo del grado di alterazione proposte in letteratura (I.A.E.G COMMISSION, 1981; GULLÀ & MATANO, 1994), adeguate per trattare problemi a scala grande e media, non sono utilizzabili operativamente per predisporre a piccola scala carte del grado di alterazione da utilizzare per avviare, impostare o definire al meglio le attività di pianificazione e programmazione richiamate. Per tale ragione è stata dunque predisposta una procedura che consente di delimitare a piccola scala zone caratterizzate da condizioni omogenee di alterazione, con una risoluzione coerente alla definizione dagli aspetti d'interesse.

Con riferimento a quanto evidenziato è illustrata la procedura utilizzata per la redazione della carta del grado di alterazione, delle rocce plutoniche e metamorfiche di medio-alto grado, relativa al territorio della Calabria (fig.1). Sono inoltre discusse le verifiche condotte per definire il livello di coerenza della procedura proposta e per migliorarlo progressivamente. La procedura proposta considera tre macro-classi di alterazione riferibili indicativamente come comportamento meccanico a: roccia sciolta (macro-classe A); roccia tenera (macro-classe B); roccia lapidea (macro-classe C) (fig.1).

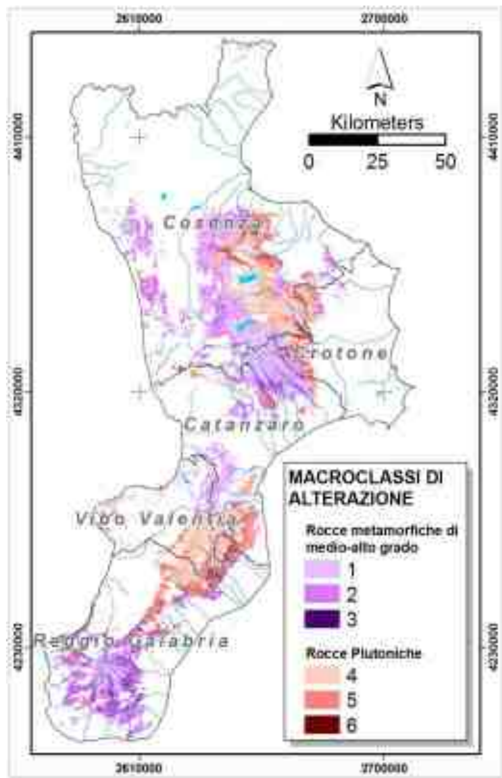

Fig. 1 – Carta del grado di alterazione (distinta in macro-classi) relativa al territori calabresi, ricavata dalla metodologia proposta: 1 e 4) macro-classe A; 2 e 5) macro-classe B; 3 e 6) macro-classe C.

La delimitazione a piccola scala delle aree con ammassi rocciosi associabili alle tre macro-classi di alterazione definite è condotta in ambiente GIS, sviluppando più fasi concatenate e riferite a semplici criteri corrispondenza.

Nella prima fase sono recuperati i dati di letteratura disponibili relativamente alla geologia a scala regionale, sulla base dei quali sono definiti i limiti delle aree dove sono presenti in affioramento rocce plutoniche e metamorfiche di medio-alto grado, ed il modello digitale del terreno, con risoluzione della cella pari almeno a 40 m x 40 m. Per il territorio della Calabria, in particolare, è stata acquisita ed utilizzata la Carta Geologica Ufficiale (CASMEZ, 1976), in scala 1:25.000. Sempre nella prima fase di lavoro è acquisito il DTM (fornito dal Centro Cartografico Regionale), con risoluzione

Lavoro eseguito nell'ambito della Commessa CNR-TA.P05.012 (Responsabile G. Gullà)

della cella pari a 40 m x 40 m, dal quale sono ricavate la carta delle pendenze e la carta delle curvature, che delimita le zone a convessità e concavità morfologica.

Nella seconda fase, facendo riferimento ad indicazioni desumibili dalla letteratura (CASCINI *et alii*, 1992; CALCATERRA *et alii*, 1996; GULLÀ *et alii*, 2004; IETTO *et alii*, 2007; PELLEGRINO & PRESTININZI, 2007), sono stati individuati, con opportune tarature preliminari, gli intervalli delle pendenze associabili alle tre macro-classi di alterazione definite. In particolare, all'intervallo di pendenze variabile tra 0 e 38% si considera associabile la presenza della Macro-classe A, all'intervallo maggiore del 38% e fino al 70% si considera associabile la presenza della Macro-classe B, a valori di pendenza maggiori del 70% si considera associabile la presenza della Macro-classe C. Per quanto concerne la curvatura, calcolata lungo la direzione di massima pendenza (profile curvature), la stessa consente di identificare le concavità morfologiche presenti sui versanti che, rappresentando zone topografiche di convergenza, sono associabili alla presenza della Macro-classe A. Pur ritenendo di mantenere questo criterio di associazione nella procedura proposta, il suo utilizzo con il DTM disponibile (cella di 40 m x 40 m) comporta una macroscopica sovrastima della Macro-classe A, in particolare nelle zone in forte incisione. In definitiva, la carta del grado di alterazione a piccola scala, redatta per il territorio della Calabria, è stata realizzata utilizzando le associazioni definite sulla base degli intervalli delle pendenze opportunamente stabiliti (fig. 1).

La terza fase di lavoro prevede la verifica del livello di coerenza della carta (corrispondenza tra quanto rilevato con tecniche speditive a piccola scala e quanto rilevabile con rilievi a scale di maggiore dettaglio) e, nel contempo, rappresenta l'avvio del progressivo miglioramento della stessa carta a piccola scala. Il lavoro previsto per la terza fase, da svolgere sempre in ambiente GIS, richiede la disponibilità di una carta del grado di alterazione, di adeguata estensione (un centinaio di chilometri quadrati), predisposta con una delle procedura messe a punto per il rilievo a media o grande scala (CASCINI *et alii*, 1992; GULLÀ & MATANO, 1994). Per una prima verifica della carta del grado di alterazione della Calabria a piccola scala, predisposta con tecniche speditive, è stata utilizzata la carta del grado di alterazione disponibile per un'area della Sila, che include l'abitato di Acri, caratterizzata dalla presenza di morfologie molto variegate (zone pianeggianti, zone in forte incisione, zone molto acclivi, ecc.) e dove sono presenti in affioramento entrambe le litologie di riferimento (BORRELLI *et alii* 2012). In particolare nella carta del grado di alterazione utilizzata sono state distinte, attraverso rilievi di dettaglio alla scala 1:10.000, le 6 classi di alterazione definite da GULLA' & MATANO (1994): classe VI (terreni residuali e/o colluviali), classe V (roccia completamente alterata), classe IV (roccia altamente alterata), classe III (roccia moderatamente alterata), classe II (roccia debolmente alterata) e classe I (roccia fresca).

Riferendosi all'area per la quale è disponibile la carta del grado di alterazione di BORRELLI *et alii* (2012), nella figura 2 sono confrontate la distribuzione areale delle macro-classi di alterazione definita a piccola scala con la procedura proposta (fig. 2b) l'analoga distribuzione ottenuta accorpando le sei classi di alterazione utilizzate da BORRELLI *et alii* (2012) nelle tre macro-classi considerate: macro-classe A (roccia sciolta), che include la classe VI e V; macro-classe B (roccia tenera), che include la classe IV e III; macro-classe C (roccia lapidea), che include la classe II e I.

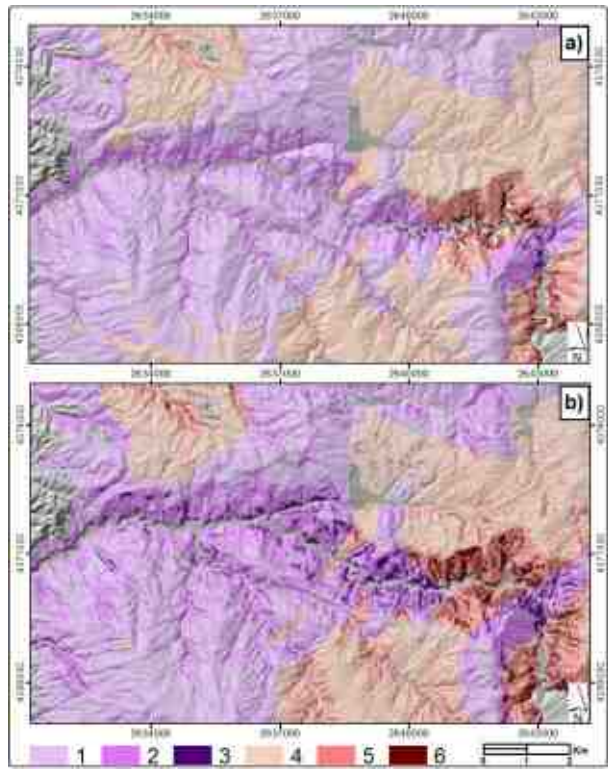

Fig. 2 – Confronto tra le carte prodotte: a) Carta delle macro-classi di alterazione prodotta accorpando le 6 classi di alterazione della carta di BORRELLI *et alii* (2012); b) Carta delle macro-classi di alterazione ottenuta dalla metodologia proposta. Legenda: 1) gneiss di macro-classe A; 2) gneiss di macro-classe B; 3) gneiss di macro-classe C; 4) granitoidi di macro-classe A; 5) granitoidi di macro-classe B; 6) granitoidi di macro-classe C.

Già l'esame visivo del confronto mostrato nella figura 2 indica un accettabile livello di coerenza, confermato dal risultato del confronto quantitativo rappresentato graficamente nella figura 3. In particolare, la percentuale di corrispondenza (in termini di superficie in affioramento) risulta essere: per i granitoidi del 78% nella Macro-classe A, del 60% nella Macro-classe B, del 57% nella Macro-classe C; per gli gneiss del 65% nella Macro-classe A, del 64% nella Macro-classe B, del 50% nella Macro-classe C.

Sulla base dei risultati illustrati si può concludere che la procedura proposta per il rilievo speditivo a piccola scala del grado di alterazione è soddisfacente, efficace e coerente per possibili utilizzi a scala regionale (pianificazione del territorio,

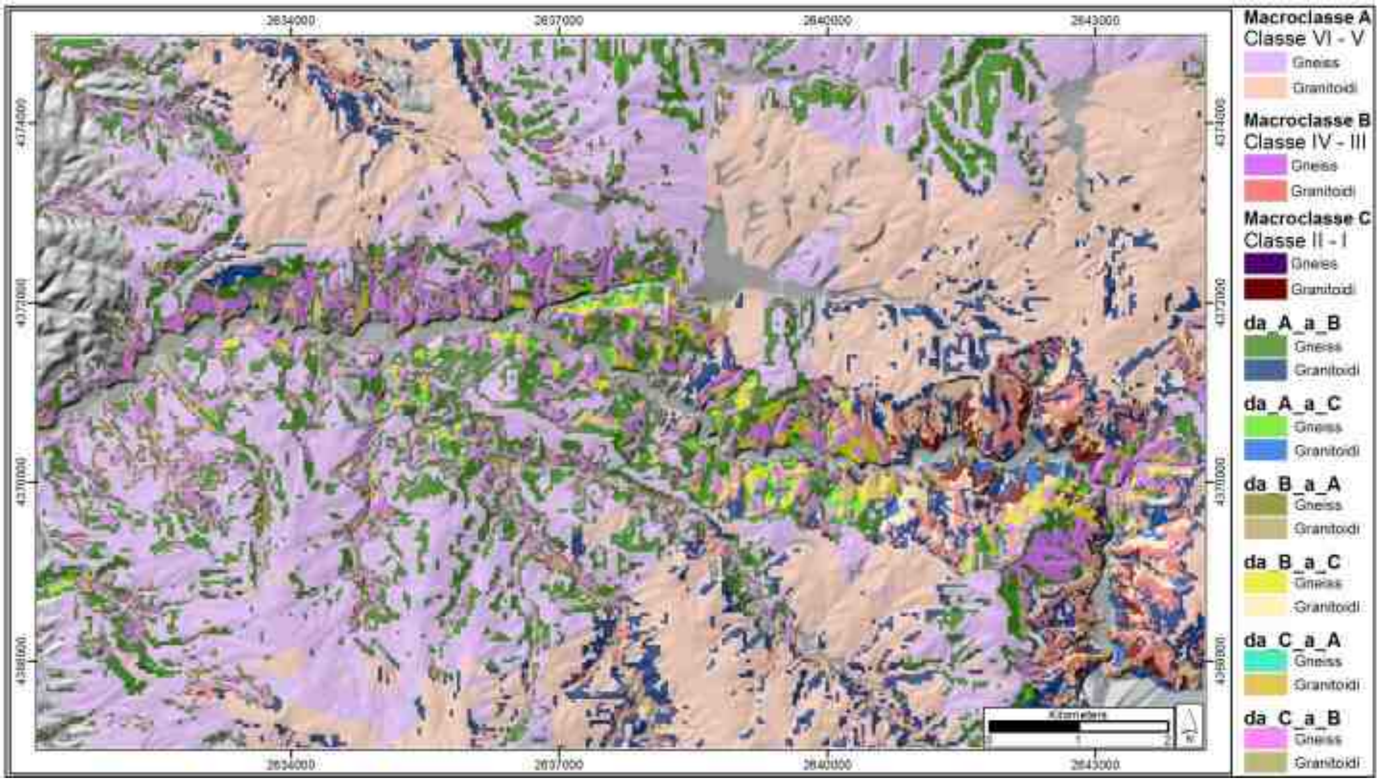

Fig. 3 – Confronto tra la Carta delle macro-classi di alterazione prodotta accorpando le 6 classi di alterazione di BORRELLI *et alii* (2012) e la Carta delle macro-classi di alterazione ottenuta tramite la metodologia proposta.

programmazione generale di rilievi e di indagini di dettaglio), in quanto con la delimitazione delle tre macro-classi di alterazione definite fornisce un inquadramento generale delle condizioni di alterazione di estrema utilità conoscitiva ed applicativa. Di fatto, la procedura illustrata avvia con la fase di verifica del livello di coerenza un progressivo affinamento della cartografia ottenibile a piccola scala, utilizzando le ulteriori carte del grado di alterazione a media e grande scala, che man mano che si rendono disponibili, per approfondire la verifica del livello di coerenza e per migliorare la taratura dei criteri utilizzati nella stessa procedura.

Nell'ottica evidenziata è ragionevole ritenere la cartografia del grado di alterazione, in particolare quella a piccola scala, come uno strumento la cui efficacia, conoscitiva e applicativa, può essere progressivamente migliorata.

Cartografia del grado di alterazione in rocce cristalline: l'esempio della carta del grado di alterazione redatta per la porzione centro-occidentale del bacino del Fiume Mucone (Calabria, Italia)

LUIGI BORRELLI (°), SALVATORE CRITELLI (*), GIOVANNI GULLÀ (°) & FRANCESCO MUTO (*)

Key words: *Alterazione, Calabria, cartografia, frane, profili di alterazione, rocce cristalline.*

ABSTRACT)

Precedenti esperienze condotte in Calabria riguardo la cartografazione delle condizioni di alterazione degli ammassi rocciosi (CASCINI *et alii*, 1992; CALCATERRA *et alii*, 1996; GULLÀ & MATANO, 1997) hanno indicato l'opportunità di riassumere, approfondire e precisare gli aspetti metodologici connessi alla redazione di una cartografia adeguatamente standardizzata del grado di alterazione, idonea a fornire un efficace supporto alla comprensione e soluzione delle problematiche inerenti gli ammassi rocciosi cristallini alterati.

La possibilità di formulare un quadro geologico generale di riferimento, l'estrema variabilità composizionale delle rocce cristalline in affioramento e la presenza di fenomeni franosi che periodicamente producono ingenti danni, hanno fatto cadere la scelta su di un'area, dell'estensione di 100 km^2, posta nel comprensorio del comune di Acri (CS), corrispondente alla porzione centro-occidentale del bacino del Fiume Mucone, la quale risulta particolarmente complessa e significativa nel contesto regionale. Il rilievo del grado di alterazione è stato condotto sia arealmente, utilizzando osservazioni e test qualitativi, sia su fronti rocciosi, utilizzando le osservazioni e i test qualitativi e semi-quantitativi condotti su oltre 100 stazioni di controllo (fronti, naturali o artificiali, con consistente sviluppo verticale). Nella stessa area è stato, inoltre, eseguito uno studio geomorfogico alla scala 1:10.000, che ha portato, tramite analisi foto-interpretativa e successivi rilievi di controllo e verifiche sul terreno (eseguiti nell'arco temporale 2004 – 2006), alla redazione della carta inventario dei fenomeni di movimento in massa.

I risultati dei rilevamenti e degli studi sono stati analizzati e riassunti nella "Carta del grado di alterazione e dei fenomeni di movimento in massa della porzione centro-occidentale del bacino del F. Mucone (Calabria, Italia)", alla scala 1:10.000 (fig. 1) (BORRELLI, 2008; BORRELLI *et alii*, 2012. In particolare, sono state riconosciute, in affioramento, cinque delle sei classi di alterazione previste dalla classificazione adottata: classe VI (terreni residuali e/o colluviali), classe V (roccia completamente alterata), classe IV (roccia altamente alterata), classe III (roccia moderatamente alterata), classe II (roccia debolmente alterata).

Dall'analisi della carta redatta si evidenziano relazioni tra l'assetto strutturale, la distribuzione delle varie classi di alterazione, e la distribuzione e concentrazione dei fenomeni di movimento in massa. In particolare una discreta corrispondenza tra l'assetto strutturale e la distribuzione delle varie classi di alterazione è bene evidente lungo le faglie N-S e NW-SE, dove l'approfondimento del reticolo idrografico, facilitato dalla fratturazione delle rocce, ha messo a giorno roccia poco alterata. I movimenti verticali tra i blocchi adiacenti lungo le faglie dirette hanno sollevato porzioni meno alterate di rocce cristalline, rappresentate principalmente da lembi di gneiss o granitoidi, da debolmente ad altamente alterati (classe II, III e IV), che si allineano lungo le principali dislocazioni, in corrispondenza delle incisioni torrentizie. In zone di interferenza tra macrostrutture appartenenti a sistemi diversi si segnala una maggiore articolazione del profilo di alterazione e la presenza di potenti coperture di natura detritico-colluviali (CASCINI & GULLÀ, 1993).

In linea generale si può affermare che l'intenso stato di fratturazione prodotto nell'area dall'attività neotettonica ha predisposto le rocce cristalline affioranti nell'area all'attacco degli agenti atmosferici. Sforzi diacroni, infatti, hanno generato fasce di fratturazione variamente orientate, che hanno conferito agli ammassi rocciosi gneissici e granitoidi diffuse anisotropie strutturali. Tali anisotropie interferendo con le anisotropie primarie di natura tessiturale e composizionale e connesse alle intrusioni pegmatitiche, hanno contribuito a generare un reticolato, più o meno fitto di discontinuità nell'ammasso roccioso, riconosciuto a varie scale. Le fasce di deformazione associate ai *thrust* rappresentano zone variamente degradate/alterate e ridotte come consistenza a terreno, spesso con importanti tratti argillificati, caratterizzate da notevoli variazioni delle proprietà tessiturali e geomeccaniche delle rocce

Lavoro eseguito nell'ambito della Commessa CNR-TA.P05.012 (Responsabile G. Gullà).

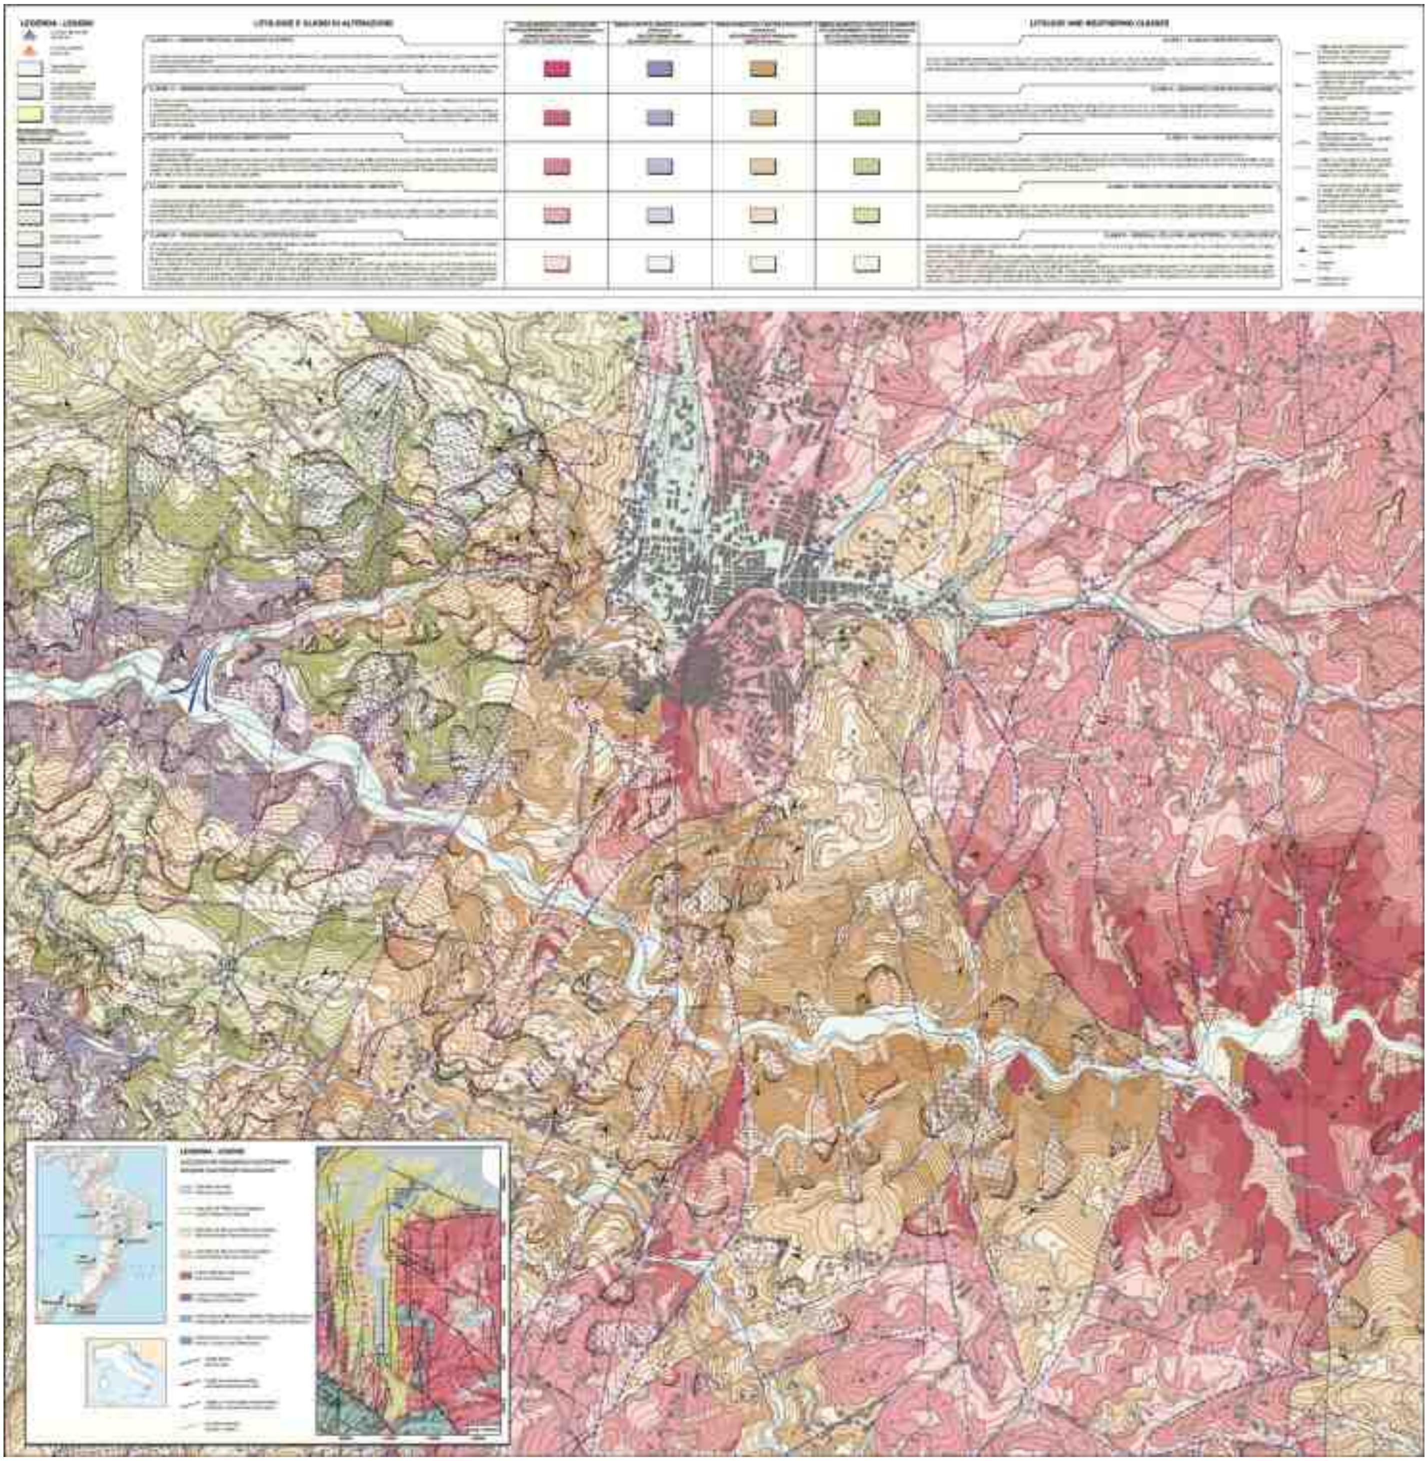

Fig. 1 – Stralcio della "Carta del grado di alterazione e dei fenomeni di movimento in massa della porzione centro-occidentale del bacino del F. Mucone (Calabria, Italia)" (da BORRELLI *et alii*, 2012).

cristalline. Le fasce di fratturazione associate ai piani di faglia sono invece tipiche delle zone cataclastiche. Tali fasce hanno consentito in misura diversa l'infiltrazione delle acque meteoriche chimicamente attive nel sottosuolo, favorendo lo sviluppo di processi alterativi anche in profondità. Lungo le linee di faglia, inoltre, la dislocazione verticale di masse rocciose ha messo in contatto differenti pozioni del profilo di alterazione ereditato, formando un complesso ed articolato substrato sede degli attuali processi alterativi di natura meteorica.

L'assetto geologico-strutturale, le condizioni di alterazione degli ammassi rocciosi in affioramento, la complessità dei profili di alterazione e di conseguenza del regime delle acque sotterranee che ne viene determinato (CASCINI *et alii*, 2006), rappresentano gli elementi di predisposizione allo sviluppo dei fenomeni di movimento in massa nell'area studiata (fig. 1). Nello specifico, sono state rilevate e cartografate quattro diverse tipologie di fenomeni gravitativi (fenomeni di scorrimento-colata di detrito, fenomeni di scorrimento di detrito, fenomeni di scorrimento in roccia e Deformazioni Gravitative Profonde di Versante tipo "Sackung"). I fenomeni di maggiori dimensioni sono confinati al settore più interno dell'area di studio, lungo i versanti che bordano il Fiume Mucone e i suoi affluenti, dove è maggiore l'energia di rilievo e dove è possibile osservare localmente, la presenza di superfici di thrust che vengono a giorno in corrispondenza delle incisioni fluviali, spesso con angoli inferiori a quelli del pendio; in corrispondenza dei piani di tali strutture, si ritrovano associate zone completamente degradate/alterate e ridotte come consistenza a terreno (di spessore variabile in funzione dell'importanza della struttura). L'interazione delle strutture tettoniche sub-orizzontali e di quelle sub-verticali (che spesso ne delimitano i fianchi e le corone), determinano le condizioni possibili per il verificarsi di meccanismi profondi (scorrimenti in roccia) e di deformazioni gravitative profonde di versante. Per quanto riguarda i fenomeni di scorrimento-colata di detrito e gli scorrimenti di detrito, gli stessi coinvolgono in prevalenza le coperture detritico-colluviali (classe VI) e solo subordinatamente le rocce completamente alterate (classe V).

I risultati conseguiti e rappresentati nella "Carta del grado di alterazione e dei fenomeni di movimento in massa della porzione centro-occidentale del bacino del F. Mucone" evidenziano l'utilità della cartografia ottenuta a fini geologico-applicativi ed ingegneristici in quanto la stessa risulta di estrema utilità sia per la pianificazione territoriale sia per definire ed affrontare le problematiche determinate dai movimenti in massa che spesso interessano gli ammassi rocciosi cristallini alterati. Essa trova, inoltre, utilizzo nell'indirizzare più efficacemente la ricerca, gli studi e le indagini, essenziali per definire ed affrontare le problematiche che spesso interessano gli ammassi rocciosi alterati.

Lo studio dei profili di alterazione, effettuato nel corso dei rilevamenti di campagna, ha permesso di individuare gli elementi litologici e strutturali caratteristici dei profili che condizionano in maniera sostanziale lo sviluppo di definite tipologie/categorie di frane (superficiali, mediamente profonde e profonde) nelle rocce cristalline alterate.

Con riferimento alle condizioni di stabilità del territorio, la carta del grado di alterazione redatta, ed i profili di alterazione ricostruiti, forniscono uno strumento di estrema importanza sia per la valutazione della pericolosità da frana sia per la tipizzazione delle frane nei contesti geologici considerati, con evidenti ricadute positive nella definizione delle azioni di mitigazione e riduzione del rischio e per la gestione delle emergenze idrogeologiche.

Suscettibilità alle frane superficiali e veloci in terreni di alterazione: un possibile contributo della modellazione della propagazione

LUIGI BORRELLI (°), DOMENICO GIOFFRÈ (*), GIOVANNI GULLÀ (°) & NICOLA MORACI (*)

Key words: *frane superficiali, modello numerico, terreni di alterazione.*

INQUADRAMENTO GEOLOGICO E GEOMORFOLOGICO

Le frane superficiali caratterizzate da evoluzione rapida, notoriamente di notevole pericolosità, sono molto diffuse dove sono presenti in affioramento di rocce cristalline profondamente alterate (DEERE & PATTON, 1971; WONG *et alii*, 1998; LACERDA, 2004). In particolare, i fenomeni di frana evidenziati, che generalmente si verificano nell'ambito di "eventi di franosità" (GULLÀ *et alii*, 2009), interessano i terreni di alterazione diffusamente presenti nel territorio della Calabria, suscettibile alle frane superficiali (GULLÀ *et alii, 2008*), figura 1.

Un contesto geo-ambientale di interesse per lo studio della problematica evidenziata è localizzato in un'area, tra Bagnara Calabra e Scilla (RC) (di seguito area di Favazzina), dove nell'ultimo decennio si sono verificate numerosi eventi di frane superficiali evoluti in colate di fango e detrito (fig. 1). L'area di Favazzina, che ospita importanti strutture e infrastrutture (ferrovia, autostrada, SS18, abitati, ecc.), è stata dunque scelta per approfondire gli studi di dettaglio in corso sugli eventi di frane superficiali (ANTRONICO *et alii*, 2004; GULLÀ *et alii, 2008*).

I rilevamenti geomorfologici, geologici e del grado di alterazione condotti nel marzo 2010 sul tratto di versante a monte dell'abitato di Favazzina (fig. 1), hanno permesso di rilevare le tracce dei fenomeni franosi superficiali del 2001 e 2005 (BONAVINA *et alii*, 2005) e di quelli relativi agli inverni 2008-2009 e 2009-2010.

Dal punto di vista morfologico il versante di Favazzina è delimitato a monte, a partire dai 600 m s.l.m., da una superficie di spianamento di origine marina (piano delle Aquile) e a valle da una stretta e discontinua fascia, pressoché sub-pianeggiante, intensamente antropizzata (località costiera di Favazzina). Il

tratto di versante oggetto di studio, con pendenze medie di 35° che localmente raggiungono circa 60°, è talora terrazzato in più ordini ed è solcato longitudinalmente da numerosi fossi e valloni, profondamente incisi, con lunghezze da circa 300 m a circa 1000 m e dislivelli massimi dell'ordine dei 600 m. I rispettivi bacini di alimentazione presentano nel complesso limitata estensione.

Dal punto di vista geologico, l'area di studio ricade all'interno del settore costiero tirrenico della Calabria meridionale, in corrispondenza dall'alto strutturale Scilla-Palmi, facente parte del contesto geologico del bordo orientale dello Stretto di Messina (FERRANTI *et alii*, 2008). Il basamento geologico nell'area di

(°) CNR-IRPI – UOS di Cosenza, Via Cavour n. 4 - 87036 Rende (CS)

Lavoro eseguito nell'ambito della Commessa CNR-TA.P05.012 (Responsabile G. Gullà) e del POR Calabria 2000-2006 - Asse 1 - Misura 1.4 – Azione 1.4. c

studio è composto da metamorfiti acide paleozoiche (paragneiss di vario tipo ed ortogneiss), di medio-alto grado, sormontate in discordanza da una copertura sedimentaria plio-pleistocenica (fig. 1). Per la diffusa presenza in affioramento di rocce cristalline variamente alterate, è stato eseguito un rilevamento speditivo del grado di alterazione degli gneiss (fig. 1) e un accurato rilievo delle relative coperture di alterazione. Sono state in tal modo delimitate aree identificabili con quattro classi di alterazione: classe VI (terreni residuali, colluviali e detritico-colluviali), classe V (roccia completamente alterata), classe IV (roccia altamente alterata), classe III (roccia moderatamente alterata), (GULLÀ & MATANO, 1997).

Per trarre indicazioni circa le modalità di propagazione delle colate, che si generano a seguito dell'innesco delle frane superficiali, e per individuare gli aspetti sui quali è più opportuno concentrare gli approfondimenti di studio per conseguire avanzamenti conoscitivi significativi, si è ritenuto di sviluppare una serie di simulazioni numeriche delle colate. In particolare, è stato considerato l'evento di frana del 12 maggio 2001 che ha dato luogo a due colate, la prima, su cui si focalizzerà l'attenzione per la modellazione numerica, si è incanalata nel vallone Favagreca, danneggiando la stazione SNAM del metanodotto, la ferrovia e la strada statale, causando il deragliamento dell'ICN Torino-Reggio Calabria, la seconda, sviluppatasi da un vallone adiacente, ha investito l'autostrada presso la Galleria.

METODOLOGIA E RISULTATI

Le frane superficiali, dal cui innesco si possono generare le colate, sono fenomeni di scorrimento traslazionale che interessano generalmente le coltri di copertura costituite da terreni residuali, colluviali e detritico-colluviali (classe VI). Gli spessori dei terreni di alterazione, rilevati in affioramento, variano da circa 1 m a circa 10 m, con i valori maggiori in corrispondenza dei ripiani morfologici localizzati lungo il versante ed alla base dello stesso, nella zona di raccordo con la fascia costiera. Spessori variabili da circa 1 m a circa 5 m si rilevano delle zone di concavità morfologica. I rilevamenti, condotti nel febbraio 2010 sul versante a monte dell'abitato di Favazzina (fig. 1), hanno evidenziato che le zone di innesco dei fenomeni franosi del 2001 e del 2005 si presentano quasi completamente svuotate, mentre i canali di flusso, nella porzione medio-alta del versante, sono pure svuotati e parzialmente rivegetati.

La modellazione della propagazione del materiale coinvolto nella prima colata del 2001 è di seguito illustrata (fig. 1). Per la modellazione del fenomeno di interesse una soluzione approssimata può essere ottenuta, in generale, ricorrendo ad un approccio numerico. Nel presente lavoro le simulazioni sono state condotte con un modello sviluppato di recente da PASTOR *et alii* (2008), basato appunto sull'approccio SPH (Smoothed Particle Hydrodinamics), diffuso in molti campi della fisica e dell'ingegneria.

Il modello numerico utilizzato, per i cui dettagli si rimanda a PASTOR *et alii* (2002), non considera l'analisi dell'innesco ed assume, sulla base di valutazioni successive agli eventi considerati, che i volumi instabilizzati alle testate siano dell'ordine dei 1100 m^3 (BONAVINA *et alii* , 2005). Le percentuali di solido e liquido della massa di frana risultano di circa 60% per cui secondo COUSSOT & MEUNIER (1996), considerando le caratteristiche granulometriche del terreno, il flusso di materiale può essere classificato come un *mudflow*. Per le simulazioni condotte il distacco della massa instabile è stato localizzato, sempre sulla base dei rilievi di dettaglio successivi agli eventi di frana considerati, all'altezza di una strada sterrata che costeggia il versante (fig. 1). Il modello reologico utilizzato è stato definito, sulla base di analisi con viscosimetro del materiale coinvolto dal colamento, con una legge viscosa di tipo *Bingham*, i cui parametri sono riportati in tabella 1. In via preliminare, si è inoltre considerato che la propagazione della colata avvenga su una base non erodibile. Sul rilievo digitale è stata realizzata una griglia regolare con 62880 nodi, in corrispondenza dei quali si interpolano le (x, y, z) che riproducono la base topografica della zona di interesse per la modellazione. L'area su cui insiste il volume della frana superficiale considerata, valutato in circa 1100 m^3, è suddivisa in 30760 particelle, con una griglia di lati $\Delta x = \Delta y = 1$ m. All'interno dell'area in frana, in ogni punto di coordinate (x, y), lo spessore h del relativo volume è ottenuto per

Fattore K	2
Raggio di influenza = k* Δx (m)	1

Tab. 1– Valori assegnati ai parametri utilizzati dal codice di calcolo per eseguire la simulazione.

differenza tra le coordinate z prima e dopo l'evento franoso. Nella tabella 1 sono mostrati i valori assegnati ai parametri richiesti dal codice di calcolo per la simulazione (GIOFFRÈ, 2005).

Una sintesi dei risultati della modellazione, proposta nella figura 2, mostra una soddisfacente simulazione della traiettoria e delle distanze percorse dalla colata, con una velocità media di propagazione di circa 5-6 m/s. Pur non avendo dati puntuali sulle reali altezze dei volumi di frana nella zona di arresto, dal confronto tra il volume effettivamente coinvolto nella colata, valutato dalle foto disponibili per la zona di valle, e quello valutato dalle simulazioni numeriche svolte, si evince che durante la propagazione si è verificato un notevole apporto al

Fig. 2 – Risultati della modellazione con posizione della colata in diversi istanti di tempo.

volume in frana dovuto a fenomeni di erosione del fondo, non considerati nelle simulazioni numeriche condotte (fig. 2).

CONCLUSIONI

I rilevamenti geologici e geomorfologici di dettaglio condotti nell'area di Favazzina hanno evidenziato la presenza di diversi elementi di predisposizione per il verificarsi di frane superficiali e veloci: elevata acclività del versante, presenza di terreni di alterazione, presenza di elementi antropici (strade, sentieri e tagli) disposti ortogonalmente alla direzione di massima pendenza. La modellazione della colata del 12 maggio 2001 fornisce soddisfacenti indicazioni circa le modalità di propagazione (traiettorie, distanze e velocità) e indica fra gli approfondimenti di studio: la circostanziata delimitazione delle possibili zone sorgenti; la valutazione degli spessori dei terreni di alterazione e la loro caratterizzazione geotecnica; le possibili condizioni e meccanismi di innesco delle frane superficiali e la loro evoluzione cinematica da scorrimento in colata; una modellazione della propagazione delle colate idonea per una valutazione adeguata dei volumi totali coinvolti.

Carta del grado di alterazione e categorie di frane nell'alta valle del Fiume Trionto (Calabria, Italia)

LUIGI BORRELLI (°), GINO COFONE (°), SALVATORE CRITELLI (*), SAVERIO GRECO (°*) & GIOVANNI GULLÀ (°)

Key words: *Alterazione, Calabria, categorie di frane, profili di alterazione, rocce granitoidi.*

ABSTRACT

Il territorio della Calabria risulta ampiamente interessato dalle più svariate fenomenologie franose che mostrano una particolare intensità nell'ambito delle rocce cristalline interessate, spesso, da profondi processi di alterazione (GUZZETTA, 1974; IETTO, 1975). Con riferimento a quest'ultimo aspetto è noto che nelle aree in cui sono presenti rocce cristalline, diffusamente presenti in tutto il globo, la stabilità dei versanti, e più in generale la dinamica evolutiva degli stessi, risulta fortemente condizionata dagli spessori di roccia attaccati dai processi d'alterazione e dall'intensità raggiunta dagli stessi (DEERE & PATTON, 1971; CASCINI *et alii*, 1992; LACERDA & SANTOS, 2000; CALCATERRA *et alii*, 1996; BORRELLI *et alii*, 2012).

In relazione a quanto evidenziato, alcune esperienze disponibili in letteratura delineano l'utilità della cartografia del grado di alterazione e dei profili di alterazione nell'identificazione di elementi di omogeneità per definite categorie di instabilità di versante (Cascini *et alii*, 1992; Borrelli *et alii* (2012). Pertanto, si è ritenuto di approfondire l'utilizzo della metodologia proposta da CASCINI *et alii* (1992), GULLÀ & MATANO (1994), BORRELLI *et alii* (2012) in un contesto di particolare complessità geologico-strutturale. In particolare, la presenza di fenomeni franosi che periodicamente producono ingenti danni ha fatto cadere la scelta su di un'area campione, dell'estensione di circa 57 km^2, posta nel comprensorio del comune di Longobucco (CS), corrispondente alla porzione occidentale del bacino del Fiume Trionto, la quale risulta particolarmente complessa e significativa nel contesto regionale.

Il rilievo del grado di alterazione (condotto a scala 1:5.000), parallelamente al rilevamento geologico di base, è stato effettuato arealmente, utilizzando osservazioni e test qualitativi e semi-quantitativi, su 25 fronti rocciosi (naturali o artificiali, con consistente sviluppo verticale), assumendo come riferimento generale l'approccio metodologico già utilizzato in altre aree della Sila Occidentale (CASCINI *et alii*, 1992; GULLÀ & MATANO, 1994; BORRELLI *et alii*, 2012). Nella stessa area è stato, inoltre, eseguito uno studio geomorfogico (sempre alla scala 1:5.000), che ha portato, tramite analisi di foto aeree di diverso periodo e successive verifiche sul terreno (eseguite nell'arco temporale 2011 – 2012), alla redazione della carta inventario dei fenomeni di movimento in massa.

I risultati dei rilievi di superficie congiuntamente a quelli derivanti dallo studio dei fronti, ha consentito la redazione della "Carta del grado di alterazione e dei fenomeni di movimento in massa della porzione occidentale del bacino del F. Trionto", alla scala 1:5.000 (fig. 1) (GRECO, 2012). In particolare, sono state riconosciute, in affioramento, cinque delle sei classi di alterazione previste dalla classificazione adottata: classe VI (terreni residuali e/o colluviali), classe V (roccia completamente alterata), classe IV (roccia altamente alterata), classe III (roccia moderatamente alterata), classe II (roccia debolmente alterata).

Dall'analisi della carta redatta si evidenziano relazioni tra l'assetto strutturale, la distribuzione delle varie classi di alterazione, e la distribuzione e concentrazione dei fenomeni di movimento in massa. In particolare una discreta corrispondenza tra l'assetto strutturale e la distribuzione delle varie classi di alterazione è bene evidente lungo le faglie N-S e NW-SE, dove l'approfondimento del reticolo idrografico, facilitato dalla fratturazione delle rocce, ha messo a giorno roccia poco alterata. I movimenti verticali tra i blocchi adiacenti lungo le faglie dirette hanno sollevato porzioni meno alterate di rocce cristalline, da debolmente ad altamente alterate (classi II, III e IV), che si allineano lungo le principali dislocazioni, in corrispondenza delle incisioni torrentizie. In zone di interferenza tra macrostrutture appartenenti a sistemi diversi si segnala una maggiore articolazione del profilo di alterazione e la presenza di coperture di natura detritico-colluviali.

Riguardo le caratteristiche del profilo di alterazione delle rocce granitoidi affioranti nell'area di studio, si è osservato, limitatamente a quanto è esposto sui fronti esaminati, che il profilo di alterazione è complessivamente semplice e con passaggi graduali da una classe d'alterazione all'altra (profilo di alterazione canonico). Localmente, in corrispondenza delle principali discontinuità tettoniche (faglie e *thrust*) possono

rinvenirsi zone maggiormente fratturate, caratterizzate da una più intensa alterazione e/o degradazione, e fasce di terreni argillificati (*fault gouge*) in corrispondenza dei piani.

L'assetto geologico-strutturale, le condizioni di alterazione degli ammassi rocciosi in affioramento e la complessità dei profili di alterazione, rappresentano nel complesso gli elementi di predisposizione allo sviluppo dei fenomeni di movimento in massa.

Il bacino del F. Trionto è, infatti, da tempo interessato da una diffusa instabilità, con fenomeni franosi che sono spesso riattivazioni di frane note già da tempo (ADORNI *et alii*, 1995). I fenomeni franosi sono confinati al settore più interno (porzione centro-orientale) dell'area di studio, lungo i versanti che bordano il Fiume Trionto e i suoi affluenti, dove è maggiore l'energia di rilievo (fig. 1). Nello specifico, sono stati rilevati e cartografati numerosi fenomeni franosi, di varia tipologia e cinematica, che per le finalità dello studio sono stati raggruppati in categorie, in funzione dello spessore di materiale coinvolto (stimato su base geomorfologica): frane superficiali, mediamente profonde e profonde.

Le frane superficiali (fig. 2), tipologicamente ascrivibili a fenomeni di scorrimento-colata di detrito, coinvolgono spessori modesti, generalmente inferiori ai 3 m, di materiale detritico-colluviale. I fenomeni interessano sia i versanti aperti sia gli impluvi, e particolarmente i tratti di rete idrografica di ordine inferiore, localizzati prevalentemente lungo i versanti del Fiume Trionto, del Torrente Macrocioli e del Torrente Manna, dove le

Fig. 2– Esempio di fenomeno franoso superficiale, di tipo scorrimento-colata di detrito: a) panoramica del fenomeno franoso; b) particolare della zona di innesco; c) particolare del canale di flusso; d) particolare della zona di accumulo.

zone sorgenti si attestano mediamente su pendenze maggiori di 45°. Le aree sorgenti sono caratterizzate da piccole nicchie o rotture di pendenza ed interessano le coperture di classe VI mettendo a nudo, una volta verificatisi, le rocce meno alterate (generalmente le classi III e IV) che caratterizzano i profili di alterazione tipici (fig. 2). I canali di trasporto coincidono, in linea di massima, con impluvi o canali preesistenti. Le aree di accumulo sono localizzate al termine del canale di trasporto e spesso originano o alimentano la formazione di conoidi detritiche.

Le frane mediamente profonde (fig. 3a), tipologicamente ascrivibili a scorrimenti rotazionali e/o rototraslazionali, coinvolgono spessori massimi di materiale dell’ordine dei 30 m e generalmente interessano i terreni di classe VI e V o la roccia alterata (classi III e IV) e fratturata, lungo discontinuità strutturali (generalmente di origine tettonica).

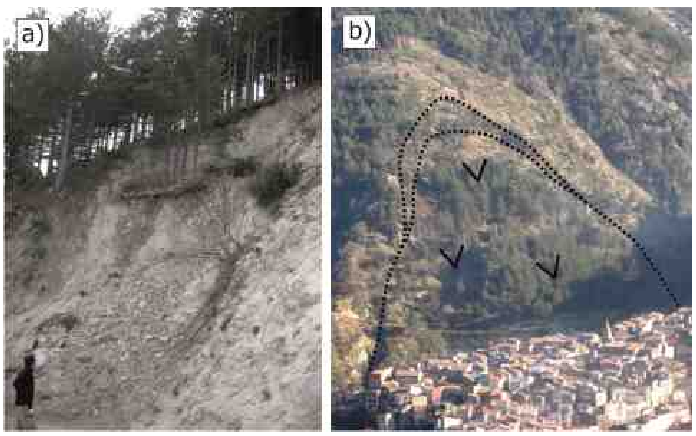

Fig. 3– Esempi di fenomeni franosi di tipo scorrimento: a) scorrimento rotazionale di terra e/o detrito, mediamente profondo; b) scorrimento traslazionale di roccia, profondo.

Le frane profonde (fig. 3b), tipologicamente ascrivibili a scorrimenti traslazionali, coinvolgono spessori massimi di materiale maggiori di 30 m, e si sviluppano nella roccia meno alterata (classi II e III), lungo discontinuità di origine tettonica a cui sono associate zone di roccia completamente degradata e ridotta come consistenza a terreno (*fault gouge*); in particolare, giocano un ruolo determinante nello sviluppo di tale categoria di frana i piani di *thrust* (quando disposti a franapoggio con angolo inferiore a quello del pendio), mentre le faglie, spesso, ne delimitano i fianchi o le zone di corona.

La sintesi dei rilievi effettuati, rappresentati dalla figura 1, rendono conto del fatto che nelle aree dove sono presenti in affioramento rocce cristalline la redazione di carte del grado di alterazione e la definizione di profili d’alterazione rappresentativi di definiti settori, può risultare di estrema utilità sia per la pianificazione territoriale sia per definire ed affrontare le problematiche determinate dai movimenti in massa oltre che per indirizzare più efficacemente gli approfondimenti di studio e le indagini.

Lo studio dei profili di alterazione consente, inoltre, di individuare elementi caratteristici che possono condizionare in maniera sostanziale lo sviluppo di definite categorie di frane (superficiali, mediamente profonde e profonde) nelle rocce cristalline alterate.

Si può dunque concludere che nei contesti caratterizzati dalla presenza in affioramento di rocce cristalline l’approccio metodologico utilizzato nella presente nota è in grado di fornire un quadro conoscitivo di estrema efficacia per la definizione di procedure specifiche per la valutazione della suscettibilità, pericolosità e rischio da frana.

Key words: *Deformazione Gravitativa Profonda di Versante, GPS, Inclinometro, Monitoraggio integrato, Rocce degradate e alterate, Spostamenti superficiali e profondi.*

INTRODUZIONE

I movimenti in massa che interessano il versante di Greci, nel comune di Lago (CS), sono oggetto di approfonditi studi a carattere geologico, geomorfologico e geotecnico da oltre 10 anni ad opera del CNR-IRPI e del Servizio Geofisica di ISPRA.

Il versante di Greci, prospicente l'abitato di Lago, è interessato da una Deformazione Gravitativa Profonda di Versante (DGPV) tipo Sackung, che coinvolge rocce metamorfiche di basso grado fratturate e profondamente degradate e alterate (SORRISO-VALVO *et alii*, 1999). Le condizioni di instabilità sono rese complesse dalla sovrapposizione alla DGPV di frane superficiali, mediamente profonde e profonde, che hanno causato negli anni danni alle strutture e infrastrutture presenti nell'area di interesse. Gli studi condotti da BONCI *et alii* (2010) hanno permesso di accertare che la DGPV presente nel versante di Greci, con spessori dell'ordine dei 100 m, si muove con velocità dell'ordine di 0.50 cm/anno. Nella stessa area sono state identificate frane mediamente profonde (zona Piscopie) e profonde (zona Acqua Fredda), caratterizzate da cinematismo prevalentemente traslazionale con velocità generalmente costanti e, rispettivamente, dell'ordine di 1 cm/anno e di 10 cm/anno, che a seguito delle rilevanti e prolungate precipitazioni piovose hanno subito significativi incrementi negli inverni 2008-2009 e 2009-2010.

Il Servizio Geofisica di ISPRA in collaborazione con il CNR-IRPI ha progettato e realizzato una rete integrata di monitoraggio permanente GPS-geotecnica finanziata con fondi del Dipartimento di Protezione Civile e della Regione Calabria (Legge n. 267/98, Decreto Sarno). La rete, operativa dal 2007, è costituita da stazioni GPS in acquisizione continua per il controllo degli spostamenti superficiali e da strumentazione geotecnica (inclinometri e piezometri). Tale strumentazione, ha integrato una rete di monitoraggio, con misure periodiche, avviata dagli anni '90 (SORRISO-VALVO *et alii*, 1999).

RETE DI MONITORAGGIO E ANALISI DEI DATI

La Rete di monitoraggio GPS originale è costituita da 24 vertici sui quali sono state effettuate misure periodiche dal 1996. Dal 2007 sono state installate 6 stazioni GPS in acquisizione continua (Fig. 1). L'architettura della rete in continuo ha previsto una stazione di riferimento (Master) ubicata su un edificio in un'area di adeguata stabilità e 5 stazioni di controllo installate nell'ambito del versante di Greci, al fine di definirne le condizioni di movimento e di stabilità. Tutte le procedure di gestione remota dei ricevitori, trasferimento dei *raw data*, controllo di qualità dei dati e archiviazione sono eseguite in automatico dal *software* di gestione presente presso il Centro di Raccolta Elaborazione e Controllo Dati di Roma nella sede del Servizio Geofisica di ISPRA. Tale *software* esegue automaticamente il processamento dei dati determinando le soluzioni giornaliere di ciascun punto di controllo rispetto alla stazione Master, considerata fissa, e gli spostamenti relativi dei punti di controllo.

La rete di monitoraggio degli spostamenti profondi, inizialmente costituita da due verticali inclinometriche spinte sino a circa 100 m (S03 - S01G, Fig. 1), dal 2007 è stata integrata con altre quattro verticali (SL4B, misurata sino a 80 m; SL5, misurata sino a 56 m; SL6, misurata sino a 59 m; SL7, misurata sino a 78 m). Nel periodo successivo tre delle quattro nuove verticali realizzate sono state rese inutilizzabili dalle deformazioni cumulate, ma il monitoraggio degli spostamenti profondi condotto ha consentito: l'accertamento della presenza sul versante di frane mediamente profonde e profonde, la validazione degli spostamenti superficiali misurati con la rete GPS. L'esito delle verticali inclinometriche ha confermato come indicazione generale l'opportunità di non utilizzare strumentazioni in continuo per le verticali inclinometriche. La

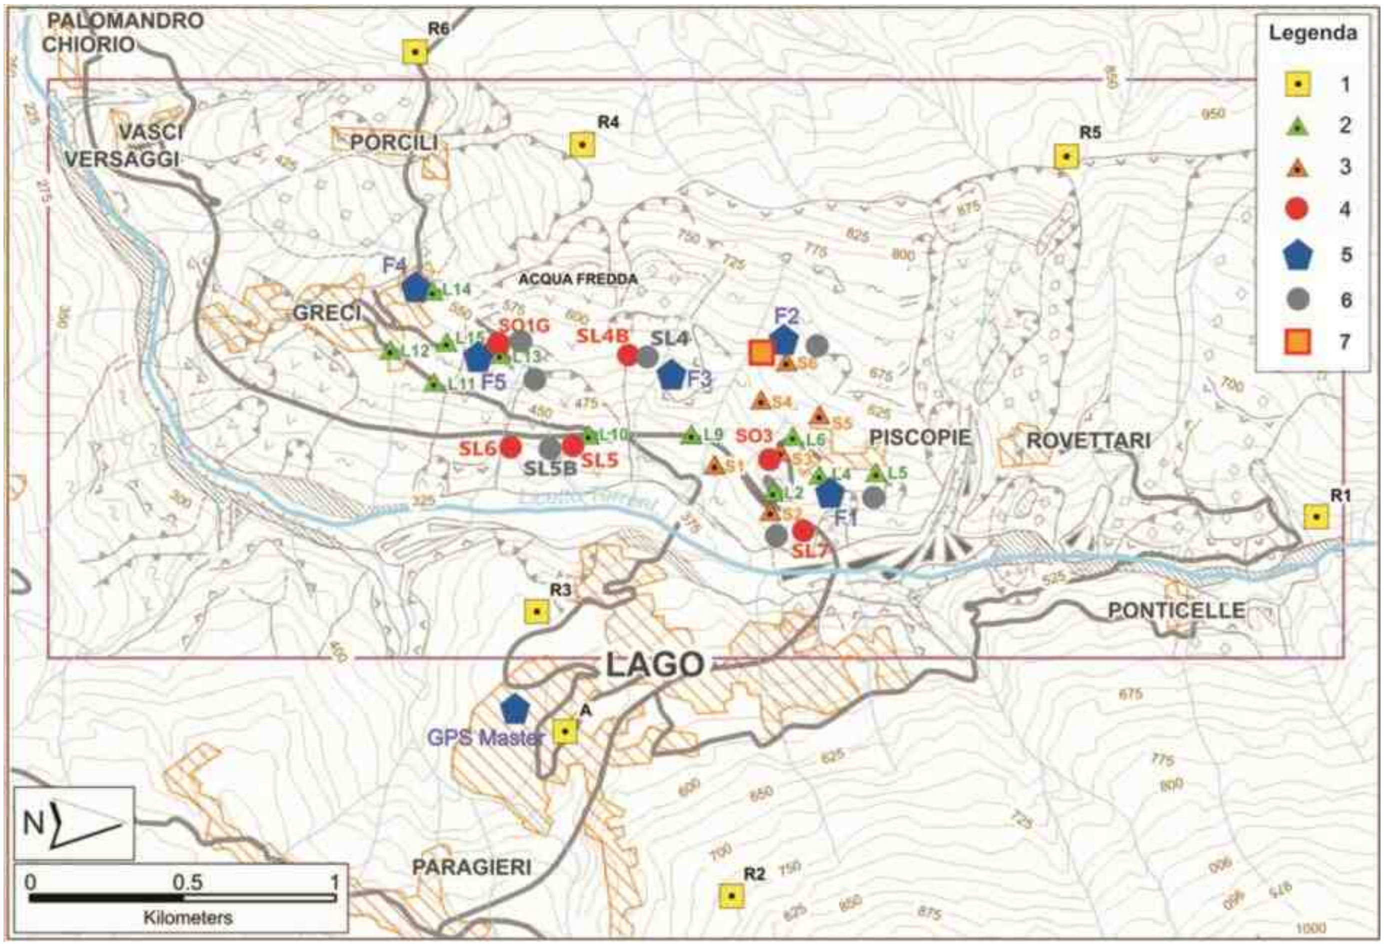

Fig. 1 – Ubicazione dei punti di monitoraggio all'interno della frana: 1) punti GPS di riferimento misurati in modalità statica; 2) punti GPS di controllo inizialmente misurati in modaltà statico rapida; 3) punti di controllo misurati in modalità statica; 4) verticali inclinometriche; 5) stazioni GPS permanenti; 6) piezometri; 7) stazione meteo.

rete integrata di monitoraggio, nella sua definitiva configurazione, ha visto la realizzazione, in aggiunta alle precedenti verticali piezometriche misurate manualmente, di due nuove verticali (SL4 e SL5B) e di una stazione meteo, con acquisizione in continuo delle misure e trasmissione in remoto.

L'installazione di stazioni GPS in acquisizione continua ha permesso di seguire con grande dettaglio l'andamento dei movimenti nei vari periodi dell'anno. Le velocità medie ottenute dalle serie storiche delle stazioni in continuo sono in accordo con quelle dedotte dalle misure periodiche precedenti, ma le prime mostrano chiaramente un andamento dei movimenti caratterizzato da accelerazioni alternate a periodi di rallentamento. L'esame complessivo delle misure GPS e inclinometriche conferma le maggiori velocità nel settore di Acqua Fredda (anche superiori a 10 cm/anno per la stazione F5), velocità contenute nel settore di Piscopie (circa 1 cm/anno) e velocità intermedie nel settore interposto (circa 2 cm/anno rilevate da GPS F3 e dall'inclinometro SL4B). Le aree di margine (GPS F4 e F1 e inclinometro SL7) appaiono sostanzialmente ferme (Fig. 2), sebbene la stazione F1 segnali un lieve movimento superficiale (0.5 mm/anno) in un'area che in precedenza non aveva mostrato spostamenti significativi.

L'analisi delle serie storiche GPS ha evidenziato negli inverni 2008-2009 e 2009-2010 un significativo incremento delle velocità di movimento. In particolare nel settore di Acqua Fredda nel periodo febbraio-giugno 2009 la stazione F5 ha registrato velocità circa quattro volte superiori la velocità media annua rilevata negli anni precedenti.

DISCUSSIONE E CONCLUSIONI

La Rete integrata di monitoraggio GPS-geotecnica di Lago è stata progettata e realizzata prendendo spunto dal quadro conoscitivo e dall'esperienza maturata su una rete integrata di monitoraggio, con misure periodiche, avviata negli anni '90. Ciò ha permesso di progettare la nuova rete, con acquisizione in continuo, allo scopo di approfondire l'andamento dei movimenti su quelle porzioni di territorio che avevano mostrato una propensione al dissesto e di verificare la stabilità dei settori ritenuti stabili, con l'obiettivo di definire un robusto modello cinematico del fenomeno di instabilità che controlla l'evoluzione del versante coinvolto dalla DGPV. La bontà della scelta dei siti è stata confermata dal confronto tra le misure effettuate con diverse tecniche (GPS e inclinometriche) e con diverse modalità (manuali e in continuo). La continuità del dato

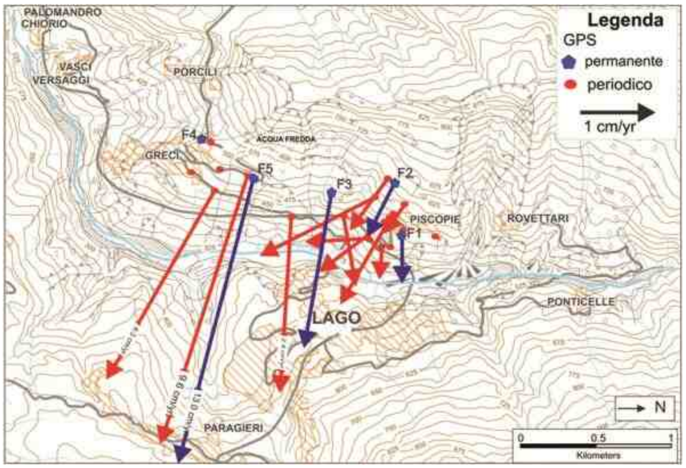

Fig. 2 – Spostamenti superficiali lungo il versante in studio rilevati con misure GPS periodiche (vettori rossi) e con stazioni in continuo (vettori blu). I punti privi di vettore non hanno mostrato spostamenti significativi.

ottenuto con stazioni permanenti permette di verificare sia le eventuali variazioni di velocità durante l'anno sia l'effetto delle precipitazioni sulla cinematica dell'area. La verifica della congruenza delle misure superficiali e profonde ha permesso di attribuire le corrette caratteristiche di movimento ai volumi instabili per gli spessori effettivamente coinvolti. Infine il significativo periodo di monitoraggio ha consentito di accertare la possibilità che sul versante di Greci, generalmente interessato da movimenti caratterizzati da velocità medie costanti, si manifestino variazioni delle stesse velocità, in presenza di piogge cumulate su periodi adeguati, in grado di determinare condizioni critiche del regime delle pressioni neutre nei volumi instabili.

La ricerca svolta, oltre a fornire un contributo conoscitivo per la comprensione dei processi di instabilità nei versanti costituiti da rocce degradate e alterate, ha importanti ricadute generali in quanto delinea un efficace percorso metodologico per il monitoraggio integrato, con particolare riferimento ai versanti in rocce degradate e alterate interessate da movimenti in massa complessi dal punto di vista geologico-strutturale e geotecnico.

Landslide susceptibility, hazard and risk zoning in weathered gneiss of the Sila massif

LEONARDO CASCINI (*)

Key words: *Landslides, weathered gneiss, susceptibility, hazard, risk*

INTRODUCTION

Landslides zoning is a powerful tool to improve land-use planning and to avoid the development of threatened areas, the most efficient and economic way to reduce future damages and loss of lives. This sentence is quoted from the Introduction of Cascini (2008), who discusses the applicability of the International Guidelines for landslide susceptibility, hazard and risk zoning for land-use planning developed by Fell et al. (2008).

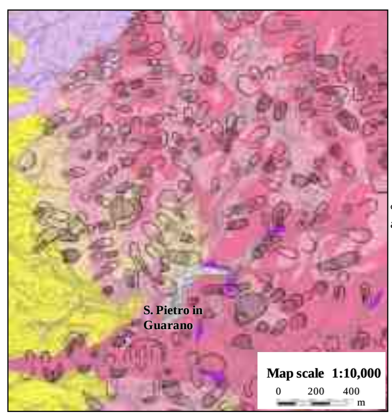
A case study clearly highlighting the relevance of the landslide zoning concerns the weathered gneiss of the Sila Grande massif in Calabria Region (Southern Italy) where the instability phenomena suffer sudden occasional reactivation after long period of total absence of displacements, also during tens of years. As a consequence, the geomorphological evidence of the landslides blurs and the urbanization of instable areas increases, improperly involving unstable areas. Indeed, susceptibility and hazard zoning can allow a better land-use planning while risk zoning makes some stabilization work possible in advance in order to avoid or limit the consequence caused to buildings and infrastructures by the occasional reactivations.

In this brief paper the zoning developed in a study area, 7.5 km^2 large, is discussed fully quoting two examples from Cascini (2008). For a thorough examination of the geological and geothecnical questions - related to the mechanical properties of the weathered gneiss and groundwater regime in the slopes - consult Cascini and Gullà (1993) and Cascini et al. (2006).

SUSCEPTIBILITY AND HAZARD ASSESMENT AT LARGE SCALE

The study area is located in the western side of the Sila massif and, as it can be read in Cascini (2008), it is characterized by complex morphology and diffuse dormant landslides not easy to be recognized due to the long period between two successive occasional reactivations essentially related to critical cumulated rainfall. Two other significant types of landforms are present in the area, i.e. hollows filled with debris and steps.

All these landforms affect the gneiss unit that is differently weathered and classified according to the methodology suggested in Cascini et al. (1992, 1994a, 1994b) that distinguishes 6 different weathering classes ranging from the fresh rock (class I) to the completely weathered gneiss (class V) and the residual soil and colluvium (class VI). The map of the weathering grade, landslides and hollows in the gneissic unit is given in Figure 1 that also furnishes some other useful data such as the landslides slope angle and the outcropping area of the weathering grade classes.



Weathering Grade or Class	Outcropping Area (km^2)	% A	Landslides Slope Angle
VI	0.590	29.6	21°-23°
V	2.459	31.0	
IV	2.831	26.9	27°-30°
III	0.054	20.2	
tot.	5.934		

% A = percentage of landslide area referred to the outcropping area of each weathering class (e.g., susceptibility descriptors).

GNEISSIC UNIT
sc SCHIST UNIT

Fig. 1 –Map of the weathering grade, landslides, and hollows in the Gneissic Units of an area in the Calabria region (southern Italy) (modified from Cascini, 2008).

Focusing the attention on the landslides affecting the weathered classes V-VI, Figure 2 shows the overlapping of the area prone to instability phenomena (landslides and hollows), the geological structural elements and the active stream down-cutting on the bedrock. It can be observed that about 90% of the landslides prone areas are influenced by the drainage network and/or tectonic structures. This allows the definition of qualitative susceptibility descriptors related to the likelihood of landsliding. Particularly, a high susceptibility can be assumed for all the landslides and hollows filled with debris, interacting with tectonic structures and/or the drainage network, while a moderate susceptibility can be attributed to the other hollows. Figure 2 also shows the frequency assessment, the hazard and the intensity

(*) Department of Civil Engineering – University of Salerno – via Ponte don Melillo – 84084 Fisciano (SA)

(expected velocity) descriptors for all the landslides prone areas. The frequency is evaluated as $f = N^*/\Delta T \cdot N_{tot}$, where N_{tot} is the total of the inventoried landslides (83) in the area and N* is the number of the recorded reactivation (11) over a period ΔT of 103 years, i.e. the period of the available incident data set.

Regarding this, Cascini (2008) observes that the frequency of occasional reactivations so estimated can be misleading due to the lack of data in the data set, essentially when the landslides involve not urbanised area. On the contrary, a more advanced estimate of the landslide return period can be obtained when the landslide develop inside urbanised area as in the case of the sample landslide hereafter discussed.

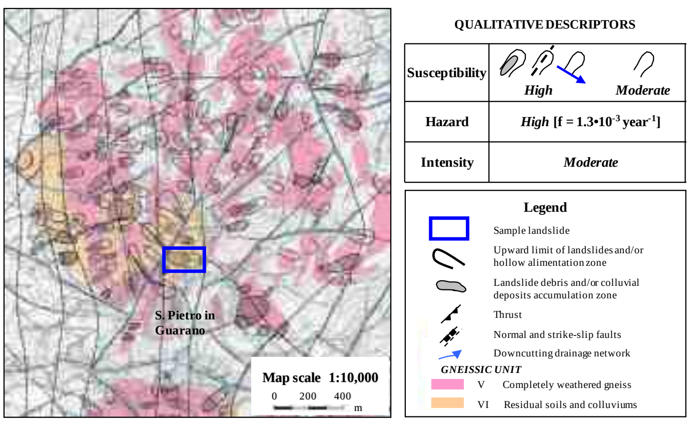

Fig. 2 – Map of landslides and hollows in weathered gneissic classes V–VI, drainage network and tectonic structures.

LANDSLIDE ANALYSIS AT DETAILED SCALE

The sample area is composed of two parts (A and B in Figure 3). Cascini (2008) points out that during the last century, part B reactivated six times (1931, 1945, 1948, 1952/53, 1976, 1981) in occasional and sudden reactivations that twice (1931, 1981) spread upslope, some hours later than the small landslide mobilization. Each event occurred during the wet season after intense cumulated rainfall and was characterized , within a short period of time (generally few hours), by small displacements not larger than few meters at the toe, and decreasing upslope. During the 1970s, after only few decades in dormant state, the landslide hazard was not recognised and many structures were built in the area. Many of these structures were seriously damaged during the last reactivation dated 1981.

In order to analyze the slope stability condition, from April 1981 three investigations were carried out (1981, 1983 and 1987) when 2 inclinometers and 46 piezometers were installed, and weekly monitored for a long period of time, in a total of 29 boreholes that cover an area of about 2ha. Moreover, undisturbed samples were systematically collected in the boreholes and laboratory tests were performed in saturated and unsaturated conditions.

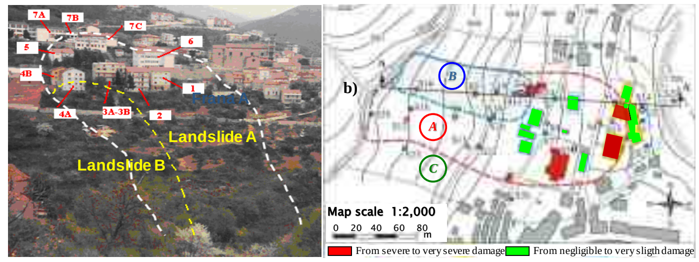

Fig. 3 – a) An overview of the landsliding zone; b) Investigations following the event that occurred in 1981 (modified from Cascini, 2008).

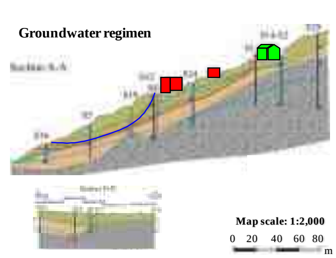
All the available data allowed i) to develop accurate geotechnical cross sections, ii) to assess reliable relationships between rainfall and the groundwater regime all over the slope, iii) thanks to these relationships to estimate the groundwater level during the reactivation stages, characterized by the residual shear strength along the slip surfaces iv) and to perform accurate and calibrated geotechnical analyses for different scenarios of the reactivation stages.

Particularly, these scenarios connect the slope safety factor and the slope displacements to cumulated rainfall having a different return period.

Figures 4 and 5 summarise the main obtained results. Referring to Figure 4, Cascini (2008) underlines that the values of quantitative hazard descriptors obtained at slope scale, and on the basis of an advanced knowledge of all the relevant factors, considerably differ from those obtained with the aid of the dataset available for the sample area (Figure 2); while similar classes are obtained when qualitative hazard descriptors are used. According to Fell et al. (2008), this confirms that in many cases there are insufficient data to reliably classify the hazard. In such cases, the available data should be used to make the best estimate of the hazard using qualitative hazard descriptors.

As it concerns the velocity assessment, Cascini (2008) observes that the values in Figure 4 were obtained by a FEM stress-strain analysis, performed using the SIGMA/W code (GeoStudio, 2004) that also furnishes the consequence scenarios in Figure 5, concerning two cumulated rainfall having a return period of T = 50 and T = 100 years.



Frequency assessment		$f = \frac{1}{T}$
Intensity assessment		Calculated mean velocity at the toe of the landslide (A)
Descriptors	Hazard	(A) High ($f = 2 \cdot 10^{-2}$ year^{-1}); (B) Very High ($f = 10^{-1}$ year^{-1}); (C) Very Low
	Magnitude	Volume ~50,000 m^3 (B); ~170,000 m^3 (A)
	Intensity	Mean velocity $2.1 \cdot 10^{-2}$ m/h

Fig. 4 – Assessment of descriptors for landslides A and B in Figure 3b (modified from Cascini, 2008).

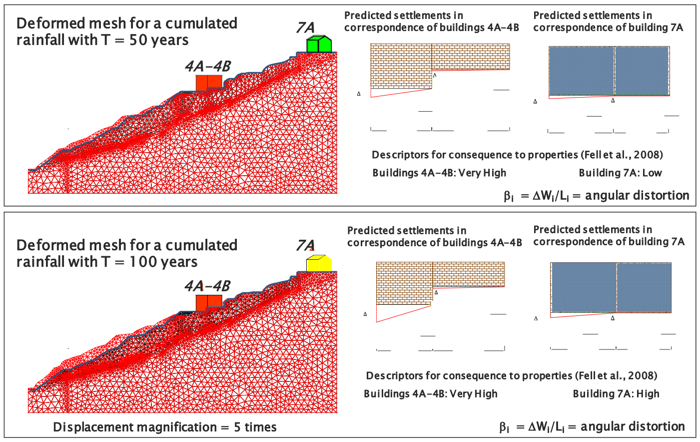


Fig. 5 – Consequence scenarios by FEM stress–strain analyses (modified from Cascini, 2008).

Referring to the shortest return period (T = 50 years), it is worth noting to observe that the analysis well explains the different damages recorded during the 1981 event, that occurred just after the last reactivation dated 1931, when building 1 was completely destroyed and building 2 suffered minor consequences (Cascini, 1983). Whereas, a different scenario characterizes the cumulated rainfall having the return period of T = 100 years that causes larger displacements, due to the highest groundwater level all over the slope. As a consequence, in such a case also the building 2 proves to be seriously damaged, considering that the angular distortion attains values of $\delta > 1/300$. Independently from the numerical results, that anyway are particularly consistent from a technical point of view, it can be concluded that analyses similar to those briefly summarized in the present paper are of fundamental relevance in geo-environmental context where slope displacements do not allow any landslides susceptibility and hazard assessment and, then, any risk estimation at slope scale.

Appendix. Terminology from Fell et al. (2008)

Landslide susceptibility zoning involves the classification, area or volume (magnitude) and spatial distribution of existing and potential landslides in the study area. It may also include a description of the travel distance, velocity and intensity of the existing or potential landsliding. Landslide susceptibility zoning usually involves developing an inventory of landslides which have occurred in the past together with an assessment of the areas with a potential to experience landsliding in the future, but with no assessment of the frequency (annual probability) of the occurrence of landslides. [...]

Landslide hazard zoning takes the outcomes of landslide susceptibility mapping and assigns an estimated frequency (i.e. annual probability) to the potential landslides. [...] The hazard may be expressed as the frequency of a particular type of landslide of a certain volume, or landslides of a particular type, volume and velocity (which may vary with distance from the landslide source). [...]

Landslide risk zoning takes the outcomes of hazard mapping, and assesses the potential damage to persons (annual probability of loss of life), to property (annual value of property loss), and environmental features (annual value of loss) for the elements at risk, accounting for temporal and spatial probability and vulnerability.

Weathering surveys and mapping in landslide hazard analysis: studies on weathered gneiss in Sila Massif (Calabria, Italy).

SILVIO DI NOCERA (*) & FABIO MATANO (**)

Key words: *weathering grade map; gneiss; landslide hazard; Calabria; Italy.*

INTRODUCTION AND WEATHERING PROFILE IN WESTERN SILA

In weathered crystalline rocks the evolution of slopes, and particularly of landslide phenomena, are mainly controlled by the characteristics and thickness of the weathering profile. Field analysis, classification and mapping of the weathering grade are therefore basic tools in geological and engineering geological studies for landslide hazard analysis (CASCINI *et alii*, 1992, 1994). The importance of a comprehensive overview of the weathering patterns also concerns territorial planning studies and landslide risk management, which need a cartographical representation of the weathering profile (Di NOCERA & MATANO, 2002).

The Sila massif crystalline rocks are characterized by a deep and complex weathering profile. GUZZETTA (1974) hypothesized an ancient tropical weathering in Calabria, so that the deep weathering profile would represent a fossil, partially eroded mantle. On the basis of petrographic analysis, CRITELLI *et alii* (1991b) consider the weathering profile of the Sila gneiss to have developed through chemical processes under humid climatic conditions. The analysis of the observed decomposition and degradation features of the weathered rocks has to consider that they result from the accumulation of the weathering effects produced under climatic conditions since the emerging of the Sila massif to the present time.

The regional tectonic evolution shows that the Sila massif structural high had already emerged after the Tortonian. The development of the weathering profiles in Sila could have occurred between the Messinian and the Pleistocene under various climatic conditions. Under the current climatic conditions the erosional processes, as activated by tectonic uplifting, prevail over the weathering processes, although not enough to completely remove the exposed, fossil, deeply weathered mantle. The saprolite and regoliths widely crop out along the top palaeosurface of the Sila massif, where they are a hundred of meters thick, while the fossil weathering profile is highly eroded along the Sila western slope.

WEATHERING SURVEYS AND MAPPING METHODOLOGY

A methodology for the survey and mapping of the weathering grade of crystalline rocks, applicable to various scales has been described (CASCINI *et alii*, 1991, 1992; GULLÀ & MATANO, 1994, 1996; LE PERA *et alii*, 2001; BORRELLI *et alii*, 2007).

The paper summarizes a methodology for the classification and survey of the weathering grade in gneiss. It consists of a detailed survey in the field, which is based on a careful analysis of the outcropping rocks and soils through observations of strength, discolouration and texture of the regolith and the results of Schmidt Hammer tests. Six weathering classes have been adopted: fresh (class I), slightly weathered (class II), moderately weathered (class III), highly weathered (class IV) and completely weathered (class V) rock, and residual and colluvial soils (class VI). The weathering grade survey on natural or artificial rock outcrops has resulted useful in the collection of data regarding thickness and features of the weathering profile horizons.

This approach has been used for deeply weathered crystalline rocks of the Sila Massif (Northern Calabria, Sothern Italy), which are strongly affected by landsliding. After a preliminary study of the weathering conditions along the western slope (gneiss) and on the plateau (granite) of the massif, detailed weathering surveys of selected sectors of the slope have been performed and various weathering maps with from 1:5.000 to 1:200 scale have been plotted. The surveys put into evidence complex and deep weathering profiles. This approach can improve our understanding of engineering geomorphological problems, such as rock slope stability and landsliding.

LANDSLIDE INVESTIGATIONS ON WEATHERED GNEISS IN SILA MASSIF WESTERN SLOPE

The studies on the instability phenomena which take place in the weathered gneiss of the western slope of the Sila Massif

(*) Dipartimento di Scienze della Terra, Università degli Studi di Napoli Federico II; sildinoc@unina.it

(**) Libero professionista; fabiomatano@libero.it

(CASCINI *et alii*, 1992, 1994) have shown that the stability conditions are quite underestimated, since there are many impulsive active landslides, generally of limited extension. In particular about 29% of a study sample area (i.d. San Pietro in Guarano village) is affected by landslides.

The key geologic element of the area is a gneissic unit, which is intensely fractured due to thrusting and to neotectonic activity, which caused the uplift of Sila Massif and the formation of steeply-dipping faults. The structural network favored chemical alteration and physical degradation which both play an important role in the development of the weathering profile and in the evolution of landslide phenomena.

The morphology is complex and uneven: flattened surfaces, structural steps, slopes with medium to steep gradient, and downcutting streams are very common.

In order to show the correlation between weathering and susceptibility to landsliding, a classification of the weathering grade was defined, with reference to the methodology proposed by the Geotechnical Control Office of Hong Kong (CASCINI *et alii*, 1992). Detailed surveys were integrated with drillings and testing of soils and rocks and permitted to obtain a weathering grade map of a sample area, 8 sq. km. large, where we observe a complex weathering profile extending to a depth of 80 m.

The analysis of structural, morphologic, petrographic, geotechnic and hydrologic data discloses a close relationship among slope movements, weathering profiles, faulting conditions of the rock mass, oscillations of the water tables and erosive action worked by the watercourses.

Two main types of landslides have been distinguished:

- the first type involves residual and colluvial soils and develops inside hollows, sometimes filled with debris and colluvium;
- the second one involves weak to hard rocks and develops along pre-existing discontinuity planes.

All the phenomena clearly show an impulsive character: as a consequence, the morphological effects of the instability phenomena can be obliterated, thus originating a potential hazard in the site. Hazard and risk implications connected with anthropic activity and urban areas development are very severe.

Terreni di alterazione da rocce cristalline

GIOVANNI GULLÀ (°), LUIGI ACETO (°) & LUIGI BORRELLI (°)

Key words: *Alterazione, caratterizzazione geotecnica, terreni di alterazione.*

ALTERAZIONE DELLE ROCCE

I processi di alterazione chimico-fisica che interessano in affioramento ed in profondità le rocce, in particolare quelle cristalline, producono importanti trasformazioni delle loro originarie caratteristiche fisiche con conseguente riduzione della resistenza a taglio.

I terreni prodotti dall'alterazione delle rocce cristalline sono oggetto di studio soprattutto nei contesti caratterizzati dalla presenza di clima tropicale (BRAND & PHILLIPSON, 1985), ma si ritrovano spessori consistenti di roccia lapidea ridotta a terreno dall'alterazione anche in altri contesti climatici e, in particolare, si riscontrano in Calabria (38% del territorio costituito da rocce cristalline, figura 1) profondi e complessi profili di alterazione, caratterizzati dalla presenza di potenti spessori di terreni di alterazione (CASCINI *et alii*, 1992; CALCATERRA *et alii*, 1996).

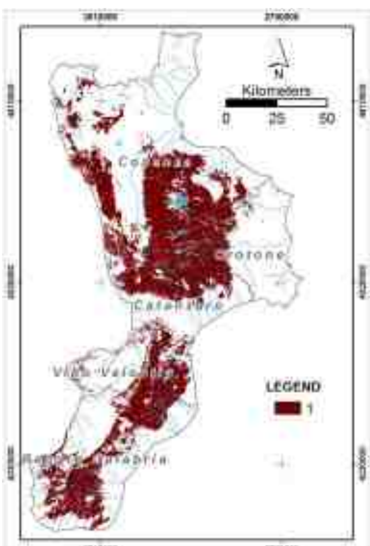

Fig. 1 – Diffusione a scala regionale delle rocce cristalline.

L'alterazione delle rocce, e in particolare la presenza di terreni di alterazione, rappresenta uno dei principali fattori di predisposizione ai movimenti in massa (DEERE & PATTON, 1971; CASCINI *et alii*, 1992; BORRELLI *et alii*, 2007).

Per caratterizzare correttamente i fenomeni naturali che possono essere condizionati dall'alterazione delle rocce, al fine di individuare efficaci soluzioni per le problematiche che ne possono derivare, è importante classificare, alla scala dell'ammasso, dell'elemento di volume e in termini mineralogico-petrografici il grado di alterazione (DEARMAN, 1976; GULLÀ & MATANO, 1997; BORRELLI *et alii*, 2012) e definire le caratteristiche fisico-meccaniche rappresentative dei diversi gradi di alterazione riscontrati, con particolare riferimento ai terreni di alterazione (LUMB, 1962; CASCINI & GULLÀ, 1993).

Nel seguito sono proposti aspetti metodologici e risultati relativi alla classificazione e caratterizzazione geotecnica di alcuni terreni di alterazione da rocce cristalline, rappresentativi di contesti significativi nel territorio della Calabria.

METODOLOGIA E RISULTATI

In generale la classificazione e caratterizzazione dei geomateriali che si riscontrano in un profilo di alterazione deve essere condotta con sperimentazioni in sito e di laboratorio (CASCINI & GULLÀ, 1993; GULLÀ & SORBINO, 1994). Nella presente nota saranno trattati gli aspetti metodologici e i risultati relativi alla sperimentazione geotecnica di laboratorio.

In particolare, l'identificazione dei terreni prodotti dall'alterazione di ammassi rocciosi è efficace sia per la ricostruzione di dettaglio delle verticali indagate sia per la classificazione dei campioni sottoposti a prove meccaniche. Può essere utile, in particolare, la determinazione delle curve granulometriche dei provini sottoposti a prove meccaniche e del materiale di risulta del campione utilizzato. Per tali prove, e in generale per le altre di seguito richiamate, se non sono già disponibili indicazioni è necessario verificare che le tecniche di preparazione e le procedure standard di prova non influenzino i risultati delle prove stesse (GULLÀ & MILITI, 1988). Per quanto attiene la classificazione del grado di alterazione, sia per le rocce gneissiche sia per quelle granitoidi, si può rilevare dalla figura 2 un incremento graduale della frazione sabbia e ghiaia, associato ad una modifica della forma della curva granulometrica,

Il lavoro è stato svolto nell'ambito della Commessa CNR-TA.P05.012 (Responsabile G. Gullà).

passando dai terreni residuali (classe VI) a quelli saprolitici (classe V).

La disponibilità di un adeguato numero di curve granulometriche, di provini e campioni, consente di definire i relativi fusi granulometrici e di verificare la rappresentatività o

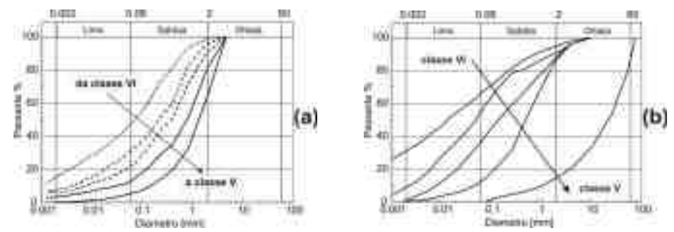

Fig. 2 – Incremento della frazione sabbia e ghiaia e variazione della forma delle curve granulometriche al ridursi del grado di alterazione di terreni: a) di origine granitoide; b) di origine gneissica.

meno dei provini rispetto ai campioni di provenienza (fig. 3).

Ulteriore elemento utile alla classificazione e caratterizzazione dei terreni di alterazione è fornito

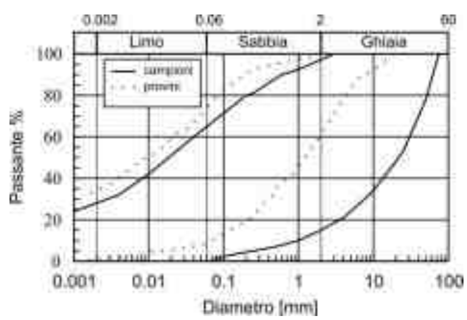

Fig. 3 – Confronto fra i fusi granulometrici relativi a campioni globali e a provini per i terreni di alterazione delle classi VI-V. Campioni globali (n=273), provini (n=180).

dall'esecuzione di prove edometriche. In particolare, il diagramma indice dei vuoti iniziale-peso secco dell'unità di volume fornisce indicazioni circa il grado di alterazione del generico provino: l'incremento dell'indice dei vuoti iniziale è indicativo di una più spinta condizione di alterazione così come una riduzione del peso secco dell'unità di volume. Nella figura 4 è mostrato il diagramma relativo a terreni di alterazione da rocce cristalline presenti in Calabria.

Ulteriori indicazioni circa il grado di alterazione può essere desunto dal valore della pressione di preconsolidazione di provini sottoposti a prova edometrica: al diminuire del valore aumenta il grado di alterazione. Valori bassi della pressione di preconsolidazione sono indicativi di collassabilità del terreno di alterazione.

La definitiva classificazione del grado di alterazione, e la caratterizzazione geotecnica alla scala dell'elemento di volume, è condotta facendo riferimento ai risultati delle prove di taglio diretto. Queste prove, anche se meno raffinate rispetto ad altre (esp. prove triassiali usuali o avanzate), sono quelle più adatte ai terreni di alterazione essendo questi campionabili con difficoltà, per la loro complessità ed eterogeneità (BRAND & PHILLIPSON, 1985; CASCINI & GULLÀ, 1993).

Per la caratterizzazione geotecnica è necessario tuttavia

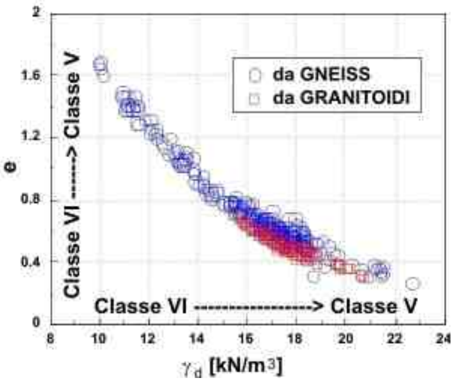

Fig. 4 – Relazione Indice dei vuoti-Peso secco dell'unità di volume per i terreni di alterazione da rocce cristalline.

verificare la possibilità di integrare la sperimentazione anche con prove triassiali, ove necessario utilizzando provini di grande diametro (CASCINI & GULLÀ, 1993). Se si utilizzano provini di dimensioni standard è opportuno verificare se e in quale misura ciò possa influenzare i valori di resistenza ottenuti. Nella figura 5 si osserva che, nel caso dei terreni di alterazione da rocce cristalline presenti in Calabria, i provini di dimensioni standard sono rappresentativi dei campioni di provenienza.

I risultati delle prove di taglio diretto, dalle quali è possibile

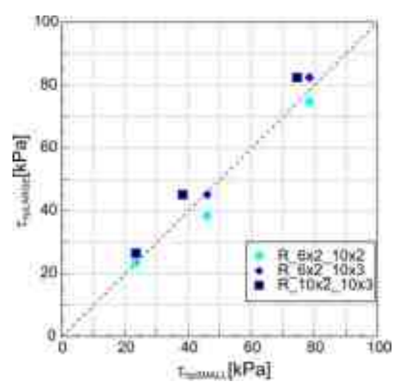

Fig. 5 – Influenza della dimensione dei provini sulla resistenza a taglio stimata mediante prove di taglio diretto.

desumere anche indicazioni circa la resistenza a taglio residua, consentono di precisare le condizioni di alterazione esaminando il meccanismo di rottura dei provini: una rottura fragile e dilatante è indicativa di una condizione di alterazione meno spinta, una rottura duttile e contraente è indicativa di una condizione di alterazione spinta. Riferendosi ai criteri richiamati è stato possibile definire, per terreni di alterazione da gneiss, gli inviluppi di rottura tipici di condizioni di alterazione variabili da residuale a saprolitico (fig. 6) (CASCINI & GULLÀ, 1993).

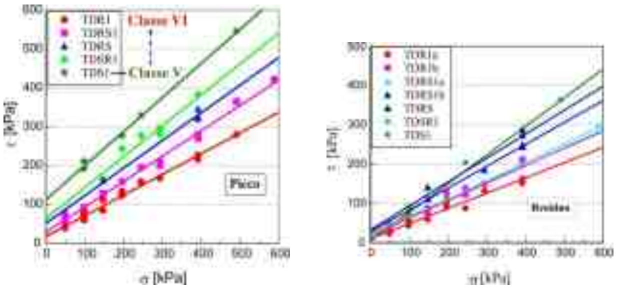

Fig. 6 – Inviluppi di rottura, picco e residuo, tipici delle classi di alterazione da VI a V, relativi a terreni di alterazione da rocce gneissiche (da CASCINI & GULLÀ, 1993 modificata).

Al fine di decidere circa l'opportunità o meno di approfondimenti sperimentali, le ulteriori caratteristiche da accertare relativamente ai terreni di alterazione da rocce cristalline riguardano la rilevanza o meno dell'anisotropia e l'influenza indicativa delle condizioni di parziale saturazione sulla resistenza a taglio.

CONCLUSIONI

La complessità ed eterogeneità dei terreni di alterazione da rocce cristalline rende essenziale la loro classificazione in termini di alterazione e la loro caratterizzazione geotecnica. La definizione degli aspetti richiamati rappresenta una premessa indispensabile per la corretta comprensione e modellazione dei fenomeni che risultano condizionati, appunto, dai terreni di alterazione.

Il percorso metodologico illustrato, proposto nei suoi punti principali, consente di individuare, verificare e definire gli elementi geotecnici necessari per tipizzare un terreno di alterazione. Procedendo nell'ottica indicata è possibile individuare al meglio, anche per terreni notevolmente complessi come quelli di alterazione, i parametri geotecnici rappresentativi al finito per i fenomeni di interesse e, quindi, affrontare e risolvere efficacemente le problematiche che da tali fenomeni possono derivare.

I risultati conseguiti per i terreni di alterazione da rocce cristalline dimostrano che è possibile predisporre un catalogo dei terreni di alterazione tipizzati, utilizzarlo per validare e potenziare i risultati ottenuti da specifiche sperimentazioni e integrarlo progressivamente per migliorarne le capacità di supporto, con particolare riferimento alla definizione di modelli di previsione dei fenomeni di interesse affidabili ed efficaci.

Geotechnical characterization and landslides in the weathered granitoids of Calabria (southern Italy)

F. IETTO (*), M. PARISE (°), M. PONTE (*) & D. CALCATERRA (**)

Key words: *Calabria, granitoids, weathering*.

The main outcrops of granitoid rocks in the southern part of the Italian peninsula are to be found in Calabria or, to be more precise, in southern Calabria (Serre massif). The widespread granitoid outcrops and the intensity of the mass wasting processes (estimated in the order of 1000-1200 t/km^2 of soil eroded in the Serre mountains, IETTO & IETTO, 2004), directly associated with the rapid uplift, have prompted a great deal of scientific interest. This, in turn, has led to several geochemical, petrographic, geomorphological, engineering-geological and geotechnical studies of the weathered sequences. The literature that, up to now, has studied the weathering processes of these rocks in Calabria, even though prevailingly dealing with the Serre mountains (MORESI, 1987; MONGELLI & MORESI, 1990; CALCATERRA *et alii*, 1993; MONGELLI, 1993; MONGELLI *et alii*, 1996; LE PERA & SORRISO VALVO, 2000, CALCATERRA & PARISE, 2005), has always implicitly or explicitly stated that weathering occurred in an environment with a “Mediterranean climate” and, consequently, during the Pleistocene, taking into account the climatic variations of this period. This assumption is the basis from which the various stages of maturity of these processes have been looked for and studied area by area, adopting classical methods of analysis or proposing some new techniques. However, our previous studies allow us to state that the beginning of the weathering processes in Calabrian granitoids dates back at least to a pre-Tortonian age and that the present-day outcrops of granitic alterites are the erosive residual of more ancient mantles (IETTO & IETTO, 2004; IETTO *et alii*, 2007).

This paper is part of a wider research program aiming at the geomechanical characterization of the crystalline massifs in Calabria and at his correlation with landslides phenomena. Here the first results are described focused on some sample-areas located on the Ionian side of the central-southern Calabrian granite massifs. The sample-areas are located near the village of Fabrizia (in the Serre Massif) and near the village of Rossano Calabro (in the Sila Massif).

In the Serre mountains, along the Molini torrent, right tributary of the Allaro river, near the village of Fabrizia, two granitoid lithotypes crop out having different litho-mechanical characteristics, that, from bottom to top consist of:

- relatively fresh granitoids showing values of Schmidt hammer rebounds in the range 20-50 (average: 42), therefore being ascribable to class III (IAEG, 1981), with 15<RQD>75%;.
- strongly disgregated and oxidised granitic saprolite, whose geomechanical properties varies from those typical of a class IV (Schmidt hammer rebounds: 11-22, IAEG 1981) and, subordinately, of a class V (Schmidt hammer rebounds: 0-16, IAEG 1981). Outcrops clearly referable to class VI have not been so far identified.

The transition between saprolite and fresher rocks is not sharp but gradual with depth. The maximum thickness of the decomposed granitoids is in the order of 40-45 m. For the latter, additional field and laboratory tests suggest:

- internal friction angle: between 36° and 44°;
- N_{SPT}: between 13 and 35, up to refusal (more than 50 blows) as depth increases;
- depth of water-table: about -13 m from ground level;
- P-wave velocities in the range of 900/1000 m/s in the saprolite. Such a velocity range is coupled by Lugeon permeability values, which usually show values of $K_e \geq 10^{-4}$ cm/s (to a depth -25 meters from ground level) for as long as the grüs, permeable by porosity, is considered. K_e, however, changes rapidly, reaching values lower than 10^{-4} cm/s when P-wave velocities increase to more than 1500 m/s, a situation occurring where the uniformly porous rock changes into terms provided with a mixed permeability, deriving from porosity and jointing.

The slopes surrounding Fabrizia and the valley of the Allaro river have a long history of landsliding and flooding events. In fact in the great flood event of 1972-73, in this area, there was the activation or reactivation of up to 7-8 landslides/Km^2. Today, in the same area, the weathered rocks evidence a wide variety of mass movements: debris flow-type instabilities dominate in the saprolite (class V in IAEG, 1981), while translational slides are more significant in the less weatherd rocks (class IV in IAEG, 1981). The sliding surfaces are often located in the transition band between the weathering mantle and the parent fresher rocks (in this area corresponding, generally, to class III - IAEG, 1981). This transitional zone, made up of an irregular mixture of saprolite and rock volumes, holds a water-table that controls the

(*) Department of Earth Science – University of Calabria;
(**) Department of Hydraulic, Geotechnical and Environmental Engineering – Federico II University of Naples;
(°) National Research Council - IRPI (Bari);

susceptibility to denudation processes. Therefore the depth of mobilized material can also reach 25-30 m especially for translational slides.

A second study area is located on the eastern side of the Sila Massif, near the village of Rossano Calabro, in the Piana dei Venti locality (730 m a.s.l.).

Fracturing at very high depth in rocky masses combined to both current and past (pre-Tortonian) climatic predisposing conditions have favoured the development of an intense weathering (GUZZETTA, 1974; IETTO, 1975; CASCINI *et alii*, 1992; 1993), responsible for the transforming the granitoids into highly-weathered low-cohesion rocks.

The penetration of meteoric waters mainly occurs through faults and thrusts, from which the weathering processes have been originated, spreading toward higher depths of the rocky masses, hence causing typical edge rounding and being responsible for the formation of boulders (TWIDALE, 1982).

The weathering profile of the outcropping granitoids has been obtained according to the Hong Kong Geotechnical Control Office approach (GCO, 1984), which, as well known, is based upon six classes. Three measurement points (P_1, P_2, P_3) on a 75 m-wide granitic outcrop have been considered. The average rebound values obtained are, respectively, equal to 40 (class III in GCO, 1984), 14 and 23 (class IV in GCO, 1984).

The mechanical parameters are highly variable; in fact the weathered profile shows a complex pattern, whose more representative terms range from "highly weathered rocks" (class IV in GCO, 1984) to "completely weathered rocks" (class V in GCO, 1984) and to "residual soil" (class VI in GCO, 1984). Geotechnical laboratory tests (grain-size analyses, direct shear tests) have been carried out on two samples of residual soil. The soil has been classified as "slightly silty sand and gravel"; direct shear tests have provided the following results:

Sample 1: cohesion = 1.4 kPa – friction angle = 30°

Sample 2: cohesion = 4.5 kPa – friction angle = 33°.

Moreover, three granitoid blocks, belonging to boulders isolated within the upper part of the investigated area, have been subjected to uniaxial compressive strength tests. The samples have shown an average UCS equal to 11 MPa. According to DEERE & MILLER (1966), they are to be ascribed to the "class E" (very low strength, less than 28 MPa).

Finally, some conclusive remarks are made, based on the preliminary results so far obtained in the above study areas, as well as on previous studies.

Una frana profonda in rocce alterate: modellazione numerica per la calibrazione del modello geotecnico

SARAH CARMEN MAIORANO (*), GIOVANNI GULLÀ (°)

Key words: *Frana profonda, modellazione numerica, rocce cristalline alterate.*

PROBLEMATICA

Lo studio di un fenomeno franoso ha, fra gli aspetti di maggiore interesse, la definizione dei fattori predisponenti e delle cause innescanti il fenomeno stesso. In alcuni contesti geologici, un ruolo di particolare rilievo è svolto dalle condizioni di alterazione delle rocce. All'avanzamento delle condizioni di alterazione corrisponde, infatti, una progressiva riduzione della resistenza meccanica, che determina una maggiore suscettibilità dei versanti interessati al verificarsi di movimenti in massa, favorendo la formazione di superfici e/o zone di rottura nelle porzioni più alterate (CASCINI & GULLÀ, 1993; CALCATERRA & DE RISO, 1995; GULLÀ & CILENTO, 2003; GULLÀ *et alii*, 2004; PELLEGRINO & PRESTINIZI, 2007;).

Le rocce cristalline, ampiamente diffuse in tutto il pianeta, sono particolarmente soggette ai processi di alterazione. Nel territorio della Calabria, gli effetti dell'alterazione sulle rocce cristalline sono particolarmente pervasivi anche a notevoli profondità, per l'imponente sviluppo spaziale di numerosi sistemi di discontinuità, generati da differenti eventi tettonici, che hanno prodotto una fratturazione degli ammassi rocciosi intensa e diffusa.

In tali contesti geologici, con particolare riferimento al territorio calabrese, si osserva una rilevante condizione di instabilità dei versanti determinata da frane che coinvolgono rocce variamente alterate per spessori di pochi metri (frane superficiali), di alcune decine di metri (frane mediamente profonde) e di diverse decine di metri (frane profonde) (CALCATERRA *et alii*, 2004; GULLÀ *et alii*, 2004; AMBROSI & CROSTA, 2006; CASCINI *et alii*, 2006;).

In questo scenario si inserisce il caso della frana profonda in rocce cristalline di Serra di Buda, nei pressi di Acri (CS (fig.1). Riferendosi agli studi condotti e, in particolare, alle indagini ed ai monitoraggi eseguiti (GULLÀ *et alii*, 2004; BORRELLI, 2008), si è ritenuto di utilizzare la modellazione numerica del fenomeno di frana, ed i dati di monitoraggio relativi ad alcune fasi di movimento, per precisare adeguatamente alcuni elementi (geometrici e meccanici) del modello geotecnico, individuati e definiti in termini generali dai risultati delle attività di indagine e di sperimentazione.

Fig. 1 – Panoramica della frana di Serra di Buda (da BORRELLI, 2008 mod).

DATI E METODOLOGIA

La frana profonda di Serra di Buda ricade all'interno di una Deformazione Gravitativa Profonda di Versante (SORRISO-VALVO & TANSI, 1996), in un contesto geologico, rappresentativo e diffuso a scala regionale, caratterizzato dalla presenza di rocce profondamente alterate e/o degradate.

Lo studio avviato a seguito della mobilizzazione avvenuta nell'inverno 1998-1999, utilizzato in prima istanza per individuare gli elementi conoscitivi necessari alla gestione dell'emergenza determinata dal fenomeno di frana (cfr. GULLÀ *et alii*, 2001; GULLÀ *et alii*, 2002), ha consentito la progettazione e la realizzazione di una rete integrata di monitoraggio, con finalità conoscitive, dalle cui misure è stato possibile desumere interessanti indicazioni circa l'evoluzione cinematica del fenomeno e riguardo alcune grandezze significative delle possibili cause di accelerazione del movimento (GULLÀ *et alii*, 2001; GULLÀ *et alii*, 2003; GULLÀ & CILENTO, 2003).

I dati forniti dalle indagini geotecniche, svolte in sito e in laboratorio, integrati con quelli ottenuti dai rilievi geologico-strutturali e geomorfologici, hanno portato alla definizione dello schema geotecnico preliminare, mostrato nella fig. 2a, caratterizzato dalla presenza in profondità di zone, associate a strutture tettoniche sub-orizzontali, costituite da roccia completamente degradata e ridotta come consistenza a terreno

(*) Associata CNR-IRPI_U.O.S. di Cosenza e Dottoranda presso l'Università degli Studi "Mediterranea" di Reggio Calabria.

(°) CNR-IRPI – UOS di Cosenza, Via Cavour n. 4 - 87036 Rende (CS).

Lavoro è stato svolto nell'ambito della Commessa CNR-TA.P05.012 (Responsabile G. Gullà).

(C_soil_1 e C_soil_2 in fig. 2a) (GULLÀ *et alii*, 2003).

La modellazione tensio-deformativa, condotta con la procedura di calcolo alle differenze finite implementata nel software FLAC (CUNDALL, 2005), utilizzando lo schema geotecnico preliminare, riesce a cogliere alcuni elementi caratteristici della cinematica ma non riesce a simulare in maniera adeguata l'andamento nel tempo degli spostamenti misurati. Ciò è dovuto alla geometria troppo semplificata assunta per le zone costituite da roccia completamente degradata e, ancora, ai valori dei parametri fisico-meccanici considerati come rappresentativi dei geomateriali coinvolti.

Utilizzando, dunque, la modellazione numerica, riferita ad un comportamento elasto-plastico dei geomateriali presenti nelle zone in cui si localizzano le condizioni di rottura e considerando posizioni rappresentative dei livelli di falda, sono confrontati gli spostamenti simulati con quelli misurati per precisare, progressivamente: la geometria delle zone C_soil_1 e C_soil_2 (variandone profondità, spessore e forma); le caratteristiche fisico-meccaniche dei geomateriali che costituiscono le stesse zone.

RISULTATI E DISCUSSIONE

La presenza negli ammassi rocciosi cristallini di zone costituite prevalentemente da roccia completamente degradata e/o alterata, localizzate a profondità consistenti e associate generalmente a strutture tettoniche sub-orizzontali, rappresenta un elemento tipico dei contesti geologici richiamati e può condizionare l'attivazione e l'evoluzione di frane profonde (spessore massimo dell'ordine di diverse decine di metri).

Partendo da uno schema geotecnico preliminare semplice, la metodologia proposta ha consentito: di precisare adeguatamente la geometria delle zone in cui si sviluppano le elevate deformazioni e le rotture che danno luogo alle condizioni di instabilità (fig. 2b), riscontrate dall'andamento degli spostamenti nel tempo; di tarare efficacemente i parametri fisico-meccanici rappresentativi del comportamento tensio-deformativo al finito dei geomateriali presenti nelle varie zone, riscontrati dal soddisfacente confronto fra gli spostamenti simulati e misurati (fig. 3). In particolare, i parametri di resistenza a taglio rappresentativi del comportamento meccanico delle fasce di debolezza, risultano essere:

c = 100 kPa per entrambe le fasce C_soil_1 e C_soil_2;

ϕ = 31° per la zona C_soil_1;

ϕ = 35° per la zona C_soil_2.

L'analisi complessiva dei risultati ottenuti dalla modellazione tensio-deformativa consente di circoscrivere in termini quantitativi la sensibilità del modello geotecnico rispetto a possibili variazioni dei parametri di resistenza a taglio e delle condizioni di falda. Questo risultato potrà risultare utile per indagare le interazioni fra il fenomeno di frana profonda e la deformazione gravitativa profonda di versante che la contiene.

CONCLUSIONI

La definizione del modello geotecnico di una frana, necessario per prevederne il comportamento al variare delle condizioni che ne possono produrre l'innesco, è generalmente molto complesso e, in particolare, nel caso di frane profonde in rocce alterate non può essere efficacemente perseguita senza il contributo della modellazione numerica, utilizzata per precisare e/o tarare alcuni degli elementi che concorrono allo schema geotecnico dello stesso fenomeno di frana.

Nel caso della frana profonda di Serra di Buda, nei pressi di Acri (CS), la modellazione numerica svolta, principalmente supportata dai risultati del monitoraggio degli spostamenti, ha consentito di migliorare significativamente la capacità di previsione del modello geotecnico discusso da GULLÀ *et alii*, 2003, precisando la geometria delle zone in cui si sviluppano le deformazioni e le rotture che danno luogo alle condizioni di instabilità e tarando opportunamente i parametri fisico-meccanici rappresentativi del comportamento al finito dei geomateriali che costituiscono le zone prima richiamate.

La strategia di analisi proposta consentirà di migliorare ulteriormente le prestazioni dello schema geotecnico in termini di previsione del comportamento del pendio instabile: precisando le

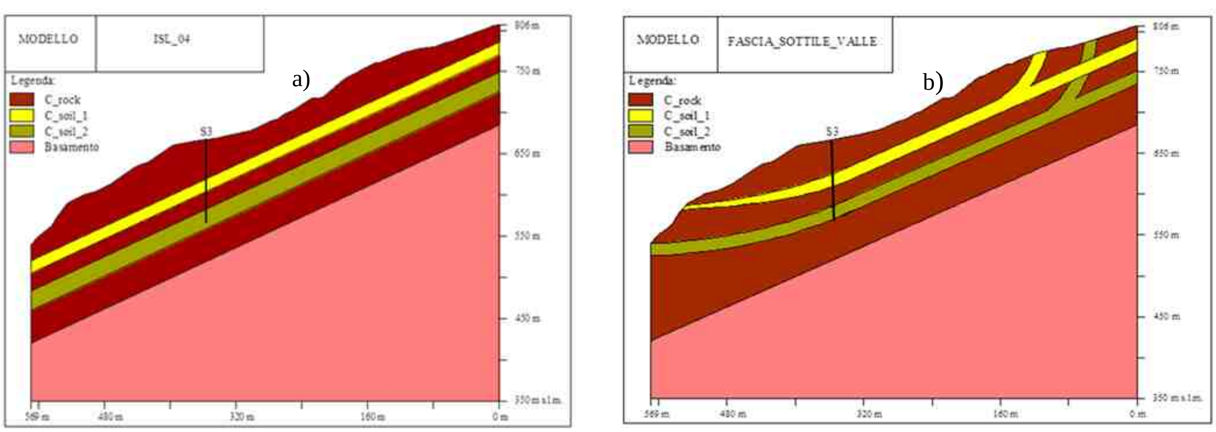

Fig. 2 – Confronto tra gli schemi geotecnici iniziale e finale utilizzati nella modellazione numerica

caratteristiche fisico-meccaniche del geomateriale denominata C_rock; considerando per i geomateriali delle zone C_soil_1 e C_soil_2 un legame costitutivo tempo-dipendente e tarandone i parametri, per simulare congruentemente l'andamento e l'entità degli spostamenti misurati con particolare riferimento alle fasi di creep; definendo uno schema tridimensionale del versante di Serra di Buda al fine di simulare le possibili interazioni tra la frana profonda e la DGPV che la contiene. La complessità del percorso metodologico delineato e il suo costo, in termini di tempo e risorse finanziarie, suggeriscono l'opportunità di utilizzare al meglio i risultati conseguiti su casi di studio significativi, quale è

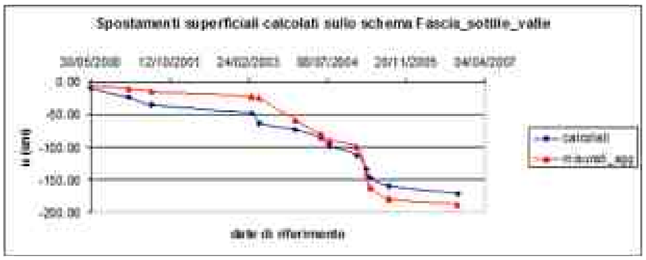

Fig. 3 – Confronto tra gli spostamenti misurati nel tempo e gli spostamenti ottenuti con la modellazione utilizzando il modello finale.

quello della frana profonda di Serra di Buda. In particolare, individuando le caratteristiche degli elementi che tipizzano casi studiati approfonditamente è possibile associare agli stessi delle situazioni simili meno note, rendendo così più semplice, in termini di tempi e di costi, la definizione del relativo modello geotecnico.

Geomechanical analysis of the rock masses outcropping in the slope between Scilla and Bagnara Calabra (RC)

M. C. MANDAGLIO (*), N. MORACI (*) & C. CRÉMER (**)

Key words: *Calabrian Peloritano arc, geomechanical analysis, in situ investigations, rock mass.*

The paper shows the results of the geomechanical analysis performed on the rock masses which make up the slope between Scilla and Bagnara Calabra (RC) (upstream of the Favazzina village). In order to characterize mechanically the slope, geostructural and geomechanical surveys, data from geological surveys, geophysical prospecting and tests on rocks have been used. The obtained data have allowed to the reconstruction of the geomechanical model of the rock masses constituting the slope using the results of a borehole that has also reached depth equal to 410 m. The studied rock mass belongs to the metamorphic-crystalline basement of the Aspromonte, a sector of the Calabrian Peloritano Arc extremely complex geologically and geostructurally, made more complicated by the presence of some local tectonic structures still poorly defined. Moreover the article illustrates the main geomechanical problems of the slope investigated.

Investigation of weathering rates and processes affecting plutonic and metamorphic rocks in Sila Massif (Calabria, southern Italy)

FRANCESCO PERRI (*), LUIGI BORRELLI (**), SALVATORE CRITELLI (*) & GIOVANNI GULLÀ (**)

Key words: *Calabria, metamorphic rocks; mineralogy; plutonic rocks; Sila Massif; weathering.*

INTRODUCTION

Climate (in terms of rainfall amount and temperature), parent rock composition (in terms of mineral stability), plant and animal activities, morpho-tectonic features and time are the most important factors affecting degree of chemical weathering. Generally, weathering of rocks involves several processes such as deposition of authigenic minerals, dissolution of primary phases, ionic exchange and sorption. Chemical weathering indices evaluate the chemical processes associated with weathering so as to understand their influence on geotechnical behavior. Furthermore, weathering produces mineralogical and petrographical transformation and, thus, a considerable decay of the physical-mechanical properties of the original rock, predisposing the slope instability processes (e.g., CASCINI & GULLÀ, 1993; GULLÀ *et alii*, 2008; BORRELLI *et alii*, 2012).

This study is focused on the western Sila Massif, one of the main mountainous massifs of the Calabria region (southern Italy). This area is characterized by crystalline rocks which have undergone intense weathering processes. For this reason, the Sila Massif is ideally suited to study relationships between landscape evolution and the genesis of clastic sediments and soils.

The results of our study regard the mineralogical, petrographical, physical, mechanical changes of the parent/fresh rocks and their weathered products of plutonic and metamorphic rocks characterizing significant cut slopes of the Sila Massif. The interdisciplinary approach used and the results proposed in this paper provides an important support for the study of mass movement phenomena related to different geological contexts mainly characterized by weathered crystalline rocks, and for the physical/mechanical characterization of weathering profiles.

GEOLOGICAL SETTING AND FIELD FEATURES

The studied area, located on the western side of the Sila Massif (Fig. 1), represents a section of the Hercynian orogenic belt of western Europe, where allochthonous crystalline basement rocks are exposed to form the highest tectonic units (Calabrian Arc) of the southern Italy fold-thrust belt (AMODIO-MORELLI *et alii*, 1976).

Fig. 1 – Geologic sketch map of the Sila Massif (modified from MESSINA *et alii*, 1994) with location of the study area. Legend: 1) predominantly clastic deposits (Recent to Tortonian). 2 to 6 = Sila Unit: 2) Mesozoic to Tertiary sedimentary cover; 3) plutonic rocks (Sila Batholith; Carboniferous-Permian); 4) low-grade metamorphic rocks (Bocchiglero Complex; Late Cambrian to Early Carboniferous); 5) low - to medium-grade metamorphic rocks (Mandatoriccio Complex; Late Cambrian to Early Carboniferous); 6) medium-to high-grade metamorphic rocks (Monte Gariglione-Polia-Copanello Complex; pre-Triassic); 7) Lower Alpine thrust nappes of the Sila Massif including Castagna, Bagni and Ophhiolitic Units (phyllite + schist and ophiolitic rocks); 8) thrust fault; 9) stratigraphic contact; 10) studied area.

The Sila Massif consists of Paleozoic intrusive and metamorphic rocks, covered in places by unmetamorphosed Mesozoic sedimentary rocks.

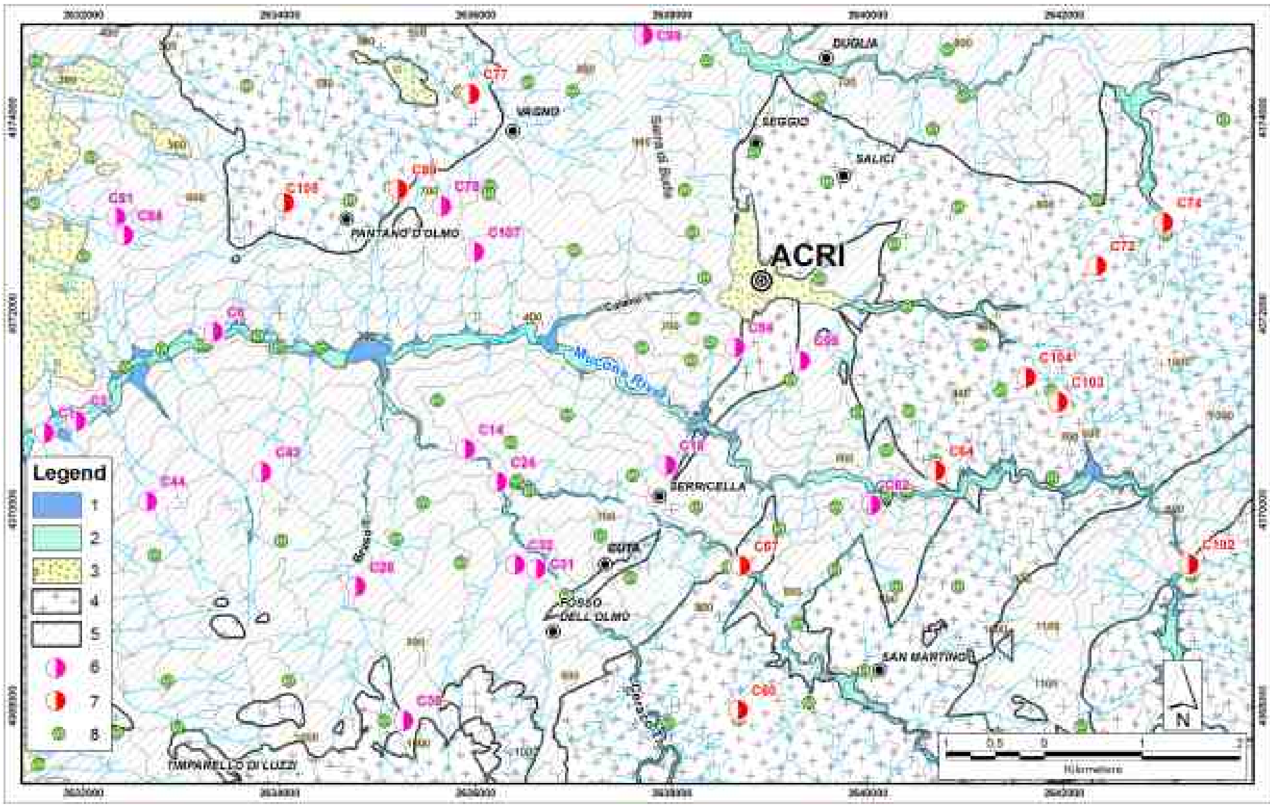

Fig. 2 – Simplified geological map of the west-central side of the Mucone River Basin (northern Calabria, Italy). Legend: 1) alluvial fan and debris fan (Holocene); 2) alluvial deposits (Holocene); 3) matrix-supported conglomerates (Lower-Middle Pleistocene); 4) granitoid rocks (Paleozoic); 5) gneissic rocks (Paleozoic); 6) sampling from cut slope weathering profiles of gneissic rocks; 7) sampling from cut slope weathering profiles of granitoid rocks; 8) studied weathering profiles.

The sampling area (Fig. 2), ranging in elevation from 200 to 1100 m a.s.l. for about 100 Km^2, is located in the west-central side of the Mucone River basin, on the north-western slope of the Sila Massif (northern Calabria). The Mucone river borders are characterized by several landslides and deep-seated gravitational deformations, where high relief energy and steep slopes are commonly associated with severe tectonic fracturing. Rock-slide, soil-slips and debris-flows are the slope movements commonly affected the sampling area.

The Palaeozoic crystalline lithologies, that outcrop in the studied area, is mainly represented by rocks of the Sila Unit (MESSINA *et alii*, 1994), including medium-to-high-grade metamorphic, and plutonic (granitoid) rocks. The plutonic (granitoid) rocks, outcropping in the eastern part of the studied area, are mainly composed of tonalite, passing locally to granodiorite, and minor granodiorite with K-feldspar phenocrysts. The granitoid rocks are also composed of plagioclase, quartz, biotite and muscovite. The high-grade metamorphic rocks are composed by medium- to coarse-grained biotite-garnet and sillimanite gneiss, outcropping along the Mucone River, and medium- to coarse-grained biotite-muscovite migmatitic gneiss, outcropping close to the contact with the granitoid rocks. In the western portions of the studied area, plutonic and metamorphic rocks are unconformably overlying by Pleistocene successions.

The several structure complexities, such as fault gouge zones, thrust planes and joint fractures, mainly related to neotectonic activity of the massif uplift, are predisposing factors for chemical weathering and physical degradation processes which both play an important role in the evolution of landslide phenomena.

DISCUSSION AND CONCLUSIONS

The geo-structural, geomorphological, compositional and textural features and the climatic characteristics of the studied area, associated with good drainage conditions favour the chemical-physical weathering and outcrops of plutonic and metamorphic masses that often display different degrees of weathering.

The field scale observation on the significant cut slopes allow us to reconstruct the typical weathering profile for both plutonic and metamorphic rocks. The cut slopes have been examined to get information about the thickness and features of weathering profiles. Generally, the weathering profile of plutonic rocks is simple whereas the weathering profile of metamorphic rocks is complex and irregular. Thus, the transition from fresh/slightly weathered rock to completely weathered rock is commonly gradual for the weathering profile of plutonic masses. The metamorphic rocks show weathering profile characterized by irregular and complex vertical and lateral transition. Near the most important discontinuities, metamorphic rocks change their texture and become soil-like in character (completely weathered rocks). The main weathered minerals observed on the studied plutonic and metamorphic rocks are plagioclase feldspar, biotite and potassium feldspar. Fine-grained sericite often occurs within plagioclase, preferentially along twin planes. As weathering

Fig. 3 – Photomicrographs of highly weathered sample (class IV) (10X, crossed polarized light).

advances, clay minerals replace fine-grained sericite, preferentially along mineral rims (Fig. 3).

Biotite, vermiculite, and mixed-layer clay minerals are major constituents of altered biotite grains; illite, illite-smectite mixed layers, kaolinite and halloysite are also present in various amount as showed by XRD analyses. Unaltered biotite is often present in some specimens in association with mixed-layer clay minerals. Generally, the initial stage of weathering produces precipitates of Fe-oxides along biotite cleavage planes. This favours the combination between ferrous iron of the iron-bearing silicates with oxygen to form ferric iron oxides (e.g., hematite). Furthermore, newly formed clay minerals (chlorite and vermiculite), replacing biotite along rims and lamellae, has also been observed in a later stage of biotite weathering. The completely weathered samples are characterized by fractured

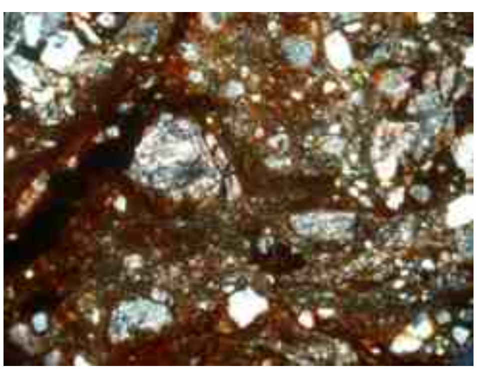

Fig. 4 – Photomicrographs completely weathered sample characterized by clasts in an oxidized and argillaceous matrix (class V-VI) (10X, crossed polarized light).

quartz grains that usually form with the detrital feldspars, the sckeleton of saprolite (Fig. 4).

The relationship between weathering state and mass movement regards the presence of neoformed clay minerals; among these, the presence of abundant expandable phases (e.g., swelling clay minerals) in the completely weathered rocks and residual soils, may decrease slope stability (e.g., CASCINI *et alii*, 1994 and references therein).

The tectonic uplift mainly related to important regional fault systems, played an important role in the Neogene-Quaternary geodynamic evolution of the central Mediterranean area (e.g., TANSI *et alii*, 2007). The presence of these fault systems may influence the morphology and the features of the weathering profiles. In particular, many fractured zone associated to fault planes and completely degraded rocks associated to thrust planes have been observed along the borehole logs studied, where physical and chemical weathering produce argillified levels. The association among fractured zones and completely degraded rocks with argillified portions represents a predisposing factor to the development of mass movements such as, in particular, DSGSD (Deep Seated Gravitational Slope Deformation) and deep landslides.

Groundwater modelling in weathered gneissic slopes

GIUSEPPE SORBINO (*)

Key words: *critical pore pressures, groundwater monitoring, landslide, rainfall, unsaturated–saturated flow model, weathered rocks.*

INTRODUCTION)

Knowledge of groundwater regime, which is generally necessary in studying the stability of slopes, is of fundamental importance in the analysis of landslides involving weathered rocks. This has been confirmed in a study area of about 7.5 km^2 in the Western Sila Massif (Southern Italy), where several geological and geotechnical investigations have been developed during the time in order to characterise the landsliding affecting the area and the involved soils (CASCINI *et alii* 1992a, 1992b, 1994). As for the soils, weathered gneiss is largely diffused in the area. The grade of weathering of the gneiss was defined following the procedures developed for Hong Kong (GCO 1988) on similar rocks (CASCINI *et alii* 1992a, GULLÀ & MATANO 1997).

This classification, together with detailed geo-morphological analyses, allowed the construction of a landslides inventory map where landslides distribution can be fully interpreted according to morphology, tectonics and weathering grade of the outcropping gneiss. The landslides inventory map reveals that the most widespread types of instability phenomena involve heterogeneous residual, colluvial and saprolitic soils (classes VI and V). These are characterised by an impulsive kinematism, with lengthy periods of total inactivity, followed by brief phases of sudden reactivations triggered by remarkable increments in pore water pressures induced by rainfall.

Similarly to landsliding that affects the territories of Brasil and Hong Kong (LACERDA 2004, BRAND 1984), in-situ measurements revealed that the pore water pressures in the landslide bodies are strictly related to transient perched water tables. These last are directly linked to the intensity and duration of rainfall events (CASCINI *et alii* 2006). Therefore, landslides characterisation calls for the definition of relationships among rainfall, pore water pressure increments in the perched water tables and the triggering phases of landsliding movements. In the following, the main results of a research on these aspects will be briefly illustrated.

(*) Dipart. of Civil Eng. University of Salerno

TEST SITES AND GROUNDWATER REGIME

The two test sites are shown in Fig. 1 and 2 respectively. The first test site concerns a small landslide, with a maximum depth of 6 m, in a slope which is part of a large ancient landslide (Fig. 1). The second test site (Fig. 2) coincides with a larger landslide, whose last reactivations (in 1931 and 1981) caused severe damage to many public and private buildings. Landslide movements during reactivations ceased within about 48 hours, (CASCINI 1986). In both test sites the landslides involve gneiss of classes VI and V, resting on a basement formed by less weathered gneiss of class IV and class III-II (CASCINI *et alii* 1992b, SORBINO 1995, GULLÀ & SORBINO 1996). The conspicuous number of piezometers installed in the two test sites –in some cases up to five piezometers per borehole– show, in the landslides debris, the presence of perched water tables having a marked transient behaviour related to the seasonal meteoric events. On the other hand, piezometers located in the basement give remarkably lower piezometric heads with annual or multiannual regime. This circumstance clearly reveals the presence of two different groundwater regimes in the subsoil of both test sites: the first in the landslides debris, the other in the basement (CASCINI *et alii*. 2006). As for the relationship between the perched water table and rainfall, soil suction data were collected within the landslide debris of Fig. 1 by means of five "Jetfill" tensiometers (GULLÀ & SORBINO 1996). They were installed along the same vertical, at depths ranging from 0.81m to 3.58m below ground surface. As for the hydraulic properties of the soils forming the landslides debris, they were provided by *in-situ* and laboratory tests. Saturated hydraulic properties were estimated by means of *in-situ* piezometer tests and by permeameter and oedometric tests in laboratory (SORBINO 1995, GULLÀ & SORBINO, 1996). As for the unsaturated hydraulic properties, they were determined in laboratory on homogenous undisturbed soil samples collected in the gneiss layers belonging to classes VI and V.

GROUNDWATER MODELLING

As well known, groundwater modelling is the subject of a vast literature, mainly because it is the key factor in the attaining of multiple objectives, such as: the interpretation of experimental data, the identification of the geotechnical slope model, back–analyses of case histories, the predicting of pore pressure regime in space and time.

Some of the above objectives represented the goals of the groundwater analyses and modelling performed for the two test sites. In particular, for both test sites, groundwater modelling of the recorded negative and positive pore water pressures was aimed at determine the representativeness of the hydraulic properties coming from in-situ and laboratory tests in interpreting the soil heterogeneity at slope scale. Moreover, for the test sites of Fig. 2, groundwater modelling was used to estimate the critical pore water pressures able to produce landslide reactivations, for which no data are available.

Referring to CALVELLO *et alii* (2008) for the results obtained for the test site of Fig. 1, here below the main results achieved for the landslide of Fig. 2 will be briefly summarised. For the landslide of concern, three different mathematical models were employed to interpret and, in some cases, simulate and/or predict piezometer levels. The first model was proposed by CASCINI & VERSACE (1986, 1988) who demonstrated - by means of statistical hydrology methods - that the critical cumulated rainfall responsible for landslide remobilisations has a return periods of about 40-50 years and is characterised by a value of 900-1000 mm over a period of 100-110 days. After systematically performing piezometer measurements over two decades, a second model was set up by CASCINI E. *et alii* (1992), who found a statistical relationship between daily rainfall and measurements taken by a piezometer representative of the groundwater regimen in the landslide soils. This model allowed the estimation of piezometer levels presumably attained during the landslide mobilizations of 1931 and 1981, just on the basis of rainfall data.

The third model analysed the rainfall infiltration processes responsible for the formation of perched water table in the landslide body and for the significant pore water pressure variations recorded during the monitoring period. To this aim, CASCINI *et alii* (1995, 2006), on the basis of a detailed analyses of the literature, proposed a saturated–unsaturated flow model, whose mathematical representation is furnished by the Richards' differential equation. This model was calibrated taking into account of both the in situ pore pressure

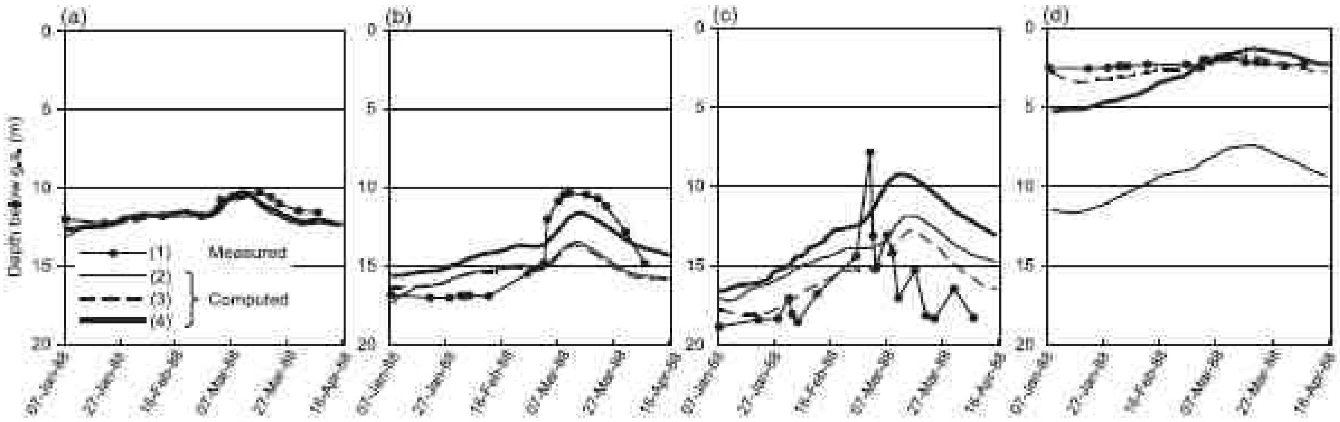

Fig. 3 – Comparison between measured and computed piezometric levels for the 1987–1988 hydrologic year at piezometers S24A (*a*), S4U (*b*), S19U (*c*), and S5U (*d*) installed in the landslide of Fig. 2. (1), measured levels; (2), computed levels assuming a homogeneous cover; (3), computed levels assuming a homogeneous cover and local boundary flows; (4), computed levels assuming a heterogeneous cover and local boundary flows, g.s., ground surface, (from CASCINI *et alii*, 2005)

measurements acquired in about 20-years time period and the geotechnical data set on soil mechanical properties.

The application of a such calibrated model allowed, first of all, to explain the hydraulic processes leading to the formation of the observed perched water table in the landslide body. On the other hand, the model gave significant insights on the role played by soils' heterogeneity at the slope scale and local boundary flows for a proper simulation of the maximum recorded levels and their temporal positions at piezometers during the observation period (Fig. 3).

Then, the calibrated model was used to predict the piezometer levels during the last landslide reactivation (1981), when only rainfall data were available. The slope stability analyses carried out on the basis of the predicted pore pressure values furnished results that are in agreement with the geological history of the landslide.

INTRODUCTION

Debris flows are fast moving landslides of mixed water and poorly sorted debris (IVERSON, 1997; CRUDEN & VARNES, 1996). Because of the high flow velocity, impact forces, and long runout, debris flows are commonly regarded as one of the most hazardous landslide types (JAKOB, 2005). The Dolomites region (NE Italian Alps) has one of the most frequent return intervals for large debris flows on the world (PASUTO & SOLDATI, 2004; SKERMER & VANDINE, 2005).

In the Dolomites the landscape is dominated by steep dolomite massifs rising up to 3300 m a.s.l. The rocky cliffs are connected to the bottom of alpine valleys by means of milder slopes where bedrock is covered by a thick debris talus, deposited in post-glacial climatic conditions. Debris flow channels are deeply incised in the talus slope and feeded by small headwater basins located on the cliffs (MARCHI & TECCA, 1992; BERTI *et alii*, 199). These basins are typically very steep (45°-60° on the average) and mostly consist of exposed bedrock with no vegetation and almost absent soil cover.

During high intensity short duration thunderstorms, rainfall water is collected by the rocky watersheds as overland flow and trunk streams incised in bedrock, and quickly delivered to the talus cones. Most of this water infiltrates into the channel bed debris and flows downstream as subsurface stormflow. However, when the infiltration capacity of the streambed is exceeded, surface flow appears in the channel and debris flows are triggered by the progressive erosion of the loose bed debris (BERTI & SIMONI, 2005).

Although this initiation mechanism has been widely recognized in the field (e.g. CANNON *et alii*, 2003), monitoring data describing the onset of channel runoff and the triggering process are still lacking. In this paper we describe the monitoring systems installed on a typical debris flow catchment of the Dolomites (Dimai basin, Cortina d'Ampezzo, Belluno), with the main aim of describing the hydrologic response in the initiation area.

THE MONITORING SYSTEM

The Dimai debris flow is located about 2 km north of Cortina d'Ampezzo (Belluno Province, Italy) (Fig. 1). The debris flow channel is incised in ancient debris flow deposits and from source area to the fan apex is nearly 900 m long.

The cross-section is reasonably uniform, typically 10 to 15 m wide, with a trapezoidal shape. The bed slope decreases from 25°-30° in the initiation area to 5° on the fan. The rocky headwater basin (Fig. 1) is very small (0.02 km^2) and steep (average slope 65°). It is almost entirely constituted of moderately fractured outcropping dolomite with small, scattered patches of sparsely vegetated debris.

Debris flows initiate in the upper reach of the channel, at the outlet of the rocky watershed. In this reach, the channel bed consists of a thin layer of poorly-sorted loose debris (with floating dolomite blocks) lying over dense talus deposits or sound bedrock. The thickness of this mobile layer is typically less than 50 cm, though relevant spatial and temporal changes may occur after major storms as a consequence of streambed dynamics.

A monitoring system was installed in summer 2010 in the initiation area of the Dimai debris flow (Figs. 2 and 3). The system consists of 1 tipping bucket rain gauge, 4 pressure sensors, and 2 digital video cameras. The rain gage is located at the toe of the rocky cliff (1680 m a.s.l.) about 2 m above the ground level. The distance from the centroid of the headwater basin is about 180 m.

Pressure sensors are temperature-compensated and differential piezoresistive, with a built-in signal amplifier to reduce electrical noise. The measurement range is 0–100 kPa (10 m of water) with a resolution of 7 mm of water. Pressure sensors are buried into the channel bed debris at shallow depth (20-40 cm) in order to detect the occurrence of subsurface stormflow. These sensors are lost in case of debris flow or substantial bed scouring and require frequent replacement.

The two video cameras frame the outlet of the rocky watershed looking upstream (camera 1) and the debris flow channel looking downstream (camera 2).

Lavoro eseguito nell'ambito del progetto PARAMOUNT (2009-2012) dell'Alpine Space Programme

Fig. 1 – Location map of the Dimai debris flow. The circle indicates the monitored area (see Fig. 2).

Video recordings are important to detect the appearance of surface runoff and document the initiation process. The videos are recorded by each camera on an internal hard disk using an image resolution of 768 x 576 pixels at 8 fps. Each 160 GB hard disk can store over 80 hours of HD video.

Monitoring data are collected by a Campbell CR800 datalogger located close to the rain gage (Fig. 2). During "normal mode" data are sampled every 5 minutes and video cameras are turned off. When the cumulative rainfall exceed the threshold of 1.5 mm in 5 minutes, the acquisition system switch into "alarm mode". Data are collected every 5 seconds and video cameras are turned on. The "alarm mode" lasts 2 hours after the last exceeding of the threshold. Data are stored on a flash memory on site and periodically downloaded via GSM.

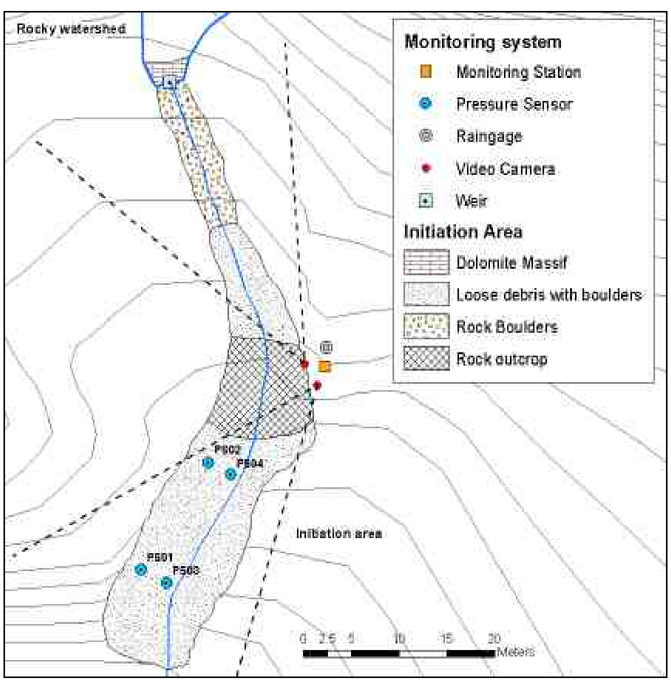

Fig. 2 – Schematic map of the Dimai monitoring system

In August 2011, a sharp crested weir was installed at the outlet of the rocky watershed (1725 m a.s.l.) (Fig. 2). The weir consist of a thin metal plate (50 cm height) secured by L profiles bolted to the rock. The discharge rates are determined by measuring the vertical distance from the crest to the water surface in the pool upstream the weir. A pressure sensor installed at the bottom of the pool is used to measure water level. The weir worked properly for a couple of weeks then, at the end of the 18 August rainfall event (see below), a large boulder fell off the channel bank and completely clogged the pool damaging the weir. The weir will be recovered in summer 2012.

PRELIMINARY DATA

About 80 rainfall events were recorded by the monitoring system during the summer seasons 2010 and 2011 (June to October).

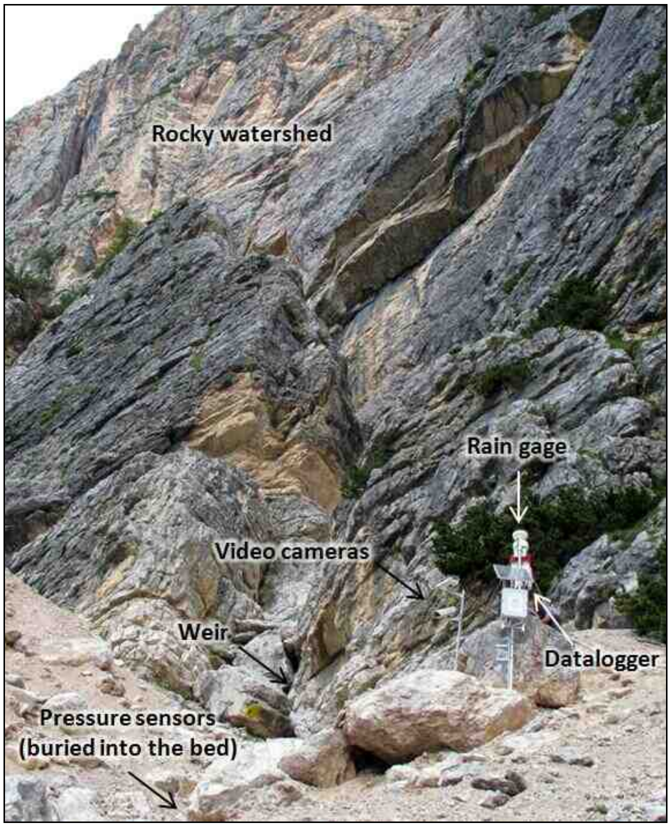

Fig. 3 – Picture of the monitoring system viewed upstream.

In 25% of the cases (20 rainfall events) the pressure sensors buried in the channel bed did not show any change in pore pressures, and no surface runoff were observed elsewhere. This indicates that no water was delivered at the outlet of the rocky basin and that subsurface stormflow was absent or negligible. In the remaining 75% of the cases (60 events) a sharp, transient increase of pore pressure was measured within the channel bed in one or more sensor (Fig. 4).

Surface runoff was observed for 15 rainfall events which exceeded about 1 mm in 5 minutes. In particular, two of them (4 July and 18 August 2011) triggered small debris flows by progressive erosion of the channel bed. The peak intensity of these **t**wo event was respectively 3 and 8 mm in 5 minutes. Peak intensities in the order of 0.3-0.5 mm/min are known to be critical in the Dolomites (BERTI & SIMONI, 2005).

Video recordings show that the rocky basin responds quickly to the rainfall events., with a lag time of few minutes. The runoff hydrograph at the outlet of the rocky watershed is available for the 18 August 2011 event. Weir data show an overall duration of 30 minutes and a peak discharge of about 0.25 m^3/s.

Ongoing analyses are focusing on the hydrologic modeling of the rocky watershed and on the prediction of the critical conditions for alarm purpose.

Development of an hydrological landslide model at regional scale. Applications in the central part of Calabria region (southern Italy)

GIOVANNA CAPPARELLI (*), DAVIDE LUCIANO DE LUCA (*) & PASQUALE VERSACE (*)

Key words: *Empirical regional modeling, rainfall, forecasting of landslides.*

INTRODUCTION

In the last years, many hydrogeological emergencies, induced by persistent and widespread rainfall events, concerned Calabria region (southern Italy), in particular during the winter season. Flood and landslide events undermined the safety of tens of thousands of people. These events, related to the period 2008-2010, are comparable, or even worse, with those occurred in the 50's and in the early 70's.

The proposed study regards the analysis of triggering conditions for landslides induced by rainfall. For this topic, many models are reported in the technical literature, which allow the definition of instability conditions for a slope, through an accurate investigation. (MONTGOMERY & DIETRICH, 1994; IVERSON, 2000; GUZZETTI, 2008; CEPEDA *et al.*, 2010).

In particular, this work describes an hydrological approach for the trigger modeling of landslides, and the applications related to the provinces of Catanzaro, Vibo Valentia and Crotone.

For each investigated province, a lot of landslide events have been documented, characterized by different kinematic, lithological and morphological conditions, but the same triggering factor, the rainfall.

The analysis was carried out by using the hydrological model named FLaIR (Forecasting of Landslides Induced by Rainfalls, SIRANGELO & VERSACE, 1992), for which some improvements were realized in the last years.

Each landslide area was investigated, and then regionalization techniques were developed, aimed at the definition of transfer functions, parameters and rainfall thresholds representative of each province.

The obtained results allow to apply the FLaIR model also in areas characterized by a lack of information for the past mobilization events.

(*) Universita' della Calabria, Dipartimento di Difesa del Suolo (Cs), Italy.

CALIBRATION OF THE REGIONAL FLAIR MODEL

The model allows the identification of rainfall threshold values Y_{cr}, above which a landslide phenomenon might occur. It is based on the identification of a mobility function $Y(.)$, evaluated by a convolution between the rainfall intensity $P(.)$ and a transfer function $\psi(.)$, that it is typical for each case study.

The FLaIR model can be considered as a general framework for hydrological modeling of rainfall-landslide relationship.

Most of hydrological approaches like I-D, or those based on long period antecedent rainfall, can be considered as special cases of FLaIR structure (CAPPARELLI & VERSACE, 2011).

SIRANGELO *et al.* (2003) show that the FLaIR model describes the relationship between rainfall and landslides by transfer functions whose shape appears strictly connected to the involved lithology and dimension. This allows a regional use of the model because it is possible to use a specific structure of the model depending on the landslide typology and investigated area (CAPPARELLI *et al.*, 2007).

On the basis of a realized database, concerning historical events (CAPPARELLI & LEONE, 2012), it was possible to apply FLaIR for each area, and to develop the model version at regional scale.

In particular, for each province three different structures of the regional FLaIR model were identified (Model 1, Model 2, Model 3). The gamma function was adopted as the transfer function (eq. 1). The values of parameters and Y_{cr} are indicated in table 1.

$$\psi(u) = \frac{u^{\alpha-1}\exp(-u/\beta)}{\beta^{\alpha}\Gamma(\alpha)} \qquad u \geq 0; \quad \alpha > 0, \quad \beta > 0 \tag{1}$$

	Model 1	Model 2	Model 3
Catanzaro	α=0.3 β=1 [g] Y_{cr}=119.5	α=1.25 β=6 [g] Y_{cr}=19.5	α=1.2 β=15 [g] Y_{cr}=15.5
Vibo V.	α=0.1 β=1 [g] Y_{cr}=141.7	α=1 β=12 [g] Y_{cr}=11.9	α=2.4 β=2.6[g] Y_{cr}=15.4
Crotone	α=1.1 β=10 [g] Y_{cr}=16	α=0.8 β=5 [g] Y_{cr}=41.7	α=1.1 β=2[g] Y_{cr}=58.5

T

Table1 - Models for every single province

As an example, the transfer functions related to Catanzaro province are reported in Fig. 1.

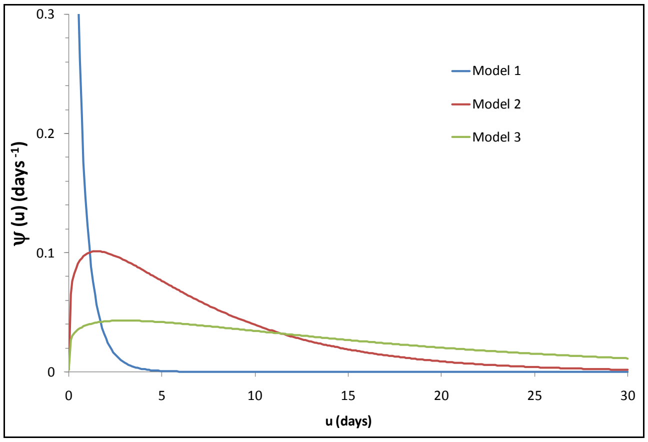

Fig. 1 – Transfer functions related to Catanzaro area

VALIDATION OF THE REGIONAL MODELS

The validation of the obtained rainfall threshold values was carried out by using the landslide events occurred in the period 2008-2010.

Only the events with an exact knowledge about the date of occurrence were considered. Moreover, the non-water induced landslides were excluded from this study. In total, the number of analyzed landslides is 193, 94 and 80 for Catanzaro, Vibo Valentia and Crotone, respectively.

From the comparison between the dates of threshold exceedance and historical occurrence, it was possible to identify Correct Alarms (C.A.), False Alarms (F.A.) and Missed Alarms (M.A.).

The ratio between the number of Missed Alarms and the total number of events (N_{events}) indicates that about half of these events was not predicted by any regional model (Table 2).

	Catanzaro	Vibo V.	Crotone
$M.A./N_{events}$	0.58	0.47	0.47

Table 2 - Number of events.

The obtained results can be considered acceptable, as the models are able to predict the 50% of the historical events with not so high number of False Alarms.

However, it is evident that these results are mainly affected by the adopted hypothesis, related to the uniqueness of Y_{cr} for each model. Because of the paucity of the available data for the calibration phase (which were different from those considered for validation), it was possible to assume only this hypothesis.

By considering also the database related to the period 2008-2010 for calibration, it will be possible to re-evaluate the threshold values. Moreover, it will be possible to consider their spatial and temporal variability. This latter feature constitutes an important aspect, as the values of mobility function, in correspondence of landslides events for the period 2008-2010, seem to decrease along the time.

Even with these limitations, the proposed regional models represent a starting point for a development of a forecasting system at regional scale.

Models for landslides induced by precipitation in Norway

DAVIDE LUCIANO DE LUCA (*), JOSÉ MAURICIO CEPEDA (**)

Keywords: *landslide prediction, infiltration, precipitation thresholds.*

1. INTRODUCTION

This work summarizes the preliminary results of a post doc project between University of Calabria and Norwegian Geotechnical Institute (NGI). The topic is the development of an integrated modeling to forecast rainfall fields and triggering mechanisms of landslides. The activities are organized in three research lines: (1) analysis and modeling of rainfall fields; (2) development of a modeling for landslide initiation; (3) integration between rainfall forecasting and landslide initiation models.

The preliminary results reported in this paper are related to the second research line, which comprises: a) development of a physically and DEM based model at regional scale for triggering of landslides; b) integration with empirical/hydrological models for early warning purposes.

Concerning the former activity, the study area, formed or not by different soil layers, has to be represented by a three-dimensional grid of cells; the study of the effects induced by precipitation on slope stability has to be performed by using models of infiltration and runoff generation, coupled with a global stability analysis.

The basic idea of this second activity is to test the feasibility of establishing relations between the results of empirical approaches, and the output of physically based models.

The advantage of this procedure consists in the use of the physically-based model only for the calibration of the aforementioned relations, while for early warning purposes it could be possible to use only the simplest model (i.e., the empirical) with a significant reduction in computational costs. The work is outlined as follows. Section 2 describes the development of an infiltration module for unsaturated layered soils and transient flow, which is a component of the physically- and DEM-based model (in preparation), comprising also modules for runoff generation and slope stability. Section 3 illustrates the results of a previous NGI project, related to the probabilistic estimation of thresholds for triggering of rapid soil slides in Norway; starting from these results, we emphasized the necessity of coupling with other data source, like radar, in order to improve the forecasting and the performance of models for landslide triggering.

2. INFILTRATION FOR UNSATURATED LAYERED SOILS

The goal is the use of analytical solution of Richards' equation, in order to reduce the computational costs for each 3D cell of the DEM-based model. Numerical techniques tend to increase this computational time and often suffer from convergence and mass balance problems. For unsaturated layered soils SRIVASTAVA & YEH (1991) have published the only analytical solution for transient flow. Even though this solution is useful for testing various numerical schemes, it has two main disadvantages: 1) it is lengthy, complex and difficult to code; 2) one of the key soil parameters, i.e. the capillary fringe, is the same for all the layers. To overcome these drawbacks, a spatiotemporal deformation of the domain is proposed, aimed at reproducing the solution of SRIVASTAVA & YEH (1991) with a reduced computational cost and extending the treatment to more general cases.

So far, at this stage of the post doc project, the case of two soil layers has been analyzed (Fig. 1), in which *L* is the thickness of the upper layer, *du* is the depth of the water table. In detail, the 1D Richards' equation is considered for two soil layers:

$$\alpha_{1,1} X_1 \frac{\partial K(\psi)}{\partial t} = \frac{\partial^2 K(\psi)}{\partial z^2} - \alpha_{1,1} \frac{\partial K(\psi)}{\partial z} \qquad (1)$$

(*) Dipartimento di Difesa del Suolo "V.Marone" – Universita' della Calabria, Arcavacata di Rende (CS), Italy.

(**) International Centre of Geohazards (ICG) & Natural Hazards Division, Norwegian Geotechnical Institute (- NGI), Oslo, Norway.

The contents of this paper include activities of the Post-Doc research of the first author. Funding for this Post-Doc was provided by the Calabria Region, through the University of Calabria (ROP ESP 2007/2013 – IV Axis Human Capital – Operative Objective M2 – Action d.5) and the International Centre for Geohazards – ICG at the Norwegian Geotechnical Institute – NGI. Their support is acknowledged with thanks. The preparation of part of the database for this project was carried out in a previous project (NGI, 2012) financed by the Norwegian Research Council, Norwegian Water Resources and Energy Directorate - NVE, the Norwegian Public Roads Administration - SVV, and Jernbaneverket - JBV. Their support is gratefully acknowledged.

$$\alpha_{1,2} X_2 \frac{\partial K(\psi)}{\partial t} = \frac{\partial^2 K(\psi)}{\partial z^2} - \alpha_{1,2} \frac{\partial K(\psi)}{\partial z} \quad (2)$$

in which all quantities with the subscripts *1* or *1,1* are related to the upper layer, while the subscripts *2* or *1,2* are associated to the lower layer. Moreover, $\alpha_{1,j} = \alpha_j \cos^2 \delta$, *j = 1, 2*, where $1/\alpha_j$ represents the vertical height of the capillarity fringe above the water table for the j^{th} layer and δ is the slope of the surface, and $X_j = (\theta_{S,j} - \theta_{R,j})/K_{S,j}$, in which $\theta_{S,j}$, $\theta_{R,j}$ and $K_{S,j}$ are saturated water content, residual water content and saturated hydraulic conductivity for the j^{th} layer, respectively.

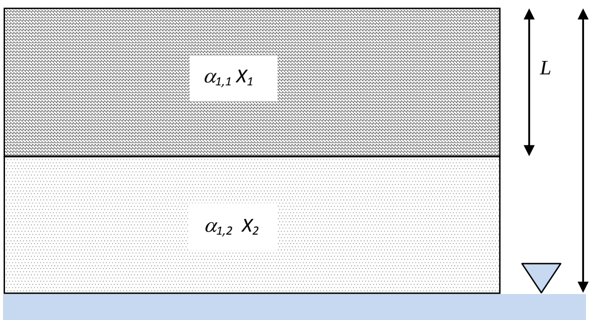

Fig. 1 – Analyzed case, related to a soil profile with 2 layers.

Considering the upper layer as the reference layer, a linear transformation for the lower layer was defined in terms of $dt = adt$ $dz = bdz$ and $dK = cdK$, where *a*, *b* and *c* are constant values. It allows to rewrite Eq. (2) as:

$$\alpha_{1,1} X_1 \frac{\partial K(\psi)}{\partial t} = \frac{\partial^2 K(\psi)}{\partial z^2} - \alpha_{1,1} \frac{\partial K(\psi)}{\partial z} \quad (3)$$

It is possible to demonstrate that:

$$a = \frac{\alpha_{1,2} X_1}{\alpha_{1,1} X_2};\ b = \frac{\alpha_{1,2}}{\alpha_{1,1}};\ c = \frac{\alpha_{1,2}^2}{\alpha_{1,1}^2} \quad (4)$$

Analytical solutions are obtained in terms of *K(z,t)* (SRIVASTAVA & YEH,1991; BAUM *et al.*, 2010) and *ψ(z,t)* by considering the inversion of the exponential GARDNER's model (1958):

$$K(\psi) = K_S \exp(\alpha\ \psi) \quad (5)$$

which is adopted in this context in order to linearize the Richards' equation.

Finally, to avoid discontinuity in terms of pressure head on the interface between the layers, a deformation for *t* is used also for the upper layer. The greater the value of *z* into the upper layer, the larger becomes the influence of the lower layer. Consequently, the following deformation is proposed:

$$dt_1 = \exp\left[U\left(\frac{z}{L}\right)^n\right] dt \quad (6)$$

with $n > 1$. For $z = L$ Eq. (6) implies:

$$U = \ln(a) \quad (7)$$

The proposed model was tested by comparison with the analytical solutions of SRIVASTAVA & YEH (1991), for different values of the parameter *n*. As an example, Fig. 2 shows the case for L = 1m; du = 2m, $\alpha_{1,1} = \alpha_{1,2} = 10\ \text{m}^{-1}$, $K_{S,1} = 2.78E-05$ m/s, $K_{S,2} = 2.78E-06$ m/s, $\theta_{S,1} = \theta_{S,2} = 0.4$, $\theta_{R,1} = \theta_{R,2} = 0.06$, initial infiltration rate equal to $2.78E-07$ m/s, and then increased to 0.0000025 m/s. The obtained results highlighted a good agreement between proposed model and the analytical solution, in particular for $n = 4$ (for $n > 4$ there are not significant improvements). Obviously, the possibility of adopting other transformations and the extension to the more general case of a number of layers greater than 2 have to be investigated.

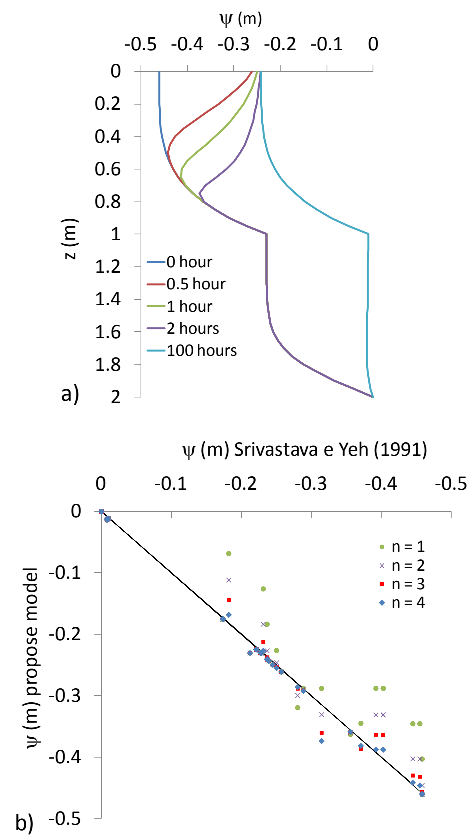

Fig. 2 - a) Pressure head profile obtained for *n* = 4; b) comparison between proposed model and the solutions of SRIVASTAVA AND YEH (1991), for several values of *n*.

3. PROBABILISTIC ESTIMATION OF PRECIPITATION THRESHOLDS

This section summarizes the results of a research project presented in NGI (2012). The aim of this project was the probabilistic estimation of thresholds for triggering of rapid soil slides in Norway. A database of 281 landslide days for the period 2000-2011 was prepared with contributions from the

Norwegian Water Resources and Energy Directorate - NVE, the Norwegian Public Roads Administration - SVV, the Norwegian National Rail Administration – JBV, and NGI reports. The database included also 15224 no-landslide days. Each event in the database was characterised by 18 different explanatory variables of meteorological and hydrological nature. Univariate and bivariate models were tested using the following classification methods: classification tree (BREIMAN *et al.*, 1984), linear and quadratic discriminant analyses (KRZANOWSKI, 1988), and Naïve-Bayes method (MITCHELL, 1997). The performance of the models was tested using cross-validation and Receiver Operating Characteristic (ROC, FAWCETT, 2006) analysis. The top ranked models were combinations of water supply (i.e. summation of rainfall and snowmelt) and ground saturation (evaluated from NVE models).

Nevertheless, the used precipitation dataset derives from an interpolation of daily measurements from the rain gauges network of Norway. As this landslide warning study was focused on short term precipitation (relative to convective precipitation cell), those rain events are very localized and unfortunately not always captured by the network due to its low density in comparison to the scale of these small meteorological phenomena. Due to this lack of spatial information, many landslides have been connected to a dry day though local witnesses have confirmed the presence of rain. This highly affects the value of the thresholds and thus alters the operability of the landslide safety map. Thus, we carried out a pre-feasibility assessment of using other data sources. As an example, Fig. 3 shows the dispersion plot between the 1-day water supply and the ground saturation (evaluated from NVE models). The results show that some landslides are characterized by low rainfall values with respect to high percentages ground saturation. Consequently, a further investigation with other data source, like radar, can improve the modeling. This aspect will be developed in the successive stages of the post-doc project.

4. CONCLUSION

The preliminary results of the proposed post doc project highlighted some important aspects:

1. Adoption of analytical solutions is useful to reduce the computational costs of a regional physically-based model. In fact, numerical procedures do not allow fast evaluations and often suffer from convergence and mass balance problems. The preliminary results presented in section 2 constitute a basis for forthcoming investigations.
